Cat fleas are also involved in disease transmission. Murine typhus, caused by *Rickettsia typhi* and *Rickettsia felis*, is a mild to severe febrile disease of people characterized by headaches, chills, and skin rashes, with infrequent involvement of the kidneys and CNS. The disease is seen in people and many small mammals along the southeastern, southwestern, and Gulf coasts. In the USA, the principal transmission cycle involves opossums and cat fleas. Cat fleas also serve as the intermediate host of the nonpathogenic subcutaneous filarid nematode of dogs, *Dipetalonema reconditum*. *Dipylidium caninum*, the common intestinal cestode of dogs and cats (and rarely children), develops as a cysticeroid in *C. felis*, *C. canis*, and *Trichodectes canis*. Flea larvae ingest the eggs of the tapeworm, which develop into cysticeroids in the body of the flea. When grooming themselves, dogs and cats may ingest infected fleas, and the cysticeroids are released.

FLEA ALLERGY DERMATITIS

Flea allergy dermatitis (FAD) or flea bite hypersensitivity is the most common dermatologic disease of domestic dogs in the USA. Cats also develop FAD, which is one of the major causes of feline miliary dermatitis. FAD is most prevalent in the summer, although in warm climates flea infestations may persist throughout the year. In north temperate regions, the close association of pets and their fleas with human dwellings creates conditions that permit a year-round problem. Temperature extremes and low humidity tend to inhibit flea development.

When feeding, fleas inject saliva that contains a variety of histamine-like compounds, enzymes, polypeptides, and amino acids that span a wide range of sizes (40–60 kD) and induce Type I, Type IV, and basophil hypersensitivity. Flea-naïve dogs exposed intermittently to flea bites develop either immediate (15 min) or delayed (24–48 hr) reactions, or both, and detectable levels of both circulating IgE and IgG antiflea antibodies. Dogs exposed continuously to flea bites have low levels of these circulating antibodies and either do not develop skin reactions or develop them later and to a considerably reduced degree. This could indicate that immunologic tolerance may

develop naturally in dogs continually exposed to flea bites. Although the pathophysiology of FAD in cats is poorly understood, similar mechanisms may exist.

Clinical Findings: Clinical signs associated with FAD are variable and depend on frequency of flea exposure, duration of disease, presence of secondary or other concurrent skin disease, degree of hypersensitivity, and effects of previous or current treatment. Nonallergic animals may have few clinical signs other than occasional scratching due to annoyance of flea bites. Those that are allergic will typically have a dermatitis characterized by pruritus.

In dogs, the pruritus associated with FAD can be intense and may manifest over the entire body. Classic clinical signs are papulocrustous lesions distributed on the lower back, tailhead, and posterior and inner thighs. Dogs may be particularly sensitive in the flanks, caudal and medial thighs, ventral abdomen, lower back, neck, and ears. Affected dogs are likely to be restless and uncomfortable, spending much time scratching, licking, rubbing, chewing, and even nibbling at the skin. Hair may be stained brown from the licking and is often broken off. Common secondary lesions include areas of alopecia, erythema, hyperpigmented skin, scaling, papules, and broken papules covered with reddish brown crusts. The rump and tailhead areas are typically the first, most evident, areas affected. As FAD progresses and becomes chronic, the areas become alopecic, lichenified, and hyperpigmented, and the dog develops secondary bacterial and yeast infections.

In extremely hypersensitive dogs, extensive areas of alopecia, erythema, and self-trauma are evident. Traumatic moist dermatitis (hot spots) can also occur. As the disease becomes chronic, generalized alopecia, severe seborrhea, hyperkeratosis, and hyperpigmentation may develop.

In cats, clinical signs vary from minimal to severe, depending on the degree of sensitivity. The primary dermatitis is a papule, which often becomes crusted. This miliary dermatitis is typically found on the back, neck, and face. The miliary lesions are not actual flea bites but a manifestation of a systemic allergic reaction that leads to generalized pruritus and an eczematous rash. Pruritus may be severe, evidenced by repeated licking, scratching, and chewing. Cats with FAD can have alopecia, facial dermatitis, exfoliative dermatitis, and "racing stripe" or dorsal dermatitis.

SHEEP KEDS

The sheep ked, *Melophagus ovinus*, is one of the most widely distributed and important external parasites of sheep. There are also keds that parasitize deer in North America (*Lipoptena depressa* and *Neolipoptena ferrisi*).

Keds are wingless dipterans. The adult is ~7 mm long, brown or reddish in color, and covered with short, bristly hairs. The head is short and broad, and the legs are strong and armed with stout claws.

The female gives birth to a single, fully developed larva, which is cemented to the wool and pupates within 12 hr. A young ked emerges after ~22 days. Females live 100–120 days and produce ~10 larvae during this time; males live ~80 days. The entire life cycle is spent on the host. Keds that fall off the host usually survive <1 wk and present little danger of infestation to a flock. Ked numbers increase during the winter and early spring when they spread rapidly through a flock, particularly when sheep are assembled in close quarters for feeding or shelter.

Pathology: To feed, sheep keds pierce the skin with their mouthparts and suck blood. They usually feed on the neck, breast, shoulder, flanks, and rump but not on the back where dust and other debris collect in the wool. Ked bites cause pruritus over much of the host's body; sheep often bite, scratch, and rub themselves, thus damaging the wool. The fleece becomes thin, ragged, and dirty. The excrement of the keds causes a permanent brown discoloration, which is likely to reduce the value of the wool. Keds also cause a defect in hides called a cockle, which affects the grade and value of the sheep skin. Infested sheep, particularly lambs and pregnant ewes, may lose vitality and become unthrifty. Heavy infestations can considerably reduce the condition of the host and even cause anemia. Keds also transmit *Trypanosoma melophagium*, a nonpathogenic protozoan parasite of sheep.

Diagnosis: Close inspection of the damaged, dirty wool and underlying skin reveals infestation by the unique appearance of these wingless, hairy flies.

Treatment and Control: Shearing removes many pupae and adults. Thus, shearing before lambing and subsequent treatment of the ewes with insecticides to control the remaining keds can greatly reduce the possibility of lambs becoming heavily infested. Sheep are usually treated

after shearing, and best results are obtained if an insecticide that has a residual activity of ≥3–4 wk is used. By this means, the keds that emerge from the pupae are also killed. Modern treatments to control lice also control keds.

Dipping is an effective method of treatment. Completely submerging the sheep in vats ensures the destruction of all keds present but, in most instances, does not kill the pupated larvae; a long-acting insecticide is required to kill newly emerging keds. Large flocks of range sheep should be treated in a permanently constructed dipping vat. Smaller flocks and farm flocks may be successfully treated in portable, galvanized-iron dipping vats or in smaller tanks, tubs, or canvas dipping bags.

Spraying may be as effective as dipping and is more convenient in some areas. Pressures of 100–200 lb/sq in. (7–14 kg/cm²) for short wool and 300–350 lb/sq in. (21–28 kg/cm²) for long wool are commonly used.

Shower dipping is also sometimes used; the sheep are held in a special pen and showered from above and below until the fleece is saturated. The run-off is returned for recirculation, and the concentration of insecticide used is the same as for dipping. The concentration of the insecticide can drop rapidly and become ineffective if the instructions for replenishment are not followed explicitly.

Jetting involves the forceful application of the insecticide by means of a hand-held, multiple-jet comb drawn through the short fleece. Although a little slower and less effective than dips or sprays, jetting may be advantageous for smaller flocks because it is economical and does not require a permanent installation.

Spot-on or pour-on formulations of the newer pyrethroids are easy to apply and very effective.

Powder dusting fits well into management practices at shearing time. It is rapid, economical, and avoids wetting the animals. Various types of equipment for dusting are available commercially.

SPIDER FLIES/NEW FOREST FLIES

The spider or new forest fly, *Hippobosca equina*, is widely distributed throughout Europe, Asia, and Africa. These winged keds parasitize horses and rarely cattle throughout the UK. Its bite is characterized as a nuisance and disturbance to large domestic animals. It has a predilection for feeding sites in the perineal region and between the hind legs.

Administration of topical or systemic residual insecticides and administration of topical, injectable, or oral IGRs have become the preferred methods to eliminate flea infestations. Several of these insecticides and IGRs have very effectively controlled fleas on pets living in infested premises. Field studies have shown that afoxolaner, fipronil with or without the addition of (S)-methoprene, imidacloprid, indoxacarb, fluralaner, lufenuron (with an adulticide), selamectin, and spinosad can effectively control flea infestations, without the need for premise treatment. Flea infestations can be eliminated via regular monthly use of topical and systemic approaches, because most fleas are killed before and/or directly inhibited from reproducing. However, even if the systemic or topical insecticide used is 100% effective, control of an existing infestation will typically take 2–3 mo because of the existing flea life stages in the environment.

If residual flea products are applied at the appropriate dose and treatment intervals, residual activity between applications may be adequate to kill many newly acquired fleas before egg production is initiated. However, flea survival and reproduction may occur before the next application for a variety of reasons: 1) residual activity <100% within the labeled time frame, 2) rate of flea kill slows during the third or fourth week, 3) delayed or infrequent product reapplication, 4) simple under-dosing, and 5) mechanical removal of water-soluble insecticides during bathing or swimming. These problems may result in delays in control or outright treatment failures.

Some of the currently available residual flea products may not be 100% effective against all cat flea strains between labeled reapplication periods because of genetic variability of different flea populations. Many of the factors that allow flea infestations to persist could possibly lead to genetic selection of resistant flea populations. Surviving fleas may be capable of producing viable eggs. Continued reproduction must be halted to prevent persistent flea infestations and selection for resistant fleas. Reproduction can be prevented by administration of topical or systemic IGRs, which provide prolonged residual ovicidal activity, interrupting future flea development even after residual activity of an insecticide is diminished. Application of methoprene or pyriproxyfen to the hair coat of dogs and cats rapidly kills developing flea eggs in addition to residual ovicidal activity. The combination of fipronil/(S)-methoprene or other adulticidal/ovicidal products has

demonstrated activity against adult fleas and provides prolonged residual ovicidal activity, thus reducing the potential for genetic selection. Not only have topically applied IGRs been shown to be ovicidal, but orally administered or injectable (cats only) lufenuron also provides ovicidal activity. Although not an IGR, selamectin also demonstrates ovicidal activity in cats.

Many pet owners mistakenly think that flea products either kill all newly acquired fleas within seconds to minutes or completely repel them. But repellency may sometimes be nonexistent, and residual products do not kill most fleas within minutes. Often fleas may live for 6–24 hr and consume blood before being killed. Therefore, close scrutiny of treated pets in an infested environment occasionally results in a few flea sightings on pets for up to 8 wk and occasionally longer until the infestation is eliminated.

An additional complication for pet owners is infestation of the yard by wildlife, feral cats and dogs, or other infested pets. Often owners will treat their pets, but do not realize the environment their pet frequents may be constantly infested with fleas by wildlife or feral animals (especially cats). Even when pets go outdoors for only brief periods, they are susceptible to becoming infested. Additionally, people can act as carriers, bringing fleas into the household and infesting unprotected pets.

In cases of severe, massive flea infestations or severe pet or human flea allergy, treatment of the premises may be necessary. Pet owners should begin by conducting a mechanical control program. Helpful procedures include washing pet blankets, throw rugs, and pet carriers; in addition, pet sleeping and resting areas should be vacuumed thoroughly to help remove flea eggs and larvae. Seat cushions and pillows on sofas and chairs should be removed and vacuumed, and special attention given to crevices in sofas and chairs and to areas beneath sofas or beds where flea eggs and feces may drop from the pet and accumulate. Intermittent-light flea traps can also be beneficial. The overall goal of mechanical intervention is to reduce preexisting biomass of immature and adult life stages in the premises. In addition, treatment of the premises with adulticides and IGRs may still be necessary in some infestations. Control may be achieved by using insecticides with residual activity (or by repeated application of short-acting insecticides) in combination with an IGR to prevent development of flea eggs and larvae. Methoprene and pyriproxyfen are the currently available

IGRs for premise application. Insecticides and IGRs can be applied by broadcast treatment (hand pump sprayers or pressurized aerosols) or with total release aerosols or "foggers." During application, the surface of all rugs and carpets must be treated adequately. Efforts should be directed to areas where flea eggs and larvae accumulate, such as carpets, cracks, grooves in hardwood floors, behind baseboards, under the edge of rugs, beneath furniture (beds, tables, and sofas), and within closets. In severe infestations, a second treatment may be necessary 7–10 days later because of continued emergence of adult fleas from cocoons hidden deep within carpets.

Elimination of fleas in the yard can be an important aspect of flea control. Outdoor treatments (eg, imidacloprid, cyfluthrin, fenvalerate) should concentrate on primary areas of flea development, including protected microhabitats such as dog houses, within garages, under porches, and in animal lounging areas beneath shrubs or other shaded areas. Spraying flea control products over the large expanse of a shade-free lawn generally is not beneficial in control efforts and is poor environmental practice.

Despite the efforts of pet owners, the total elimination of fleas may not be

feasible in some situations or may not occur rapidly enough to control clinical signs of FAD. Supportive medical therapy must be instituted to control pruritus and secondary skin disease in hypersensitive animals. Systemic glucocorticoids are often needed to control inflammation and associated pruritus. Short-acting prednisone or prednisolone can be administered initially at a dosage of 0.5–1 mg/kg/day, tapering the dosage and using alternate-day therapy until the lowest dose possible that still controls the pruritus is given. As soon as flea control is accomplished, the glucocorticoid can be discontinued. Anti-inflammatory therapy should never be used as a substitute for flea control.

Secondary bacterial skin infection can be associated with FAD. Systemic antibiotics are commonly used to control the pyoderma and thus reduce the associated inflammation and pruritus. Selection of an appropriate antibiotic should be based on bacterial cultures and results of antibiotic sensitivity tests.

Hyposensitization consists of administering allergens to a hypersensitive animal on a regular basis in an attempt to obtain a state of clinical nonreactivity to flea bites. The effectiveness of currently available whole flea extracts is controversial.

FLIES

Flies belong to the order Diptera, a large, complex order of insects. Most members of this order have two wings (one pair) as adults. However, there are a few wingless dipterans. Dipterans vary greatly in size, food source preference, and in the developmental stage that parasitizes the animal or produces pathology. As adults, dipterans may intermittently feed on vertebrate blood or on saliva, tears, or mucus. These dipterans are referred to as periodic parasites and may serve as intermediate hosts for helminth parasites or for protozoan parasites. They may also alternately feed both on feces and on food and may possibly serve as vectors for bacteria, viruses, spirochetes, chlamydiae, etc. As larvae (maggots), dipterans may develop in the subcutaneous tissues of the skin, respiratory passages, or GI tract of

vertebrate hosts and produce a condition known as myiasis.

DIPTERANS WITH BITING MOUTH PARTS

Blood-feeding dipterans can be classified based on which sexes feed on vertebrate blood and on food preference. In certain species of dipterans, only the females feed on vertebrate blood, which is required for egg laying; these species include black flies, sand flies, biting midges, mosquitoes, horse flies, and deer flies. In other species of blood-feeding dipterans, both male and female flies feed on vertebrate blood; these species include stable flies, horn flies, buffalo flies, tsetse flies, sheep keds, and hippoboscids or louse flies.

BLACK FLIES

Members of the family Simuliidae are commonly called black flies (although their coloration may vary from black to gray to yellow to olive) or buffalo gnats (because their thorax is humped over the head, giving the appearance of a buffalo's hump). Black flies are the tiniest of the blood-feeding dipterans, 1–6 mm long. They have broad, unspotted wings with thick, prominent veins along the anterior margins. Black flies have compound eyes; eyes of females are distinctly separated, whereas those of the males are contiguous above the antennae. The palps have five segments. Female black flies have scissor-like mouthparts with tiny, sharp, serrated edges. The female flies require a blood meal to lay eggs. Males are never bloodfeeders but instead feed on nectar from flowers.

Although there are >1,000 species of black flies, only a few are considered important as pests. Black flies feed on all classes of livestock, wildlife, birds, and people.

Black flies are distributed throughout the world in areas where conditions permit development of the immature forms. Larvae nearly always are found in swiftly flowing, well-aerated water; shallow mountain torrents are favored breeding places. Some species breed in larger rivers; others live in temporary or semipermanent streams. Black flies are particularly abundant in the north temperate and subarctic zones, but many species are found in the subtropics and tropics where factors other than seasonal temperatures affect their developmental and abundance patterns.

Larval black flies are cylindrical and attach themselves by a large posterior sucker. On the anterior end are the mouthparts and a pair of brush-like organs. The larvae are carnivorous. Just below the mouthparts is an arm-like appendage called the proleg. Larvae attach to rocks or other solid objects in the stream, sometimes clinging to aquatic or emergent vegetation. The mature larva spins a triangular cocoon on the floor of the stream. The oblong pupa has one dorsal and one ventral respiratory tube, the branches of which float out of the cocoon.

Black flies produce one to six generations per year, depending on the species and climatic conditions. Adult female feeding activity may last from 2–3 wk to 3 mo. Adult black flies may fly 8–11 miles (12–18 km) from swiftly flowing streams; migrating windborne swarms have been known to travel ≥250 km.

Pathology: Because of their tiny, serrated mouthparts, female black flies inflict painful bites. The ears, neck, head, and abdomen of cattle are favorite feeding sites. In addition to local reactions (redness, itching, wheals) at the bite site, there may be general conditions that vary in intensity with the sensitivity of the animal and the number of bites. Attacks by large numbers of black flies can cause severe damage and high mortality in livestock. People may be similarly attacked.

Death from black fly attack apparently results from a toxin in the saliva, which increases capillary permeability and permits the fluid from the circulatory system to ooze into the body cavity and tissue spaces. The animal rapidly succumbs to a mass attack but can recover quickly if protected from further attacks. Reduced milk, meat, and egg production may result from less extensive attacks. Certain species of black flies sometimes cause losses in poultry, either by direct attack or through transmission of *Leucocytozoon* spp. In Africa, *Simulium damnosum* and *S. neavei* are important as vectors of *Onchocerca* spp. *S. neavei* is an important vector of *O. volvulus*. In Central America, *S. ochraceum*, *S. metallicum*, *S. callidum*, and *S. exiguum* are important vectors of *Onchocerca* spp. *S. ochraceum* and *S. metallicum* also are vicious biters.

Diagnosis: Black flies are most often collected in the field and not found on the animals. Adult flies can be identified by their small size, humped back, prominent venation in the anterior region of the wings, and tiny, serrated mouthparts. Identification of black flies to genus and species is probably best left to an entomologist.

Treatment and Control: If public funds and trained supervisory personnel are available, large-scale control of black flies is possible by treating breeding streams with an approved larvicide. However, black fly control is difficult because of the large number of flowing water breeding sites. Streams can be treated using the natural product, *Bacillus thuringiensis* var *israelensis*, a product with no mammalian toxicity.

Treatment of streams and rivers involves techniques similar to those used by mosquito abatement programs. As a rule, pesticides should not be used owing to their potential negative effects on the environment. Pesticide treatments involving water surfaces or large land areas are subject to governmental regulation and must be

performed with due regard for possible deleterious environmental effects and residues in food products.

Adult black flies are small enough to pass through window screens or may come indoors on or within a pet's hair coat. More often, the adult female flies prefer to feed outdoors and during the daylight hours. Because black flies feed predominantly during the daylight hours, it is wise to limit exposure of pets to swiftly flowing streams. Pet owners concerned about black fly bites may use over-the-counter insect repellents. Aerosols containing pyrethrins may provide only temporary relief.

Because area-wide control of black flies is difficult and expensive, livestock producers frequently resort to the daily use of repellents to protect their animals. Extension entomology personnel should be contacted for the latest approved recommendations and withdrawal times.

SAND FLIES

The phlebotomine sand flies, *Phlebotomus* spp (Old World sand flies) and *Lutzomyia* spp (New World sand flies), are members of the family Psychodidae. These flies are confined primarily to the tropical and subtropical regions of the world. Members of these genera are tiny, moth-like flies, ~1.5–4 mm long. The legs are as long as the antennae, comprising 16 segments that often have a beaded, hairy appearance. They are commonly known as sand flies, moth flies, or owl midges. The key morphologic feature for identification is that the body of the sand fly is covered with fine hairs. The females have piercing mouthparts and feed on blood of a variety of warm-blooded animals, including people. Many species feed on reptiles. Male sand flies suck moisture from any available source and are even said to suck perspiration from people. Sand flies tend to be active only at night and are weak fliers; their flying is deterred by air currents, even slight ones. During the day, sand flies seek protection in crevices and caves, among vegetation, and within dark buildings. They often seek protection within rodent and armadillo burrows; these mammals can serve as reservoir hosts for *Leishmania* spp. Sand flies breed in dark, humid environments that have a supply of organic matter that serves as food for the larvae. They do not breed in aquatic environments.

Pathology: These tiny flies serve as an intermediate host for *Leishmania* spp, a protozoan parasite that infects the

reticuloendothelial cells of capillaries, the spleen, and other organs but may be seen in monocytes, polymorphonuclear leukocytes, and macrophages of people, dogs, cats, horses, and sheep (see p 800).

Diagnosis: Like black flies, sand flies can most often be collected in the field and are not found on animals. They can be identified by their small size and hairy wings and bodies. Identification of genus and species is probably best left to an entomologist.

Treatment and Control: Insecticide spraying of larval habitat is usually not possible because of the difficulty of accessing breeding sites. Removal of dense vegetation discourages breeding. Spraying of residual insecticides on surfaces in the home is the main way to control sand flies; however, this is ineffective for species that bite away from the home. In general, populations of sand flies have been reduced as a result of intense mosquito control programs. Deltamethrin-impregnated collars may be recommended to dog owners to protect their pets from sand fly bites.

BITING MIDGES

The biting midges, “no-see-ums,” or punkies belong to the family Ceratopogonidae. The most common biting midges are *Culicoides* spp. They are associated with aquatic or semiaquatic habitats, eg, mud or moist soil around streams, ponds, and marshes. Biting midges are tiny gnats (1–3 mm long) and, like black flies, inflict painful bites and suck the blood of their hosts, both people and livestock.

Pathology: *Culicoides* spp are vicious biters and can cause intense irritation and annoyance. In large numbers, they can cause livestock to be nervous and interrupt their feeding patterns. These gnats tend to feed on the dorsal or ventral areas of the host; feeding site preference depends on the species of biting gnat. They fly only in the warm months of the year and are most active before and during dusk. They feed often on the mane, tail, and belly of horses. Horses often become allergic to the bites, scratching and rubbing these areas, causing alopecia, excoriations, and thickening of the skin. This condition has several names, including culicoid hypersensitivity in Canada, Queensland itch in Australia, Kasen in Japan, sweat itch, and sweet itch. Because it is often seen during the warmer months of the year, it is also referred to as

summer dermatitis. These flies also serve as the intermediate host for *Onchocerca cervicalis*; the microfilariae of this nematode are found in the skin of horses. Onchocerciasis (see p 905) is a nonseasonal dermatosis that is similar to sweet itch but usually is less pruritic and affects the head, neck, and belly. These flies also transmit the bluetongue virus (see p 738) in sheep and cattle.

Diagnosis: Like black flies and sand flies, biting midges are most often collected in the field and not found on the animals. In contrast to the clear, heavily veined wings of black flies, the wings of *Culicoides* spp are mottled. Identification is probably best left to an entomologist.

Treatment and Control: Larvae may be attacked in their breeding grounds. Extension entomology personnel should be contacted for the latest approved recommendations.

Bio Kill Stable Spray™, a modified permethrin, is approved for the spraying of stables and horseboxes to aid in the control of biting midges. A backpack or handheld bulk pesticide spray pack, turbo-blower, or fogger should be used. A fine spray should be produced under pressure, in the amount of 500–750 mL per stable (stable size: 3 m × 3.5 m to 4 m × 4 m). All surfaces in the stable should be sprayed. A reapplication 7–10 days later is needed. Thereafter, application every 3–4 wk should provide ample product buildup on the walls.

Because *Culicoides* spp are poor flyers, an electric fan may be used in the stable to create air movement around the horses. Fly repellent ear tags attached to the horse's mane and tail (not approved in the USA); pyrethrum synergized with piperonyl butoxide, applied weekly; butoxypolypropylene glycol 800, applied daily; stable blankets; and fine screens on stable doors and windows have been used with mixed success. Topical insecticides such as pyrethrins (eg, cypermethrin or cyfluthrin), especially in pour-on formulations, may also be used to control these adult pests in large animals.

MOSQUITOES

Mosquitoes are members of the family Culicidae. Important genera include *Aedes*, *Anopheles*, *Culex*, *Culiseta*, and *Psorophora*. Although they are tiny, fragile dipterans, mosquitoes are perhaps some of the most voracious of the blood-feeding arthropods. Approximately 300 species

have been described worldwide, with ~150 species found in the temperate regions of North America. Mosquitoes are found in such diverse areas as salt marshes of the coastal plains to snow pools above 14,000 ft (4,300 m) to the gold mines of India 3,600 ft (1,100 m) below sea level. The volume of water in which mosquitoes will breed varies from that within an empty can or tree hole to large shallow pools of accumulated, standing water from either rain or snow melt.

Mosquitoes lay their eggs either on the surface of standing water (eg, *Aedes* and *Psorophora* spp) or on a substrate (such as damp soil) where the eggs hatch after inundation from rainfall, irrigation, snow melt, etc. Larval mosquitoes are known as wrigglers, whereas pupal mosquitoes are known as tumblers. These stages are always aquatic and are found in a wide variety of habitats. Large numbers of mosquitoes can be produced from eggs laid in relatively small bodies of water. Some species have several generations per year. The flight habits of adult mosquitoes vary with the species; some *Aedes* sp migrate many miles for their aquatic, larval habitat. In strong winds, mosquitoes may be carried great distances. Some species overwinter as eggs, while others overwinter as adults.

Pathology: Only female mosquitoes actively take a blood meal so that they can lay eggs. Males feed on nectar, plant juices, and other liquids. Mosquitoes annoy livestock, cause blood loss, and transmit disease. Also, the toxins injected at the time of biting may cause systemic effects. The feeding of large numbers of swarming mosquitoes can cause significant anemia in domestic animals. Although they are known for spreading malaria, yellow fever, dengue, and elephantiasis in people, mosquitoes are probably best known in veterinary medicine as the intermediate host for the canine heartworm, *Dirofilaria immitis*, and as the vectors of the equine viral encephalitides, including West Nile virus.

Anopheles quadrimaculatus is the intermediate host for malaria (*Plasmodium* spp) in people and other primates. *Aedes aegypti* is the yellow fever mosquito, transmitting this virus among people. *Psorophora columbiae* is a severe pest of both livestock and people in the rice fields of Louisiana and Arkansas. *Culex tarsalis* is an important vector of Western equine encephalitis and is found in the western, central, and southern USA. *Aedes vexans* is an important nuisance species found in the Midwest. *Aedes albopictus* is a recently

introduced Asian species that also spreads yellow fever, dengue, and equine encephalitis. Certain *Mansonia* spp are severe pests of livestock in Florida. In Central and South America, the adult female bot fly *Dermatobia hominis* fastens her eggs to a species of *Psorophora* mosquito, which then transmits them to the mammalian host during feeding.

Diagnosis: Adult mosquitoes are most often collected in the field and are not found on animals. Adults are 3–6 mm long and slender, with small, spherical heads and long legs. The wing veins, body, head, and legs are covered with tiny, leaf-shaped scales. The long, filamentous antennae have 14–15 segments and are plumose in the males of most species. They also have proboscides designed for lacerating tiny blood vessels and sucking up pooled blood. Identification of the plethora of mosquito species (adult, larval, and pupal stages) is probably best left to an entomologist.

Treatment and Control: Area control of mosquitoes usually involves the cooperation of many individuals and can be accomplished successfully by experienced personnel with proper equipment. Areas that can serve as breeding sites for mosquito larvae should be eliminated or reduced. In addition, area programs generally include extensive use of larvicides; however, mosquito larvicides can disrupt the normal ecologic balance within an ecosystem. Recently, the use of various species of fish as biologic controls has been successful. In massive emergence of adult mosquitoes, particularly when disease transmission is a concern, application of an insecticide active against the adult may be necessary.

Caution is advised with area treatment programs, because many nontarget organisms (eg, fish, shrimp, bees) may be exposed to insecticides. A local extension entomologist should be consulted regarding appropriate materials for use on animals or within premises. Large-scale programs usually are coordinated by mosquito abatement district or other government agencies.

It is difficult for individual producers to protect their animals; residual sprays on the animals do not prevent feeding females from landing, and currently available repellents do not confer adequate protection during massive emergence. Protection from adult mosquitoes may be provided by ground and, in some cases, aerial application of an insecticide at the time of emergence. Depending on local conditions, this protection may be of short duration.

Valuable animals should be housed in closed or screened buildings and the mosquitoes inside killed with a fog or aerosol formulation of an approved insecticide. Temporary relief may be afforded by a spray or “wipe on” of materials commercially available.

Walking pets or allowing pets free range, outdoor access in the early morning or early evening hours when adult mosquitoes are most abundant should be avoided to reduce exposure to mosquito bites. Imidacloprid has been used as a topical prevention and treatment of ticks, fleas, and mosquitoes on dogs and puppies ≥ 7 wk old, weighing >2 lb (0.91 kg). It has been shown to repel adult female mosquitoes for as long as 4 wk. Unfortunately, it cannot be used on cats. Mosquitoes are not attracted to light; thus, electrocution devices are not helpful in mosquito control and may actually be detrimental, because they may destroy beneficial insects that prey on mosquitoes.

A combination of two compounds, imidacloprid and permethrin, works to repel and kill the many species of blood-feeding mosquitoes that often feed on dogs. Monthly application of this product repels and kills mosquitoes, preventing their blood-feeding activity and ostensibly helping to prevent transmission of organisms such as *Dirofilaria immitis* from dog to dog. This product may not be used on cats.

HORSE FLIES AND DEER FLIES

Tabanus spp (horse flies) and *Chrysops* spp (deer flies) are large (up to 3.5 cm long), heavy bodied, robust dipterans with powerful wings and very large eyes. They are swift fliers. These flies are the largest in the dipteran group, in which only the females feed on vertebrate blood. Horse flies are larger than deer flies; many horse flies are highly colored. Deer flies are medium sized; they have a dark band passing from the anterior to the posterior margin of the wings and a yellow to brown abdomen with black patches and longitudinal bands.

Adult horse flies and deer flies lay eggs in the vicinity of open water. Larval stages are found in aquatic to semiaquatic environments, often buried deep in mud at the bottom of lakes and ponds. The developing larval stages have sharp mandibles and are predatory on smaller vertebrates and invertebrates; they will even lightly nip at the toes of people wading in shallow water. This is an unusual dipteran fly in that both larval stages and adult flies are capable of inflicting pain as they bite.

Pathology: Adults are seen in summer, particularly in sunlight. Adult females of both species feed in the vicinity of open water and have reciprocating, scissor-like mouthparts, which they use to lacerate tissues and lap up the oozing blood. They consume 0.1–0.3 mL of blood at a single feeding. Bites are painful and irritating. These flies feed primarily on large animals, such as cattle and horses, which become restless when the flies are present. Site preferences include the underside of the abdomen around the navel, the legs, or the neck and withers. Horse flies and deer flies feed a number of times in multiple feeding sites before they become replete. When disturbed by the animal's swatting tail or by the panniculus reflex, the flies leave the host, yet blood continues to ooze from the open wound. These flies may act as mechanical transmitters of anthrax, anaplasmosis, tularemia, and the virus of equine infectious anemia.

Diagnosis: These flies can be identified by their large size, powerful wings, compound eyes, and lacerating scissor-like mouthparts. Species identification of intact adult and larval horse and deer flies is probably best left to an entomologist.

Treatment and Control: Horse flies and deer flies are the most difficult to control of all of the bloodsucking flies. Many of the adulticide compounds used for other biting flies can kill both horse and deer flies. However, because these flies are intermittent feeders that alight on the host for only a short time, they may not be exposed to these compounds long enough to be affected. Thus, larger doses of the compounds may be required.

Horse fly traps have been effective when used around cattle confined to manageable areas. For livestock, pyrethroid pour-ons function as limited repellents. Self-application techniques are usually not effective for horse and deer flies.

Manipulation of these flies' aquatic habitat has been attempted by removing unnecessary woody plants from residential areas or draining wet areas. Application of insecticides in the water may have detrimental environmental effects.

STABLE FLIES

The stable fly, *Stomoxys calcitrans*, is often called the biting house fly. It is about the same in size and general appearance as *Musca domestica*, the house fly. It is

brownish gray, the outer of four thoracic stripes is broken, and the abdomen has a checkered appearance. It has a bayonet-like, needle-sharp proboscis that, when at rest, protrudes forward from the head. The wings, when at rest, are widely spread at the tips. These flies are found throughout the world. In the USA, they are found in the midwestern and southeastern states.

The larval and pupal forms develop in decaying organic matter, including grass clippings and seaweed along beaches. In the midwestern USA, larvae can be found in wet areas around the edges of hay stacks and silage pits. Where cattle are fed hay, breeding can occur at the edge of the feeding area where hay has become mixed with urine and feces. The life cycle in the field can be completed in 2–3 wk, and adults may live ≥3–4 wk.

Pathology: Both male and female stable flies are avid blood feeders, feeding on any warm-blooded animal. Stable flies stay on the host for short periods of time, during which they obtain blood meals. This is an outdoor fly; however, in the late fall and during rainy weather, it may enter barns.

Horses are the preferred hosts. The fly usually lands on the host with its head and proboscis pointed upward and inflicts painful bites that puncture the skin and bleed freely. It is a sedentary fly, not moving on the host. Stable flies usually attack the legs and ventral abdomen and may also bite the ears. They can be a problem in cattle feedlots in the Midwestern USA. The damage inflicted to cattle is caused by the painful bite and blood loss, and the irritation results in a reduced efficiency in converting feed to meat or milk. In pets, stable flies prefer to feed on the tips of the ears of dogs with pointed ears, especially German Shepherds.

Stable flies are mechanical vectors of anthrax, surra, and equine infectious anemia. They are the intermediate host for *Habronema muscae*, a nematode found in the stomach of horses.

Diagnosis: Stable flies are easily identified by their size (about the same as that of the house fly), coloration, and bayonet-like proboscis that protrudes forward from the head.

Treatment and Control: The main consideration in stable fly control is sanitation, which can effect up to 90% control. Areas along fence rows, under feed bunks, or wherever manure and straw or

decaying matter can accumulate should be kept clean, because these substrates provide the medium in which the larval flies develop. If good sanitation procedures are practiced, chemical control is less likely to be needed. Various insecticides can be sprayed where flies may be resting in barns or on fence rows.

Stable flies feed on the lower portions of cattle, around the legs and belly, including the udder. They usually feed only once or twice daily for short periods, thus minimizing exposure to compounds applied to these areas. Often, insecticides applied to these body regions are rubbed off by contact with dense vegetation and mud or rinsed off when dairy cattle are rinsed before milking. Direct animal application of sprays and dusts may be used in some instances to protect large animals. Insecticides used for direct animal application usually have short residual activity. This type of application is quite labor intensive.

A combination of two compounds, imidacloprid and permethrin, works to repel *S. calcitrans*. Monthly application repels these flies and prevents their blood feeding on dogs, but the product does not kill this type of biting fly.

HORN FLIES

The common name of *Haematobia irritans* comes from the fact that these flies often cluster in the hundreds around the base of the horns of cattle. This major pest of cattle is found in most cattle-producing areas of the world. Populations are common in Europe, North Africa, Asia Minor, and the Americas. Throughout North America, horn flies are found almost exclusively on cattle, but they will feed on horses, sheep, goats, and wildlife. Horn flies are found in much larger numbers and for longer periods of time in the southern and southwestern USA.

Adult horn flies spend their entire life on their host, and females leave only to oviposit eggs on fresh cow feces, where larval and pupal development occurs. In the southern USA, the life cycle can be as short as 1 wk, but in cooler climates and in the spring or fall, development can take 2–3 wk. In some warmer areas (south Florida and southernmost Texas), horn flies reproduce throughout the year.

When the air temperature is $<70^{\circ}\text{F}$ (21°C), horn flies cluster around the base of the horns of cattle. In warmer climates, the flies often cluster in large numbers on the shoulders, back, and sides; these areas are

least disturbed by tail switching. On hot, sunny days, horn flies accumulate on the ventral abdomen.

Newly emerged flies seeking their host may travel 7–10 miles (11–15 km) but usually find a host in much shorter distances. Migration seldom occurs over any great distance. In the southern USA, fly populations on individual animals may be in the thousands, especially on bulls not receiving chemical treatment; in the north, they may not exceed 100, although the damage inflicted is similar.

Pathology: Horn flies feed frequently (as many as 20 times/day), sucking blood and other fluids; female flies are more aggressive than males. Feeding causes pain, annoyance, and blood loss in cattle. Irritated animals also lose weight because of their less efficient use of feed. Heavy infestations cause lesions along the ventral midline of the animal. Horn flies cause great economic losses annually in the USA; 14% reductions in weight gains on range cattle and losses of 12–14 lb (5–6 kg/head) in weaned calves are common. In dairy cattle, milk production may be reduced 10%–20%. These flies also serve as the intermediate host for *Stephanofilaria stilesi* (see p 907), a filarial parasite that produces plaque-like lesions on the ventral abdomen of cattle.

Diagnosis: Horn flies can be easily identified by their dark color, size (~3–6 mm long, approximately half the size of a stable fly), and bayonet-like proboscis that protrudes forward from the head.

Treatment and Control: Horn flies are relatively easy to control with whole-animal chemical sprays and with self-treating devices (eg, dust bags or back rubbers) in a forced-use manner. Dust bags are most effective when cattle are required to pass under them daily to reach water or mineral supplements. Dust bags leave a deposit of insecticides along the dorsum, the areas where horn flies spend most of their time. Back rubbers allow cattle to treat themselves as they scratch. The insecticide should be diluted with a good grade of mineral oil according to label instructions. Feed additives pass through the animal to kill larval stages that develop in fresh cow feces. All animals must consume a minimum dose of a feed additive regularly. Insect growth regulators also prevent development of larvae in cow feces. When used according to label directions,

insecticide-impregnated cattle ear tags (eg, pyrethroids) release small amounts of insecticides that are distributed over the animal during grooming or rubbing. Animals should be tagged at or near the beginning of fly season, the tags removed at or near the end of fly season, and alternative methods with nonpyrethroid insecticides used near the end of fly season. Pour-on insecticide formulations are also effective against horn flies. These compounds are applied to cattle in measured doses based on body weight. Most of these pour-ons function as contact insecticides.

BUFFALO FLIES

Buffalo flies, *Haematobia irritans exigua*, are similar to horn flies in size and appearance and in feeding and breeding habits. The buffalo fly is a primary pest of cattle and water buffalo but occasionally feeds on horses, sheep, or wildlife. It is distributed throughout northern Australia and New Guinea and is found in parts of southern, southeastern, and eastern Asia as well as Oceania; it is not found in New Zealand. Its life cycle is similar to that of the horn fly; the adult leaves the host long enough to oviposit on fresh manure, where development occurs. The life cycle may take as few as 7–10 days, depending on weather conditions.

Pathology: Buffalo flies irritate and annoy animals, usually biting at the shoulders and withers. Bite wounds may provide a site for screwworm (*Chrysomya bezziana*) infection. During hot weather, the flies move to shaded parts of the body. Affected animals suffer blood loss and are irritated by the flies; feed efficiency and production may be affected adversely.

Diagnosis: Buffalo flies can be identified by their dark color, size (approximately half that of a stable fly), and bayonet-like proboscis that protrudes forward from the head.

Treatment and Control: Insecticides should be avoided in the treatment of buffalo fly populations. Many of the chemicals used to treat these flies result in meat residues. Buffalo flies have developed resistance to the synthetic pyrethroids and to some of the organophosphates. Buffalo fly traps have been developed in Australia. The trap consists of a rounded, clear plastic tent through which the cattle walk. The flies are brushed off the cattle within the tent and are then trapped inside where they die of desiccation. These traps

remove ~80% of the buffalo flies each time the cattle pass through. When cattle pass through the trap every day or every second day, sufficient fly control is usually achieved.

TSETSE FLIES

The tsetse flies, *Glossina* spp, are important blood-feeding flies found in Africa (latitude 5°N to 20°S). Tsetse flies are narrow bodied, yellow to dark brown, and 6–13.5 mm long. When resting, their wings are held over the back in a scissor-like configuration. The thorax has a dull greenish color with inconspicuous spots or stripes. The abdomen is light to dark brown.

Both sexes are avid blood feeders. One copulation renders a female fly fertile for her lifetime, during which she can produce as many as 12 larvae. She produces one larva at a time, retaining it within her uterus; after ~10 days, the larva is deposited on loose, sandy soil, where it digs in and begins pupation within 60–90 min. This pupation period averages ~35 days, after which the adult emerges. Adult flies feed avidly on vertebrate blood approximately every 3 days.

Pathology: Tsetse flies serve as the intermediate hosts for several species of trypanosomes that cause fatal diseases of both domestic animals (nagana) and people (African sleeping sickness). Trypanosomes invade the blood, lymph, CSF, and various organs of the body, such as the liver and spleen. Nagana, a related complex in cattle caused by *Trypanosoma brucei*, has occurred throughout enormous areas estimated to be as great as one quarter of the African continent. The disease is fatal to horses, mules, camels, and dogs. Cattle, sheep, and goats usually survive, except when parasitized by certain strains. Many wild ungulates native to Africa show no evidence of harm. (See also *TRYPANOSOMIASIS*, p 35.)

Diagnosis: Tsetse flies can be identified by their honeybee-like appearance, the long proboscis with its onion-shaped bulb at the base, and the unique wing venation with the characteristic cleaver- or hatchet-shaped cell in the center of the wing.

Treatment and Control: Tsetse flies can be controlled by catching and trapping (tsetse traps), bush clearing, fly screens, repellents, insecticides, and sterile male release techniques.

SHEEP KEDS

The sheep ked, *Melophagus ovinus*, is one of the most widely distributed and important external parasites of sheep. There are also keds that parasitize deer in North America (*Lipoptena depressa* and *Neolipoptena ferrisi*).

Keds are wingless dipterans. The adult is ~7 mm long, brown or reddish in color, and covered with short, bristly hairs. The head is short and broad, and the legs are strong and armed with stout claws.

The female gives birth to a single, fully developed larva, which is cemented to the wool and pupates within 12 hr. A young ked emerges after ~22 days. Females live 100–120 days and produce ~10 larvae during this time; males live ~80 days. The entire life cycle is spent on the host. Keds that fall off the host usually survive <1 wk and present little danger of infestation to a flock. Ked numbers increase during the winter and early spring when they spread rapidly through a flock, particularly when sheep are assembled in close quarters for feeding or shelter.

Pathology: To feed, sheep keds pierce the skin with their mouthparts and suck blood. They usually feed on the neck, breast, shoulder, flanks, and rump but not on the back where dust and other debris collect in the wool. Ked bites cause pruritus over much of the host's body; sheep often bite, scratch, and rub themselves, thus damaging the wool. The fleece becomes thin, ragged, and dirty. The excrement of the keds causes a permanent brown discoloration, which is likely to reduce the value of the wool. Keds also cause a defect in hides called a cockle, which affects the grade and value of the sheep skin. Infested sheep, particularly lambs and pregnant ewes, may lose vitality and become unthrifty. Heavy infestations can considerably reduce the condition of the host and even cause anemia. Keds also transmit *Trypanosoma melophagium*, a nonpathogenic protozoan parasite of sheep.

Diagnosis: Close inspection of the damaged, dirty wool and underlying skin reveals infestation by the unique appearance of these wingless, hairy flies.

Treatment and Control: Shearing removes many pupae and adults. Thus, shearing before lambing and subsequent treatment of the ewes with insecticides to control the remaining keds can greatly reduce the possibility of lambs becoming heavily infested. Sheep are usually treated

after shearing, and best results are obtained if an insecticide that has a residual activity of ≥3–4 wk is used. By this means, the keds that emerge from the pupae are also killed. Modern treatments to control lice also control keds.

Dipping is an effective method of treatment. Completely submerging the sheep in vats ensures the destruction of all keds present but, in most instances, does not kill the pupated larvae; a long-acting insecticide is required to kill newly emerging keds. Large flocks of range sheep should be treated in a permanently constructed dipping vat. Smaller flocks and farm flocks may be successfully treated in portable, galvanized-iron dipping vats or in smaller tanks, tubs, or canvas dipping bags.

Spraying may be as effective as dipping and is more convenient in some areas. Pressures of 100–200 lb/sq in. (7–14 kg/cm²) for short wool and 300–350 lb/sq in. (21–28 kg/cm²) for long wool are commonly used.

Shower dipping is also sometimes used; the sheep are held in a special pen and showered from above and below until the fleece is saturated. The run-off is returned for recirculation, and the concentration of insecticide used is the same as for dipping. The concentration of the insecticide can drop rapidly and become ineffective if the instructions for replenishment are not followed explicitly.

Jetting involves the forceful application of the insecticide by means of a hand-held, multiple-jet comb drawn through the short fleece. Although a little slower and less effective than dips or sprays, jetting may be advantageous for smaller flocks because it is economical and does not require a permanent installation.

Spot-on or pour-on formulations of the newer pyrethroids are easy to apply and very effective.

Powder dusting fits well into management practices at shearing time. It is rapid, economical, and avoids wetting the animals. Various types of equipment for dusting are available commercially.

SPIDER FLIES/NEW FOREST FLIES

The spider or new forest fly, *Hippobosca equina*, is widely distributed throughout Europe, Asia, and Africa. These winged keds parasitize horses and rarely cattle throughout the UK. Its bite is characterized as a nuisance and disturbance to large domestic animals. It has a predilection for feeding sites in the perineal region and between the hind legs.

The winged adult is ~10 mm long with a flattened, shriveled body. The life cycle is similar to that of *Melophagus ovinus*, in that the female produces one larva at a time, and at the time of maturity the larva falls away from the female fly and pupates in the soil.

Treatment is rarely indicated, but many of the repellents used for other blood-feeding periodic parasites may be used.

HIPPOBOSCID OR LOUSE FLIES

The hippoboscids or louse flies, *Pseudolynchia* and *Lynchia* spp. are winged versions of the keds. They infest many song birds, raptors, and pigeons. The pigeon fly, *P. canariensis*, is an important parasite of domestic pigeons throughout the tropical and subtropical regions of the world. It is found throughout the southern USA and northward along the Atlantic coast to New England. These dark brown flies have long wings (6.5–7.5 mm) and are able to fly swiftly from the host.

Pathology: Hippoboscids move about quickly on their avian hosts and bite and suck blood from parts that are not well feathered. They may serve as intermediate hosts for many avian blood protozoans of the genus *Haemoproteus*. Pigeon flies readily attack people who handle adult birds; the bite is said to be as painful as a bee sting, and its effects may persist for 25 days.

Diagnosis: Close inspection of the ruffled feathers and underlying skin reveals infestation by the unique appearance of these winged, swiftly flying flies.

Treatment and Control: Any flies on the birds can be killed by spraying the birds with permethrin. Thorough cleaning of the premises and destruction of the debris are essential for control. Spraying the loft with permethrin, when coupled with cleaning, will alleviate the infestation.

DIPTERANS WITH NONBITING MOUTHPARTS

FACE FLIES

Face flies, *Musca autumnalis*, are so named because they gather around the eyes and muzzles of livestock, particularly cattle. They may also be found on the withers, neck, brisket, and sides. Their mouthparts are adapted for sponging up saliva, tears,

and mucus. Face flies are usually not considered blood feeders because their mouthparts are a sponging type and not piercing or bayonet-like, as are those of *Stomoxys calcitrans*. However, they follow blood-feeding flies, disturb them during the feeding process, and then lap up the blood and body fluids that accumulate on the host's skin. Face flies are found on animals that are outdoors and usually do not follow animals into barns.

Face flies are found on range cattle throughout southern Canada and most of the USA. The mouthparts consist of sponging labellae, and there are four longitudinal stripes on the abdomen. Although similar in appearance to the common house fly, face flies can be differentiated by the closeness and angles of the interior margins of the eyes and by the distinctive coloration of the face and abdomen. Speciation requires the skills of a trained entomologist.

Cattle are the principal host of the face fly in the USA, but face flies will also feed on horses and probably sheep and goats. The face fly is a pest of range cattle; it is not seen in feedlot situations and thus is not a parasite of confined cattle. The eggs are laid in fresh cattle feces in rangeland situations and hatch in ~1 day. The yellowish larvae develop in 2–4 days and, when mature, leave the manure to pupate in the surrounding soil. The complete life cycle from egg to adult requires 12–20 days, depending on climatic conditions. The diapausing adult overwinters within buildings and other protective places.

Pathology: Face flies annoy the host and ultimately interfere with the host's productivity. Females feed on facial secretions, such as tear fluid, nasal mucus, and saliva, to obtain protein for egg development. The irritation around the host's eyes stimulates the flow of tears, which attracts even more flies.

Face flies also feed on other fluid sources, such as blood from wounds and milk on calves' faces. Because face flies have small, rough spines (preoral teeth) on their sponging mouthparts, they can cause irritation and mechanical damage to the eye tissue of the host. The feeding activity of face flies enhances transmission of *Moraxella bovis* (see p 512). Face flies can also serve as intermediate hosts for *Thelazia* spp (see p 510) and for *Paratyphlocyba* (see p 906).

Diagnosis: Adult face flies are morphologically similar to house flies. These two

species can be differentiated only by minor differences in eye position and color of the abdomen. Speciation requires the skills of a trained entomologist. In general, if a medium-sized fly is seen feeding around the eyes and nostrils of a cow or horse, it is most probably a face fly.

Treatment and Control: Control of face flies is difficult. Much effort has been made using various insecticides and application techniques, such as dust bags, mist sprays, and wipe-on formulations. Also, insecticides and insect growth regulators are used as feed additives. However, results are usually less than satisfactory. The introduction of insecticide-impregnated ear tags has provided somewhat better control, but generally, seasonal face fly reduction of only 70%–80% has been achieved, even with two tags (one in each ear) per animal.

HEAD FLIES

(Plantation flies)

Head flies or plantation flies, *Hydrotaea irritans*, are nonbiting flies found in large numbers in northern European countries, especially Denmark and Great Britain, where they are pests of cattle, sheep, and other livestock. This fly resembles the house fly and is ~4–7 mm long. The thorax is black with gray patches, the abdomen is olive green, and the wing bases are orange yellow.

Head flies are a nuisance to domestic animals and people because they are attracted to the mouth, nose, ears, eyes, and wounds to feed on secretions. Unlike other *Hydrotaea* spp, *H. irritans* produces one generation per year, with three larval instar stages. Eggs deposited in late summer hatch out larvae within a few days. The saprophagous stage is brief, before development to the stage that is predatory on other insect larvae. Overwintering occurs as late-stage larvae. Adults are most active from early June until late September and are common in the vicinity of thickets or woodlands in which they shelter between periods of feeding.

Pathology: In Great Britain, sheep are mainly affected. Large swarms of flies, attracted by the movement of animals, congregate to feed on secretions from the eyes and nose and on the cellular debris at the grown horn base. To alleviate the persistent irritation, sheep scratch and rub their heads, resulting in raw wounds or "broken heads," especially on the poll.

Flies, attracted by the blood, settle on these self-inflicted lesions and extend the margins by their feeding activity. Sheep of all ages are involved, but breeds with horns and without wool on the head are most severely affected.

Head flies also attack people, deer, horses, cattle, and rabbits. Although no corresponding broken head lesions develop in cattle, the occurrence of summer mastitis (due to *Trueperella pyogenes*) and the seasonal activity of head flies are closely associated, especially in Denmark. Head flies may also be involved in the spread of myxomatosis in rabbits (see p 1950).

Treatment and Control: The development, emergence, and congregation of head flies, which occur away from farm areas, preclude the traditional methods of insecticide spraying of generalized breeding sites and resting habitats. Control at the point of contact between the feeding adult insects and the mammalian hosts is also limited in value. With sheep, the retention of organophosphate compounds or pyrethrin derivatives on the susceptible head areas is of short duration, which necessitates impractical reapplications in free-ranging animals. Use of insecticide-impregnated ear tags in cattle decreases the incidence of summer mastitis, presumably by reducing transmission by head flies.

Removal of livestock from infested locations during the fly season is the only completely effective way to prevent damage. Once broken heads have occurred, the housing of sheep is the only successful method to stop further fly damage.

FILTH-BREEDING FLIES

The following adult dipterans are often referred to as filth-breeding flies: *Musca domestica* (the house fly); *Calliphora*, *Phaenicia*, *Lucilia*, and *Phormia* spp (the blow flies or bottle flies); *Sarcophaga* spp (the flesh flies); *Fannia* spp (the little house flies); *Muscina* spp (the false stable flies); and *Hermetia illucens* (the black soldier flies). Large populations of these adult flies are often found around facilities associated with animal feces. Larval stages may be associated with skin wounds contaminated with bacteria or with a matted hair coat contaminated with feces (see p 897). The life cycle of *M. domestica* will be used as a representative example of the life cycles of the assorted filth-breeding flies.

The house fly is commonly found around livestock and poultry operations, where it readily breeds in accumulating manure

sources. It is a medium-sized (as large as 9 mm), grayish fly with four dark thoracic stripes and sponging, nonbiting mouthparts designed for sucking semiliquid food (there are no mandibles or maxillae). The labium is expanded into two labellae that can transfer fluids and semifluids.

After oviposition, the creamy-white, banana-shaped egg (~1 mm long) hatches in 6–12 hr in optimal conditions. The eggs are not resistant to drying, and few appear to survive temperatures $>40^{\circ}\text{C}$ or $<15^{\circ}\text{C}$. Larvae may develop in a few days to 3 wk, depending on the temperature and availability of food. When temperature for larval development is optimal ($\sim 36^{\circ}\text{C}$), the larvae develop to pupae in ~6 hr. Pupae persist 4–5 days in warm weather. After the adults emerge, the flies search for food and copulate after a few days. The life cycle is usually completed in ~3 wk, although it can be completed in as little as 10–14 days under favorable conditions. In temperate climates, it is thought that house flies overwinter as pupae.

Pathology: Even though these flies do not feed on blood, annoyance caused by their movement on and off animals can lead to reduced performance. In addition, they have been implicated in the transmission of numerous pathogens (helminth, protozoan, bacterial, and viral) of people and other animals. Large populations of these adult flies often are found around poorly managed livestock or poultry facilities and become a public annoyance. These are synanthropic flies, ie, they are often associated with human dwellings. The flies are “vomit drop” feeders and fly from feces to food, spreading bacteria on their feet and within their disgorged stomach contents.

Diagnosis: All adult filth-breeding flies have similar sponging, nonbiting mouthparts, designed for sucking semiliquid food. The identification of adult flies is probably best left to a specialist. House flies are medium-sized, grayish flies with four dark thoracic stripes. A preliminary identification of blow flies or bottle flies may be made on the basis of the metallic coloring of the adults. Flesh flies are medium-sized, grayish flies with a checkerboard abdominal pattern.

Treatment and Control: A thorough sanitation program is necessary to control fly populations in and around livestock and poultry facilities. All manure accumulations should be removed at least twice a week or handled properly, if stored on the premises,

to minimize fly breeding. If solid manure management practices are applied, efforts should be made to reduce manure moisture. If a liquid manure pit is used, manure should not be allowed to accumulate above the waterline, either floating or sticking to the sides, because this is an ideal site for fly reproduction. Insecticides should be considered as supplementary to sanitation and management measures aimed at preventing fly breeding. Residual sprays providing 2–4 wk control with one treatment may be applied to fly-resting surfaces. Space sprays, mists, or fogs with quick knockdown but no residual action can be used for immediate reduction of high numbers of adult flies. Other measures for control of adult flies include use of insecticide resin strips or various fly baits. These measures also can be applied directly to fly-breeding sources; however, this should be considered only for fly-breeding spots that cannot be eliminated by normal sanitation practices.

EYE GNATS

The eye gnats or the eye flies (*Hippelates* spp) are very small (1.5–2.5 mm long) flies that frequently congregate around the eyes as well as mucous and sebaceous secretions, pus, and blood.

In the desert and foothill regions of southern California, adult *Hippelates* flies are present throughout the year; they are annoying from April through November. During the peak months, they are noticeable in the early morning and late afternoon. They gather in deep shade, such as among densely planted shrubs or in the shade of a dwelling. The eggs are ~0.5 mm long, fluted, and distinctly curved. They are deposited on or below the surface of the soil. The larvae hatch and feed on decaying organic matter, including excrement. The larval stage lasts 7–11 days. During the winter months, the larval and pupal stages may persist for many weeks. Pupation occurs close to the surface of the soil and lasts ~6 days. The entire life cycle lasts ~21 days. The adults are generally strong flyers, flying both with and against the wind.

Pathology: Some species are attracted to the genital organs of mammals; for example, *H. pallipes* clusters around a dog's penis. These gnats quietly approach their mammalian hosts. They usually alight some distance from their feeding site and then crawl over the skin, or fly intermittently and alight, thus avoiding annoyance to the host. They are persistent and, if brushed away,

quickly return to continue engorging themselves. They are nonbiting flies; however, the labellae have spines that scarify host tissue and allow entrance of pathogenic organisms. *Hippelates* flies often hover around the body orifices of calves, yearlings, pregnant heifers, and lactating cows. They feed on lacrimal fluid, fatty body secretions, milk droplets, and on secretions at the tips of the teats of animals. *Hippelates* flies also serve as vectors for *Trueperella pyogenes* (summer mastitis) and *Moraxella bovis* (pinkeye, see p 512).

Diagnosis: These small flies have sponging type mouthparts. Although eye gnats have much smaller mouthparts, they closely resemble house flies in form and structure and have short aristate antennae.

Treatment and Control: Repellents, such as those recommended for mosquitoes, provide temporary relief from eye gnats. Applications of insecticides on a community-wide basis (as would take place with mosquito abatement) may provide temporary control of adults, but more adults invade the treated area after the insecticide has dissipated.

Larval dipterans may develop in the subcutaneous tissues of the skin or organs of many domestic animals, producing a condition known as **myiasis**. There are two types of myiasis based on degree of host dependence. In **facultative myiasis**, the fly larvae are usually free-living; however, in certain circumstances, these larvae can adapt themselves to a parasitic dependence on a host. In **obligatory myiasis**, the fly larvae are completely parasitic, ie, they depend on the host to complete the life cycle. Without the host, obligatory parasites will die.

FACULTATIVE MYIASIS-PRODUCING FLIES

Facultative myiasis-producing flies of veterinary importance covered in other chapters include *Gasterophilus* spp in horses (see p 315), *Oestrus ovis* in sheep (see p 1473), and *Cuterebra* spp in dogs and cats (see p 879). The following larval dipterans are often referred to as facultative myiasis-producing flies: *Musca domestica* (the house flies); *Calliphora*,

Phaenicia, *Lucilia*, and *Phormia* spp (the blow flies or bottle flies); and *Sarcophaga* spp (the flesh flies). Their adult stages are synanthropic flies, ie, they are often associated with human dwellings and readily fly from feces to food. Larval stages are usually associated with skin wounds of any domestic animal that have become contaminated with bacteria or with a matted hair coat contaminated with feces. In the larval stages, the characteristics of the distinctive posterior spiracular plates and the cephalopharyngeal skeleton are unique for each species and are used for identification.

The life cycle of *M domestica* is a representative example of that of the filth-breeding flies (see p 895). Several species of blow flies cause myiasis in sheep. Primary flies in the USA and Canada are *Phormia regina* and *Protophormia terraenovae* (the black blow flies) and *Lucilia sericata* (the green bottle fly). *L illustris*, *Cochliomyia macellaria* (secondary screw worm), and some others are usually secondary invaders. *L cuprina* is the most important primary fly in Australia and South Africa; *L sericata* in Great Britain; and *L cuprina*, *L sericata*, and *Calliphora stygia* in New Zealand.

Pathology: In normal conditions, adult flies of these genera lay their eggs in feces or in decaying animal carcasses. In facultative myiasis, the adult flies are attracted to a moist wound, skin lesion, or soiled hair coat. A common site is the breech, where flies may be attracted to wool soaked with urine or feces. As adult female flies feed in these sites, they lay eggs, which hatch within 24 hr if conditions are moist. Larvae (maggots) move independently about the wound surface, ingesting dead cells, exudate, secretions, and debris, but not live tissue. This condition is known as strike or fly strike. The larvae irritate, injure, and kill successive layers of skin and produce exudates. Maggots can tunnel through the thinned epidermis into the subcutis. This process produces tissue cavities in the skin that measure up to several centimeters in diameter. Once established, strikes can spread rapidly and attract more blow flies, secondary as well as primary. Mild strikes can cause rapid loss of condition, and bad strikes can be fatal. Unless the process is halted by appropriate therapy, the infested animal may die from shock, intoxication, histolysis, or infection. A peculiar, distinct, pungent odor permeates the infested tissue and the affected animal. Advanced lesions may contain thousands of maggots.

The body of the sheep also may be struck. This is usually associated with soaking rains that cause the development of fleece rot, often characterized by discoloration due to *Pseudomonas* spp or dermatophilosis. Other sites are the horns of rams, wool around the prepuce, sides where feet with footrot come in contact with fleece, and wounds.

As adults, these flies can be pestiferous in veterinary clinics, farms, or poultry operations. The flies are vomit drop feeders and fly from feces to food, spreading bacteria on their feet and from their disgorged stomach contents.

These fly larvae have also been associated with toxic effects in chickens. Botulism (see p 2889), also known as limberneck in chickens, has been associated with ingestion of large numbers of larvae of *Lucilia caesar*, *Phaenicia sericata*, and other species of flies. *Clostridium botulinum* multiplies in carrion, where it may be picked up by fly larvae breeding in that medium and then passed on to chickens that eat the maggots. Dead animals should be quickly and safely disposed of, preferably by incineration.

Diagnosis: Strikes should be diagnosed early; behavior of sheep is a good indicator of myiasis. Affected animals become depressed, stand with their heads down, do not feed, and attempt to bite the infested areas. Screw worm may be suspected if the larvae are associated with wounds.

The species of myiasis-producing flies can be definitively identified by closely examining the larvae. The extreme caudal ends of several third-stage larvae infesting the wound should be sliced using a scalpel blade held perpendicularly to the larval body. When the sliced caudal ends are placed cut surface down on a glass slide, covered with a coverglass, and examined under a compound microscope, a dichotomous key can be used to identify the genus or genera of flies within the wound. The unique spiracular plates are distinct for a particular genus, much like a human fingerprint. Several specimens should be examined because more than one genus may be present within the lesion. The first larvae to hatch in the lesion often create a favorable medium attractive to flies of other genera. Also, the possibility of obligatory myiasis caused by *Cochliomyia hominivorax* (see below) or *Chrysomya bezziana* (see p 900) should be considered, depending on geographic locale.

Treatment and Control: Blow fly infestation of the breech can be effectively controlled for ~6–8 wk by tagging or crutching (ie, wool is shorn between the legs and around the tail). Complete shearing controls outbreaks involving other parts of the body. Wool removed from around the head and the prepuce can prevent strike in these areas. Urine staining of the crutch of Merino ewes can be virtually eliminated by removal of breech wrinkles (Mules operation), and fecal contamination can be greatly reduced by docking tails at the third joint. Scouring should be controlled. Odors and associated moisture attract flies and stimulate oviposition, particularly during hot, humid weather.

Chemoprophylaxis consists of wetting to complete saturation of susceptible areas with suitable insecticidal and larvicidal preparations, such as the organophosphate insecticides or cyromazine, a specific larvicide in dips and sprays. Jetting is the most efficient procedure—insecticide is forced into the fleece, usually locally to the breech and along the back and head, under high pressure. Protection can last 6–8 wk, but where the primary fly is resistant (eg, *L. cuprina* in Australia), it may last only 2–3 wk. Weekly application of agents such as ronnel (2.5%) under pressure to wounds until healed can be highly beneficial, particularly for screwworm infestation. Before suitable agents are applied, all wool should be removed from the struck area and around it.

Burning or deep burying of the carcass may be a valuable general hygienic measure but may have little effect on primary strikes. The main source of primary flies is the struck sheep. A genetic manipulation approach has been used to control a strain of blow fly in Australia; male flies are partially sterile but transmit a gene that causes blindness in female offspring.

Treatment and control measures for myiasis in dogs and cats are limited. If these larvae are detected in small animals, immediate therapy is necessary. The hair coat should be clipped to determine the extent of the lesion and to remove many of the larvae present in the hair. Removing maggots from existing deep tissue pockets may be difficult, and sedating or even anesthetizing the animal may be necessary. The lesion should be examined on successive days; adult flies lay eggs in the wound at different times, and hatching of larvae may not be synchronous.

Depressed, febrile, and prostrate animals should be treated according to their clinical signs. Ideally, culture and sensitivity studies

should be performed on samples or scrapings of the wounds. If secondary bacterial or fungal infections are present, administration of broad-spectrum antibiotics is advisable.

With respect to prevention, owners should be educated about the effectiveness of treating all skin wounds. Animals with skin wounds should be confined to fly-free areas. The hair coat should be kept clean of urine or feces and should not be permitted to become matted. Contaminated wounds and matted hair coats soaked in urine or feces rapidly attract adult myiasis-producing flies. The control of adult flies in the field and the destruction of their breeding places are excellent preventive measures. All areas should be free of opened garbage cans and decaying carcasses or carrion.

OBLIGATORY MYIASIS-PRODUCING FLIES

Many dipteran flies produce larvae that must lead a parasitic existence and result in obligatory myiasis. Only one fly in North America, *Cochliomyia hominivorax*, is a primary invader of fresh, uncontaminated skin wounds of domestic animals. Another species of screwworm, *Chrysomya bezziana*, is found in Africa and southern Asia, including Papua New Guinea.

Cochliomyia hominivorax

(Primary screwworm, New World screwworm)

Cochliomyia hominivorax is distributed throughout the neartic and neotropical regions of the western hemisphere. As a result of massive state, federal, and international eradication programs, extant populations of *C. hominivorax* are no longer found in the USA or Mexico; isolated reports are often traced to importation of infested animals from locations where the screwworm is still prevalent. Extant populations are found in Central and South America and in certain Caribbean Islands.

Adult female flies lay batches of 200–400 eggs in rows that overlap like shingles in a mass on the edge of a fresh wound. After 12–21 hr, larvae hatch, crawl into the wound, and burrow into the flesh. The larvae feed on wound fluids and live tissue. After 5–7 days, grown larvae exit from the wound, fall to the ground, and burrow in the soil to pupate. The pupal period varies from 7 days to 2 mo, depending on the temperature. Freezing or sustained soil temperatures <46°F (8°C) kill the pupae. Adults breed only once during their lifetime, a fact

that can be used as an advantage in biologic control. Adult flies usually mate when 3–4 days old, and gravid females are ready to oviposit when ~6 days old. In warm weather, the life cycle may be completed in 21 days. Only female flies feed and oviposit on wounds; males and younger, virgin females gather to mate in vegetation, especially flowering vegetation.

Pathology: Newly infested wounds contain screwworm larvae of a single age; older, larger wounds may contain larvae of various ages and of different species of flies. The malodorous, reddish brown fluid produced in the wound usually drains and may stain the hair or wool around or below the wound. As annoyance increases, the infested animal seeks protection by retreating to the densest available shade. Even a small and relatively inconspicuous wound infested with screwworm larvae attracts not only more screwworm flies but also facultative myiasis-producing flies. Necrotic tissues attract even more flies. The wound can become greatly enlarged due to multiple infestation and, unless treated, usually results in death of the animal.

Diagnosis: The parasitic larvae are tapered and have mouth hooks at the narrow end and breathing spiracles at the wide end. Body segments are ringed with spines. Fully grown larvae can be as long as 1.5 cm. Larvae are often identified by their “wood screw” shape and appearance and can be distinguished from the larvae of the facultative myiasis-producing flies by the darkly pigmented tracheal tubes on the dorsal aspect of the posterior end of third-stage larvae. These tubes can be easily visualized through the larval cuticle.

Adult screwworm flies are similar in appearance to other blow flies. The adult stage is never recovered in a veterinary case scenario. They are bluish to bluish green, have a reddish orange head and eyes, and are slightly larger than a house fly. If collected, they are difficult to distinguish from other blow flies or bottle flies. Identification of adult screwworms is probably best left to an entomologist.

Treatment and Control: Screwworm infestation must be reported to both state and federal authorities. *C. hominivorax* has been eradicated from the USA but occasionally enters the country surreptitiously on imported animals. In the USA, if a wound is thought to be infested with screwworm larvae, the USDA can be contacted.

Screwworms in wounds can be killed by direct application of a wound dressing, called a smear. Such smears, which contain lindane or ronnel, may be difficult to find in the USA because of the eradication program. Smears are best applied with a 1-in. (2.5-cm) paint brush and should reach all of the many pockets formed by the burrowing larvae in deep wounds. A thin layer should also be applied to the skin surrounding the wound to protect it from reinfestation. Wounds may also be treated with aerosol, dust, or foam formulations of coumaphos, lindane, or ronnel. To protect animals from infestation and also to kill larvae in small wounds that are difficult to detect, animals can be sprayed thoroughly with ronnel or sprayed with or dipped in coumaphos.

Sterile Male Release Eradication Program:

In 1958, the USDA initiated a program in the southeastern states to eliminate screwworms by the sterile male release technique. When reared artificially and exposed to irradiation shortly before they emerge from the pupae, male flies are able to mate but sterile. The female mates only once and, when mated with a sterile male, lays eggs that do not hatch. Therefore, release of sufficient numbers of sterile males in an area throughout a period of time leads to eradication. By 1959, screwworms had been eliminated from Florida.

This program was expanded to cover the rest of the area involved in the USA and then, via a joint Mexico–USA agreement, to include most of Mexico. This, along with the use of screwworm attractant and an insecticide system that attracted and killed adults, led to eradication of screwworms from Mexico. There is interest in expanding this area throughout Central America and the Caribbean. However, until this has been achieved, constant vigilance by all who deal with animals in the southern USA and Mexico is necessary to detect an infestation quickly and to eradicate it before the flies reproduce and spread.

Chrysomya bezziana

(Old World screwworm, Oriental fly, Bezzi's blow fly)

Chrysomya bezziana is found in Africa, the Indian subcontinent, and southeast Asia from Taiwan in the north to Papua New Guinea in the south. This fly is not indigenous to Australia. Owing to its geography, the most likely potential port of entry for *C. bezziana* to the USA is Hawaii.

Adult screwworms are usually not seen in the field. The adult fly has a dark metallic green body with abdominal segments with narrow bands along the posterior margins. The legs are black or partially brown. The face is orange/yellow. The first larval stage probably goes unnoticed because of its small size, as long as 3 mm at the time of its molt to the second stage. The second stage is quite similar to the third but is 4–9 mm long. The third-stage larvae are large, as long as 18 mm. The body is composed of 12 segments that have broad encircling bands of spinules. All three stages are maggot-like in their appearance and have posterior spiracles that are unique to the species. The posterior end of the larva has its spiracular plate located in a deep cleft at the end of the eighth abdominal segment. The spiracular plates are large and well separated. The peritreme and the three breathing slits are wide.

C. bezziana produce a particularly vile myiasis. Female flies are attracted to open wounds of people and domestic and wild animals, laying their eggs in masses of 150–500 at the edge of wounds or near body orifices. Larvae develop to the third stage ~2 days after hatching. They burrow deep into the wound such that only their posterior ends are visible. The entire larval stage lasts 5–6 days. The pupal stage lasts 7–9 days in tropical conditions and longer in cooler environments. The adult flies emerge later to mate, locate a new host, and continue the cycle. Female flies mate only once during their lifetime—a fact paramount in prevention and control. Under favorable conditions, there may be ≥8 generations per year.

Pathology: The larvae of *C. bezziana* are obligatory wound parasites, never developing in carcasses or decomposing organic material. Although female flies are attracted to open wounds, occasionally eggs are deposited on the unbroken, soft skin of various parts of the body, especially if contaminated by blood or mucous discharge. When the larvae hatch, they burrow into the flesh of the host, using their hooked mouthparts to scrape away at the tissues and lacerate the fine blood vessels. Larvae are voracious blood feeders. During the bloodsucking phase, only the caudal ends of the maggots with their blackish peritremes remain visible at the surface of the lesion, enabling the larvae to breathe. As many as 300 maggots have been seen in some wounds. In untreated wounds, the destructive activity of the larvae may lead to the death of the animal within a very short time.

Secondary infestation with the facultative myiasis-producing flies (see p 897) may complicate treatment and control.

Diagnosis: The identification of the rarely observed adult flies and their associated larval stages is best left to an entomologist. A definitive diagnosis can be made only after observation, extraction, and identification of typical larvae. Diagnosis may often be made by residence in or history of travel to an area endemic for *C bezziana*. If a wound is thought to be infested with larvae of *C bezziana*, samples should be collected and sent to appropriate eradication officials.

Treatment and Control: Treatment of screwworm infestation involves killing the larvae in the lesions, promoting healing, and preventing secondary reinfestation with larvae of the facultative myiasis-producing flies. The extent of the lesions is determined by clipping the hair coat and removing as many larvae as possible. The larvae that are removed should be killed to prevent them from pupating and developing into adults. Larvae located deep within tissues must be extracted.

Ivermectin at dosages of 50, 100, and 300 mcg/kg administered to infested cattle resulted in 100% larval mortality for at least 6, 12, and 14 days, respectively. Depending on their age, larvae survived in established strikes after treatment at 200 mcg/kg. Mortality was 100% in larvae up to 2 days old but less in older larvae. However, many of the larvae that survived ivermectin therapy failed to develop to the adult stage. After treatment with 200 mcg/kg, residual protection lasted 16–20 days, 2–3 times that of most insecticide smears.

All wounds on domestic animals should be properly dressed, and all elective surgical procedures avoided during the fly season.

The fact that the female flies mate only once during their lifetime is an important fact to consider in the control of *C bezziana*. Pupal flies exposed to irradiation lead to sterile adults that can be released to mate with wild male and female flies. As a result, no viable offspring are produced in the wild.

Wolves (Warbles) of Small Animals

Larvae of the genus *Cuterebra* are often referred to as wolves, warbles, rabbit bots, or rodent bots. These fly larvae infest the skin of rabbits, squirrels, mice, rats, chipmunks, and occasionally dogs and cats. (For clinical findings, diagnosis, and treatment, see p 879.)

Gray Flesh Flies

The gray flesh fly, *Wohlfahrtia vigil*, is responsible for cutaneous myiasis in North America, particularly in southern Canada and the northern part of the USA. The adult flies have been recorded from the New England states to Alaska, but most reports are from eastern sections of Canada and the neighboring northeastern parts of the USA. All reports of infestation are in the skin of healthy animals, particularly the unbroken skin of the young.

All three larval stages are maggot-like in their appearance and have posterior spiracles unique to the species. The first larval stage is 1.5 mm at hatching and grows to 3.5 mm at the time of its molt to the second stage. The third stage is 7–18.5 mm long. Its posterior end is narrow, and it is covered with many irregular rows of small spines that have dark points and are directed posteriorly. This larva is better adapted to maintain an attachment to living tissues. The oral hooks are strongly developed. The posterior end of the larva has its spiracular plate located in a deep pit formed by the margins of the segment. The posterior spiracles have wide slits and a strong peritreme.

The gray flesh fly is larviparous—it deposits larvae instead of eggs on healthy, uninjured skin of suitable hosts, particularly young animals. Larvae penetrate the unbroken skin and form a boil-like (furuncular) swelling. Development to the infective third-larval stage is usually completed in 9–14 days. The parasites then drop to the ground and pupate for ~11–18 days, varying with the season of the year and the temperature. When cold weather approaches, the pupation period is greatly prolonged. Under laboratory conditions, it has been observed to last 7 mo. Parasites survive the winter in pupal form. Adults emerge and mate after ~3–4 days. Female flies begin larviposition ~1 wk later, depositing 6–16 larvae at a time. Female flies live for 35–40 days; males seldom survive >3 wk.

Pathology: Female *W vigil* deposit active larvae near or directly on the host. Although larvae usually penetrate unbroken skin, in small animals, penetration may go deeper than the dermal tissue, even into the coelomic cavity.

The first indication that an animal is infected is exudation of serum and matting of the hair coat over the site of penetration. In light-skinned animals, a small inflammatory area, with a tiny hole visible in the

center or to one side, is noticeable. These lesions may be palpated as they develop. On the third or fourth day, the larvae are 1.5–2 cm long and produce abscess-like lesions resembling those of *Hypoderma* spp in cattle. These lesions vary in size, shape, position, and the number of larvae they contain. The hair coat often becomes parted over the summit of the lesions and reveals an opening 2–3 mm in diameter. The posterior aspect of the larva is visible in these openings, through which it breathes. Openings are generally circular and well-defined; however, if several larvae are present in a single lesion, the shape of the opening is quite variable. Small animals infected with ≥ 5 larvae for several days become emaciated, and the skin becomes dry and loses its luster.

The penetration of the skin by the larvae, their development in the subcutaneous tissues, and secondary bacterial infection produce intense irritation and inflammation. Attempts by the animal to remove the larvae or relieve the irritation tend to aggravate the condition. Young animals may die from exhaustion. It has also been suggested that the larvae may produce toxic secretions. *W. vigil* has been isolated from the skin of young children, particularly infants.

Diagnosis: Adult gray flesh flies are nonparasitic and as a result will probably not be seen by owners or veterinarians. They are large grayish flies (~13 mm long), about twice the size of a house fly. The dorsal surface of the thorax is marked with three longitudinal bands, and the dorsal surface of the abdomen has three well-defined rows of oval black spots that are confluent with one another.

The identification of adult flies and their associated larval stages should be left to an entomologist. The presence of a dermal swelling with a central opening may lead to a tentative diagnosis of myiasis due to *W. vigil*. A definitive diagnosis can be made only after extraction and identification of a typical larva. Extensive descriptions and dichotomous keys for the three larval stages are available. A tentative diagnosis may often be made by a history of either residence in or travel to a geographic area endemic for *W. vigil*.

Treatment and Control: Larvae must be extracted from the skin. Applying heavy oil, liquid paraffin, or petrolatum jelly to the opening of the lesions will occlude the airway of the larvae. Applying a small amount of chloroform or ether to the

opening may be helpful before removing larvae with forceps. Lidocaine hydrochloride can also be injected into the furuncular lesion to facilitate extraction. Great care should be taken during the extraction process to avoid rupturing larvae in situ, although anaphylaxis has not been reported. Antibiotics should be prescribed.

W. vigil often infects young mink. A teaspoon of ronnel can be placed in the bedding of mink nest boxes as a control measure; however, ronnel should not be used in the bedding of kits <3 days old. Protection can be provided by using wire gauze to keep flies out of cages.

African Tumbu Flies

(Mango fly, Skin maggot fly, Ver du Cayor, Worms of Cayor)

The African tumbu fly, *Cordylobia anthropophaga*, is responsible for another boil-like (furuncular) myiasis in both people and animals in Africa, particularly in the sub-Saharan regions.

The adult flies are nonparasitic and as a result are not seen by owners or veterinarians. They are stout, compact flies, 6–12 mm long. They are light brown, with diffuse blue-gray patches on the thorax and dark gray on the posterior part of the abdomen. The face and legs are yellow. The second- and third-stage larvae are the stages usually seen in the animal's skin.

Second-stage larvae are slightly club-shaped and exhibit large, black cuticular spines directed posteriorly and distributed irregularly over segments 3–8. Segments 9–11 are almost bare when compared with the preceding segments. The segments have a few rows of small, pale spines posteriorly. Segment 12 is densely covered with these spines. Segment 13 is indistinctly demarcated, lacking spines but possessing two pairs of short processes. Each tracheal tube opens through two slightly bent slits. The second-stage larvae are 2.5–4 mm long. The size of advanced second-stage larvae varies greatly, as does the size of third-stage larvae. Fully mature larvae are 1.3–1.5 cm long. The body is cylindrical with 12 identifiable segments. Curved spines that are directed posteriorly are densely arranged at least up to segment 7; the last 5 segments may be either partially or densely covered with spines.

After fertilization, female flies produce 100–500 banana-shaped eggs, usually depositing them in dry, shady, sandy soil that has often been contaminated by urine or feces. Eggs are never deposited on the

skin of the host. Eggs hatch after 1–3 days, and the larvae are initially 0.5–1 mm long. Larvae can survive as long as 15 days while waiting for a host and can penetrate the host in as little as 25 sec. After penetration, larvae reside in a cavity in the dermis and hypodermis. This cavity communicates to the external environment by means of a central breathing pore, which corresponds to the caudal end of the larva with its spiracles. A single larva is found in each cavity, within which the larva develops to the second and third stages. Larvae require 7–15 days to mature and then emerge through the breathing pore and drop to the ground, where they pupate. Adult flies emerge 10–20 days later, and the cycle begins again.

Rats and dogs are the usual definitive host; however, people, mice, monkeys, mongooses, squirrels, leopards, boars, antelopes, cats, goats, pigs, rabbits, guinea pigs, and chickens can be infested.

Pathology: Clinically, the infestation is characterized by a small erythematous papule that appears 2–3 days after larval penetration. Within days, the papule enlarges until it becomes a nodule that resembles a boil (furuncle); hence, the description furunculoid myiasis. At the center of the nodule is a pore through which serous fluid oozes. This fluid can be hemorrhagic or purulent and contains larval feces.

Dogs with thin, soft skin seem to be more suitable hosts for larval development than dogs with thick skin. Preferred sites of infestation are the feet, genitals, tail, and axillae. In endemic areas, mild infestations in dogs do not produce clinical distress. Massive infestation may induce marked swelling and edema, especially if larvae are in close proximity to each other. Larvae can penetrate deep into tissues and cause considerable damage and even death.

Diagnosis: The presence of a dermal swelling with a central opening may lead to a tentative diagnosis of myiasis due to *C. anthropophaga*. A definitive diagnosis can be made only after extraction and identification of typical larvae. The identification of adult flies and their associated larval stages should be left to an entomologist.

A tentative diagnosis may often be made by a history of either residence in or travel to a geographic area endemic for *C. anthropophaga*. However, the parasite has also been diagnosed in travelers and their accompanying pets from geographic areas where the parasite is not found.

Treatment and Control: Larvae can be removed by coating the breathing pore with a thick, viscous compound, such as heavy oil, liquid paraffin, sticking plaster, or petrolatum jelly. Clogging the pore causes the larva to become hypoxic and leave the cavity in search of oxygen. Light pressure at the edge of the lesion also aids in larval removal.

Lidocaine hydrochloride can be injected into the furuncular lesion to facilitate larval extraction with thumb forceps. Surgical excision is usually unnecessary and unwarranted while the larvae are alive but is used to remove dead or decaying larvae. Great care should be taken during the extraction process to avoid rupturing larvae in situ, although anaphylaxis has not been reported. Antibiotics should be prescribed.

Adult flies should be killed if seen indoors. Larvae should be removed from animals entering the house and destroyed. All rats should be killed and burned. Prevention of an infestation depends on cleanliness and regular disinfection of the animal's sleeping quarters. In the case of valuable animals (eg, Angora rabbits), flies may be kept out of rabbit pens using wire gauze.

Because the adult female flies lay eggs in sandy soil contaminated by feces or urine, the parasite can be controlled in the pet's environment by prompt removal of the pet's feces and by covering urination sites on the premises with a layer of dirt.

PSEUDOMYIASIS

In pseudomyiasis, dipteran larvae have been accidentally ingested and are found within an animal's GI tract, where they are not able to continue their development. Dogs or cats infested with larvae of the facultative myiasis-producing flies in wounds or in the hair coat often ingest larvae while licking or grooming. These larvae pass through the GI tract and appear in the feces undigested. Dipteran larvae may also be passed in the feces when a roaming dog or cat ingests carrion that contains maggots; these maggots pass to the external environment undigested.

Pseudomyiasis can also occur if feces submitted for parasitologic examination are not fresh. Adult facultative-myiasis flies may have laid their eggs in these feces, and larval development may have begun.

Eristalis tenax, the rat-tailed maggot, may be seen in the gutter behind cows in dairy barns. These maggots are associated with liquid feces and with feces that have

not been removed from the environment. The larvae are known as rat-tailed maggots because their breathing pores are found at the tip of a long, siphon-like breathing tube

on their posterior end. Many farmers erroneously assume that the cows defecated these maggots. The adults are nonparasitic, free-living flies.

HELMINTHS OF THE SKIN

CUTANEOUS HABRONEMIASIS

(Summer sores, Jack sores, Bursatti)

Cutaneous habronemiasis is a skin disease of Equidae caused in part by the larvae of the spirurid stomach worms (see p 315). When the larvae emerge from flies feeding on preexisting wounds or on moisture of the genitalia or eyes, they migrate into and irritate the tissue, which causes a granulomatous reaction. The lesion becomes chronic, and healing is protracted. Diagnosis is based on finding nonhealing, reddish brown, greasy skin granulomas that contain yellow, calcified material the size of rice grains. Larvae, recognized by spiny knobs on their tails, can sometimes be demonstrated in scrapings of the lesions. Many different treatments have been tried, most with poor results. Symptomatic treatment, including use of insect repellents, may be of benefit, and organophosphates applied topically to the abraded surface may kill the larvae. Surgical removal or cauterization of the excessive granulation tissue may be necessary. Treatment with ivermectin (200 mcg/kg) has been effective, and although there may be temporary exacerbation of the lesions (presumably in reaction to the dying larvae), spontaneous healing may be expected. Moxidectin at 400 mcg/kg also appears to be active against *Habronema* spp in the stomach. Control of the fly hosts and regular collection and stacking of manure, together with anthelmintic therapy, may reduce the incidence.

DRACUNCULUS INFECTIONS

Dracunculus insignis is found mainly in the subcutaneous connective tissues of the legs of raccoons, mink, and other animals, including dogs and cats, in North America and possibly other parts of the world. The females (≥ 300 mm long) are much longer than the males (~ 20 mm). They produce ulcers in the skin of their host, through which

their anterior end is protruded on contact with water. Females produce characteristic long, thin-tailed larvae. Water fleas (*Cyclops* sp) are the intermediate host in which infective larvae develop. Dogs become infected through ingestion of contaminated water or a paratenic host (frogs).

Subcutaneous, serpentine, inflammatory tracts and nonhealing, crater-like, edematous skin ulcers are seen. Infections are rare but are occasionally found in animals that have been around small lakes and bodies of shallow, stagnant water. Treatment is by careful, slow extraction of the parasite. Administration of miridazole or benzimidazole compounds may be useful.

D. medinensis, the guinea worm of parts of Africa, Asia, and the Middle East, although primarily a parasite of people, is also found in dogs and other animals.

ELAEOPHOROSIS

(Filarial dermatosis, "Clear-eyed" blindness, Sorehead)

Elaeophora schneideri is a parasite of mule deer and black-tailed deer found in the mountains of western and southwestern USA and in Nebraska; it also has been found in white-tailed deer in southern and southeastern regions in the USA. Adult parasites are 60–120 mm long and usually are found in the common carotid or internal maxillary arteries. The microfilariae, which are ~ 275 μ m long and 15–17 μ m thick, normally are found in skin capillaries on the forehead and face. Development in the intermediate hosts, horse flies of the genera *Tabanus* and *Hybomitra*, requires ~ 2 wk. Infective larvae invade the host as the horse fly feeds, migrate to the leptomeningeal arteries, and develop to immature adults in ~ 3 wk. These young adults migrate against the blood flow and establish in the common carotid arteries, where they continue to grow. The parasites reach sexual maturity ~ 6 mo later and begin producing microfilariae. The life span of adults is 3–4 yr.

Clinical Findings: Clinical disease has not been reported in mule deer and black-tailed deer; therefore, they are considered to be the normal definitive hosts. When horse flies transmit the infective larvae to elk, moose, domestic sheep and goats, sika deer, and possibly white-tailed deer, the larvae develop in the leptomeningeal arteries and cause ischemic necrosis of brain tissue, resulting in blindness, brain damage, and sudden death. Blindness in these animals is characterized by absence of opacities in the refractive media of the eye ("clear eyed" blindness).

Domestic sheep and goats, especially lambs, kids, and yearlings, may die suddenly 3–5 wk after infection. Death is usually preceded by incoordination and circling and often by convulsions and opisthotonos. Numerous thrombi occur in the cerebral and leptomeningeal arteries. One or more young adult *E. schneideri* accompany each thrombus. If sheep or goats survive the early infection, a raw bloody dermatitis on the poll, forehead, or face ("sorehead") develops 6–10 mo later. Lesions occasionally develop on the legs, abdomen, and feet. These lesions are an allergic dermatitis in response to the microfilariae lodged in capillaries. Lesions persist, with periods of intermittent and incomplete healing for ~3 yr, followed by spontaneous recovery. Hyperplasia and hyperkeratosis develop in the epidermis of the parasitized area.

Diagnosis: Differential diagnoses include coenurosis (*Taenia*, see p 1311), cerebrocortical necrosis (see p 1281), and enterotoxemia (see p 609). Elaeophorosis should not be considered unless sheep have been in endemic areas during the summer. Diagnosis in lambs, kids, or elk yearlings or calves usually is made at necropsy; numerous thrombi and parasites are found in the common carotid, internal maxillary, cerebral, and leptomeningeal arteries. Presumptive diagnosis in mature sheep is based on history and location and type of lesion. The skin lesion must be differentiated from that of ulcerative dermatosis (see p 872). Confirmation is by recovery of microfilariae from the lesion or by post-mortem recovery of the adult parasites. A skin biopsy of the lesion is macerated in isotonic saline solution and allowed to stand ≥6 hr at room temperature. The skin is strained off and the fluid examined for the typical microfilariae.

Treatment: Piperazine salts (220 mg/kg, PO) are effective. Complete recovery

occurs in 18–20 days. No treatment is available for the cerebral form of the disease.

ONCHOCERCIASIS

The taxonomic status of the three species of *Onchocerca* currently recognized in the USA, and other previously recognized species, is under debate. *O. cervicalis* is found in the ligamentum nuchae and possibly other sites in Equidae. In cattle, *O. gutturosa* locates in the ligamentum nuchae, and *O. lienalis* in the gastrosplenic ligament. Adults are associated with connective tissues; they are very thin and 3–60 cm long. Microfilariae are found in the dermis and on rare occasions circulating in peripheral blood. The microfilariae lack a sheath and are 200–250 µm long with a short, sharply pointed tail. *Culicoides* spp (see p 887) are the intermediate hosts for *O. cervicalis*, and *Simulium* spp for *O. gutturosa* and *O. lienalis*.

Clinical Findings: *O. cervicalis* has been associated with fistulous withers, poll evil, dermatitis, and uveitis in horses. However, because *O. cervicalis* in large numbers is common in horses without these diseases, there is some debate about its role in the pathogenesis of these conditions.

Adults in the ligamentum nuchae induce inflammatory reactions ranging from acute edematous necrosis to chronic granulomatous changes, resulting in marked fibrosis and mineralization. Mineralized nodules are more common in older horses. Although lesions are found in these areas, presumably associated with dead parasites, it is generally agreed that fistulous withers and poll evil are not caused by *O. cervicalis* infections.

Microfilariae concentrate in the skin of the ventral midline. Large numbers can be found in horses without dermatitis as well as in horses with dermatitis of the face, neck, chest, withers, forelegs, and abdomen. These lesions may be pruritic and often include areas of scale, crusts, ulceration, alopecia, and depigmentation. The dermatitis may be associated with an immunologic reaction to dead and dying microfilariae. Although the pathogenesis of these lesions is unclear, treatment with microfilaricidal drugs may result in dramatic improvement. Allergic reactions to the bites of small flies may produce similar lesions or exacerbate microfilaria-associated dermatitis. Thus, diagnosis of *Onchocerca*-associated dermatitis may be based on responsiveness to microfilaricidal treatment.

Microfilariae also accumulate in the eyes of horses, but not all agree that a clear association has been made between microfilariae and equine uveitis (see p 508) or other ocular lesions in horses.

Diagnosis: The most effective method of diagnosis is by skin biopsy, preferably a full-thickness biopsy ≥ 6 mm. The tissue is minced and macerated in isotonic saline for several hours. Microfilariae are concentrated and stained with new methylene blue after removal of skin pieces. The microfilariae can be differentiated microscopically from *Setaria* spp. found in the blood of cattle, and Equidae by the presence of a sheath around *Setaria*.

Treatment: No treatment is effective against the adults. Ivermectin (200 mcg/kg) and moxidectin (400 mcg/kg) are efficacious (>99%) against microfilariae and produce marked clinical improvement in horses with onchocercal dermatitis. A small portion of horses infected with *O. cervicalis* react to the treatment with a marked, edematous ventral midline swelling 1–3 days after treatment. Ocular lesions have also been reported. These reactions usually resolve spontaneously, but symptomatic treatment may be necessary.

PARAFILARIA INFECTION

Parafilaria bovicola

This filarial parasite of cattle causes subcutaneous lesions that resemble bruising. It also has been reported from water buffalo (*Bubalus bubalis*). The worm is whitish; adult females are 50–65 mm long, and males 30–35 mm. It is found in Asia (Philippines, Japan, Russia, Pakistan, India), Europe (Bulgaria, Romania, France, Sweden), and Africa (Morocco, Tunisia, Rwanda, Burundi, South Africa, Namibia, Botswana, Zimbabwe). A specimen was recovered in Canada from a bull imported from France, but *P. bovicola* does not appear to have established itself on the American continents and has not been reported from Australia.

Parafilaria infection has been identified as a source of considerable economic loss to the beef industries of South Africa and Sweden, despite their climatic differences. It is found primarily in range cattle in the savanna areas of southern Africa, whereas in Sweden it has emerged as a problem in cattle following spring turnout to pasture after winter housing.

Clinical Findings: The only external signs of infection in cattle are focal cutaneous hemorrhages (“bleeding spots”) that may ooze for some hours before clotting and drying in the matted hair of the coat. Bleeding spots are induced by the female worm, which causes the formation of a small nodule, perforates the skin, and oviposits in the blood dripping from the central wound. The tiny eggs contain the first larval stage (microfilariae) of the parasite. In both the northern and southern hemispheres, bleeding spots are markedly seasonal, being most common in spring and early summer. Most bleeding spots occur along the dorsum of the animal, particularly in the forequarters.

The invertebrate hosts are face flies of the genus *Musca* (subgenus *Eumusca*), which ingest the eggs when feeding at the bleeding spots. *M. autumnalis* has been identified as a host in Sweden, *M. lusoria* and *M. xanthomelas* in South Africa, and *M. vitripennis* in Asia. Development to infective third-stage larvae in the fly takes 10–12 days. Transmission to cattle probably occurs when the flies feed on wounds, *Parafilaria* bleeding spots, or ocular secretions.

Because of seasonal bleeding and the cutaneous nodules, severe infections of *P. bovicola* have been reported to impair the productivity of working bullocks in India; however, the major importance of *Parafilaria* in beef-producing countries is damage to the subcutaneous tissues. Carcasses of infected animals display irregular, edematous, greenish yellow lesions that resemble bruising. These are usually superficial but occasionally underlying muscles are extensively involved. Lesions are most severe during the spring and summer.

Trimmed carcasses are often seriously disfigured and consequently downgraded. In severe cases, the carcass may be condemned. Lesions are more common and severe in bulls than in steers, which in turn are less severely affected than female animals.

Diagnosis: The seasonal bleeding spots are sometimes confused with those caused by thorns, wire, ticks, or biting insects. For differentiation, either fresh or dried blood should be mixed with water in a test tube and centrifuged. The characteristic eggs are found on microscopic examination of the sediment.

Carcass lesions can be differentiated from bruising by the presence of numerous eosinophils in Giemsa-stained impression

smears made from the lesions. In addition, affected tissue has a characteristic, disagreeable, metallic smell.

Usually, only small numbers of worms are present in affected carcasses and are often difficult to find because of their color and the accompanying inflammatory reaction. Affected tissues can be incubated in warm saline to facilitate the recovery of parasites. An ELISA for the detection of antibodies against *P. bovicola* is available.

Treatment and Prevention: Ivermectin (200 mcg/kg) or nitroxylin (20 mg/kg) given SC reduces the number and surface area of *Parafilaria* lesions. Animals should be treated at least 70–90 days before slaughter to provide sufficient time for lesions to resolve. The treatment-to-slaughter interval should not be >120 days, because unaffected larval forms of the parasite may induce fresh lesions as they mature.

In trials in Sweden, use of pyrethroid-impregnated ear tags gave good control of flies and reduced parafilarial lesions at slaughter by 75%. Ear tagging all cattle in an area resulted in total control of the parasite. The use of residually active, synthetic pyrethroid dips has also effectively reduced transmission.

It may be possible to screen imported animals with an ELISA to prevent spread of the disease to unaffected countries or, in conjunction with residual insecticides and effective anthelmintics, to eradicate new foci of infection.

Parafilaria multipapillosa

P. multipapillosa is found in the subcutaneous tissues of horses in various parts of the world; it is especially common in the Russian steppes and eastern Europe. It is similar in size, appearance, life cycle, and development to *P. bovicola*. Bloodsucking *Haematobia* spp are thought to be the invertebrate hosts.

In spring and summer, the parasite causes skin nodules, particularly on the head and upper forequarters. These bleed transiently but often profusely ("summer bleeding") and then resolve; other hemorrhaging nodules develop as the parasite moves to a different site. Occasionally, the nodules suppurate. The nodules and bleeding are unsightly and interfere with harnesses of working horses but generally are of little consequence. The clinical signs are pathognomonic.

No satisfactory treatment has been reported, but fly control may reduce the incidence.

PELODERA DERMATITIS

(Rhabditic dermatitis)

This rare, nonseasonal, acute dermatosis results from invasion of the skin by larvae of the free-living saprophytic nematode *Pelodera strongyloides*. The larvae are ubiquitous in decaying organic matter and on or near the surface of moist soil but are only occasionally parasitic. Exposure to the larvae occurs through direct contact with infested material such as damp, filthy bedding. The larvae may not be able to invade healthy skin; preexisting dermatoses or environmental conditions favoring maceration of the skin, eg, constant exposure to mud or damp bedding, may facilitate invasion. *Pelodera* dermatitis has been reported in dogs, cows, horses, sheep, guinea pigs, and people.

Typically, lesions are confined to body areas in contact with the infested material, such as the extremities, ventral abdomen and thorax, and perineum. Affected skin is erythematous and partially to completely alopecic, with papules, pustules, crusts, erosions, or ulcerations. Pruritus is usually intense but can be moderate or even absent. Differential diagnoses include demodicosis, canine scabies, dermatophytosis, pyoderma, and other rare cutaneous larval infestations such as hookworm dermatitis, dirofilariasis, dipetalonemiasis, and strongyloidiasis.

Diagnosis is confirmed easily by finding live, motile *P. strongyloides* larvae in skin scrapings of affected areas. The larvae are cylindrical and ~600 × 38 µm. Histologic examination of skin biopsy specimens reveals larvae in the hair follicles and superficial dermis and usually an inflammatory dermal infiltrate. The larvae are readily cultivated on blood agar plates at 77°F (25°C).

Effective treatment consists primarily of removing and destroying moist, infested bedding material and moving the animal to a clean, dry environment. Usually, spontaneous recovery ensues. It may be desirable to dip or spray the affected animals with an insecticidal preparation at least twice at weekly intervals. Short-term use of corticosteroids may be indicated if pruritus is severe.

STEPHANOFILARIASIS

(Filarial dermatitis of cattle)

Stephanofilaria stilesi is a small, filarial parasite that causes a circumscribed dermatitis along the ventral midline of

cattle. It has been reported throughout the USA but is more common in the west and southwest. Adult worms are 3–6 mm long and usually are found in the dermis, just beneath the epidermal layer. Microfilariae are 50 µm long and are enclosed in a spherical, semirigid vitelline membrane. The intermediate host for *S stilesi* is the female horn fly, *Haematobia irritans* (see p 892). Horn flies feeding on the lesion ingest microfilariae that develop to third-stage infective larvae in 2–3 wk. The infective larvae are introduced into the skin as the horn fly feeds.

The dermatitis develops along the ventral midline, usually between the brisket and navel. With repeated exposure, the lesion spreads and often involves the skin posterior to the navel. Active lesions are covered with blood or serous exudate, while chronic lesions are smooth, dry, and devoid of hair. Hyperkeratosis and

parakeratosis develop in the epidermis of the parasitized area.

Deep skin scrapings are macerated in isotonic saline solution and examined microscopically for adults or microfilariae. The microfilariae must be differentiated from microfilariae of *Onchocerca lienalis*, *O gutturosa*, and *Setaria* spp, which are much larger (200–250 µm), and *Pelodera strongyloides* (see above), a small free-living nematode occasionally responsible for a moist, superficial dermatitis. The rhabditiform esophagus of *P strongyloides* is not found in filarial nematodes.

No approved treatment is available for *S stilesi*, but topically applied organophosphates (trichlorfon 6%–10%, daily or on alternate days for 7 days) have proved effective against other species of *Stephanofilaria*. Ivermectin is reported to be effective against microfilariae of *S zaheeri*.

LICE

(Pediculosis)

Numerous species of lice parasitize domestic animals. Lice are largely host specific, living on one species or several closely related species. Lice are obligate ectoparasites and depend on the host to complete their life cycle. Recent taxonomic changes have complicated the orders and suborders of lice. In general, lice are divided into two categories: bloodsucking (or sucking) lice (order Anoplura) and chewing (or biting) lice (formerly the order Mallophaga, now composed of three suborders). Bloodsucking lice are parasites of mammals, whereas chewing lice infest both mammals and birds. Lice live within the microenvironment provided by the skin and its hair or feathers, and are transmitted primarily by contact between hosts. All life stages occur on the host, although lice may survive off the host for a period of time. In temperate regions, lice are most abundant during the colder months and often are difficult to find in the summer. Infestations are most often seen on stressed animals, and husbandry and individual health are important in treatment and management of these parasites. (See also p 2875.)

Etiology and Pathogenesis: Lice are wingless, flattened insects, usually 2–4 mm

long, although the species infesting animals may range from 1–8 mm long. The claws of the legs are adapted for clinging to and moving among hairs or feathers; the size and shape of the claws tend to be specialized for the average width of a hair shaft of the host species. This characteristic plays an important role in host specificity. The mouthparts also aid in attachment to the host. Chewing lice have ventral chewing mandibles; they feed on epidermal debris, primarily skin scales, sebaceous secretions, and feathers, if applicable. The heads of chewing lice have a blunted appearance, with the head being wider than the thorax. As the name implies, bloodsucking lice have piercing mouthparts that allow them to feed on the blood of their host. In contrast to the heads of chewing lice, those of bloodsucking lice have a pointed appearance, and the heads are narrower than the thorax. When not in use, their mouthpart stylets are retracted within the head. The distinction between chewing lice and bloodsucking lice is important when choosing an effective therapy for treatment of pediculosis.

On mammalian hosts, louse eggs, sometimes called “nits,” are glued to hairs near the skin surface and are pale, translucent, and suboval. The three

nymphal stages, of increasing size, are smaller than adults but otherwise resemble adults in habits and appearance. Approximately 3–4 wk are required to complete one generation, but this varies by species. Adult lice are visible to the naked eye, but magnification is often required to identify the species.

Pediculosis can result in dermatologic disease, production loss, and occasionally anemia due to blood loss. Additionally, lice may be vectors of more arthropod-borne infections than previously believed. Lice have been shown to transmit viruses, bacteria, fungi, and protozoa. Most of the research has focused on agents transmitted by human lice species that are known to transmit a variety of pathogens to their hosts, including the causative agents of epidemic typhus (*Rickettsia prowazekii*), louse-borne relapsing fever (*Borrelia recurrentis*), and trench fever (*Bartonella recurrentis*), among others. Until recently, relatively few diseases were known to be vectored by domestic animal lice. A number of agents are now known or suspected to be vectored by lice.

Clinical Findings and Diagnosis:

Pediculosis is manifested by pruritus and dermal irritation, with resultant scratching, rubbing, and biting of infested areas. A generally unthrifty appearance, rough coat, and lowered production in farm animals is common. In severe infestations, there may be loss of hair and local scarification. Extreme infestation with bloodsucking lice can cause anemia. In sheep and goats, rubbing and scratching often results in broken fibers, which gives the fleece a “pulled” appearance. In dogs, the coat becomes rough and dry and, if lice are numerous, the hair may be matted. Sucking lice cause small wounds that may become infected. The constant crawling and piercing or biting of the skin may cause restless behavior in hosts.

Diagnosis is based on the presence of lice. The hair should be parted, and the skin and proximal portion of the coat examined under good lighting conditions. The hair of large animals should be parted on the face, neck, ears, topline, dewlap, escutcheon, tail base, and tail switch. The head, legs, feet, and scrotum should not be overlooked, particularly in sheep. On small animals, the ova are more readily seen. Occasionally, when the coat is matted, the lice can be seen when the mass is broken apart. Biting lice are active and can be seen moving through the hair. Sucking lice usually move more slowly and are often found with mouthparts

embedded in the skin. Diagnosis may be aided by use of a magnification device. An otoscope, without the otoscopy cone, may be useful for this purpose.

Pediculosis of livestock is most prevalent during the winter; severity is greatly reduced with the approach of summer. Infestations of both chewing and sucking lice may become severe. In dairy herds, the young stock, dry cows, and bulls may escape early diagnosis and suffer more severely. Young calves may die, and pregnant cows may abort.

Transmission usually occurs by host contact. Lice dropped or pulled from the host die in a few days, but disengaged ova may continue to hatch over 2–3 wk in warm weather. Therefore, premises recently vacated by infested stock should be disinfected before being used for clean stock.

Treatment: Successful louse control is a multifactorial process. Factors to address include treatment of the affected animal(s), treatment of contact animals, environmental control, and properly addressing the stressors that either permitted initial infestation or exacerbated infestation. Effective treatment results in prompt improvement of clinical signs. Specific pediculosis treatments are discussed below.

It is the practitioner's duty to recommend a safe and effective treatment regimen. In the USA, ectoparasiticides are regulated by the Environmental Protection Agency (EPA) or the FDA Center for Veterinary Medicine. As a general rule, if a product is applied topically to an animal to treat ectoparasites, and the compound is not absorbed systemically, it likely falls under the jurisdiction of the EPA. If a product is administered parenterally, or if it is applied topically for systemic absorption, it likely falls under the jurisdiction of the FDA. This distinction is important for practitioners to recognize, because there is no legal extra-label use of products regulated by the EPA. Label directions must be followed regarding species treated, product concentration, product dosage, individuals allowed to administer application, and re-treatment interval. Because products regulated by the FDA are approved animal drugs, extra-label use may be allowed under the Animal Medicinal Drug Use and Clarification Act (AMDUCA) (see p 2748 and see p 2637). The Food Animal Residue Avoidance Databank (FARAD) can be consulted for extra-label drug use recommendations and calculated meat and milk withdrawal times.

Treatment of individual animals may be aided by debulking the infested coat if weather and coat type permit. Clipping an infested animal's long, heavily soiled, or matted coat can immediately reduce the parasite burden on an affected animal, allow topical products to be distributed evenly, and allow for treatment of secondary infections if present. Many compounds effectively kill adult and nymphal life stages, but few have been tested for ovicidal capabilities. Therefore, many sources recommend re-treatment at intervals of 7–10 days until the infestation has been controlled. Contact animals should also be treated to prevent spread of infestation within a herd, flock, or household. Animal equipment or bedding should be washed frequently with hot, soapy water until infestation is controlled. Finally, addressing animal overcrowding, poor feed quality, and underlying health issues are the final steps to manage pediculosis and prevent recurrence. New animals should be quarantined and inspected for infestation before herd or flock integration.

CATTLE

In temperate climates, domestic cattle may be infested with one species of chewing louse (*Damalinia bovis*, formerly *Bovicola bovis*) and four species of bloodsucking lice (*Linognathus vituli*, *Solenopotes capillatus*, *Haematopinus eurysternus*,

and *H quadripertuses*). Except for *H quadripertuses*, these lice have a cosmopolitan distribution, ie, they are found throughout most of the world. *H quadripertuses*, the cattle tail louse, is a tropical louse that has extended its distribution into subtropical areas. In the USA, *H quadripertuses* has been reported in California, Florida, and in other Gulf Coast states. The cattle tail louse is known to parasitize both European and Zebu breeds of cattle.

Cattle, especially young animals, may be infested with multiple species of lice simultaneously. *S capillatus* and *H eurysternus* infestations are more often recognized on mature animals, whereas *L vituli* is more commonly seen on calves and on dairy stock. For all age classes of cattle, stressors such as high stocking density, poor feed quality, gestational status, and underlying health issues are often contributing factors to susceptibility and degree of infestation. For site predilection on the host, see TABLE 1.

Pathogenesis and Disease Transmission: Pediculosis in cattle can decrease weight gain and milk production, result in weight loss, and cause hide and hair damage. Some sources have reported up to 9% reduced gain in cattle moderately to heavily infested with lice.

L vituli can serve as a mechanical vector for *Anaplasma marginale*, the causative

TABLE 1 SITE PREDILECTION OF CATTLE LICE

Site Predilection	
CHEWING LICE	
<i>Damalinia bovis</i> (cattle biting louse, red louse)	Most commonly found on dorsum Infestation may extend cranially to head and caudally to tailhead
BLOODSUCKING LICE	
<i>Linognathus vituli</i> (long-nosed cattle louse)	Most commonly found over withers, lateral shoulders, and dewlap May have generalized distribution over animal In early infestations, may be found in clusters In heavy infestations, may be found over most of body
<i>Haematopinus eurysternus</i> (short-nosed cattle louse)	Often found on front half of host from ears to dewlap Infestations tend to be heavier in anterior portions of the body, including the ears, during warm weather
<i>Solenopotes capillatus</i> (little blue cattle louse)	Found in distinct clusters, mainly on head and face Heavy infestations may extend to dewlap or surround eyes
<i>Haematopinus quadripertuses</i> (cattle tail louse)	Adults often confined to the tail, eggs commonly noted on tail switch

agent of bovine anaplasmosis (see p 18). Outside the USA, *H. eurysternus* populations have been found to contain multiple *Rickettsia* spp, but the role lice play in transmitting rickettsial agents is not well understood.

Treatment: A variety of compounds effectively control lice in cattle, including synergized pyrethrins; the synthetic pyrethroids cyfluthrin, permethrin, zetacypermethrin, and cyhalothrin (including gamma- and lambda-cyhalothrin) (beef cattle only); the organophosphates phosmet, chlorpyrifos (beef and nonlactating dairy cattle only), tetrachlorvinphos, coumaphos, and diazinon (beef and nonlactating dairy cattle only); and the macrocyclic lactones ivermectin, eprinomectin, and doramectin. Pour-on formulations are effective against biting and bloodsucking lice, whereas injectable formulations are primarily effective against bloodsucking lice.

Multiple pour-on formulations of 5% permethrin/5% piperonyl butoxide, 5% diflubenzuron/5% permethrin, and gamma-cyhalothrin are labeled for season-long control (~3–4 mo) of lice on beef and dairy cattle. Although both amitraz and spinosad are effective against lice, the last cattle products containing amitraz were removed from the USA market in 2014. Spinosad formulations for use on cattle were officially discontinued in the USA in 2010.

Certain Brahman and Brahman-cross cattle have organophosphate hypersensitivity, which should be considered when selecting a treatment compound.

Because of ease of application and reduced stress to the treated animal, the

pour-on method has become a popular way to apply insecticides. Self-treatment devices also can be used, such as back rubbers, oilers, dust bags, and ear tags. Cattle dips have fallen out of favor in the USA because of the labor-intensive nature of the process and amount of chemical needed to keep vats charged with active compound. The compound chosen must be appropriate for the animal's age, reproductive status, and production system. The treatment of meat and dairy animals must be restricted to uses specified on the product label, and all label precautions should be carefully observed. Appropriate meat and milk withdrawal times must be observed. In most countries, regulatory agencies specify tissue residue limits of insecticides and carefully regulate insecticide use on livestock. All regulations are subject to change, and pertinent current local laws and requirements should be determined before treatment.

Husbandry issues (overcrowding, poor feed quality, etc) and underlying health conditions in animals should be addressed. Treatment will be most effective if stock trailers, chutes, and other areas cattle have contacted are cleaned and treated with an appropriate premise spray.

SHEEP AND GOATS

Sheep may become infested with one species of chewing louse, *Damalinia ovis* (formerly *Bovicola ovis*), and three species of bloodsucking lice: *Linognathus pedalis*, *L. ovillus*, and *L. africanus* (see TABLE 2). Outside the USA, *D. ovis* is also referred to as the sheep

TABLE 2 SITE PREDILECTION OF SHEEP LICE

Site Predilection	
CHEWING LICE	
<i>Damalinia ovis</i> (sheep biting louse)	Most commonly found on the dorsum Infestation may extend cranially to head and caudally to tailhead
BLOODSUCKING LICE	
<i>Linognathus pedalis</i> (sheep foot louse)	Confined to hairy parts of the foot, except in very heavy infestations
<i>Linognathus ovillus</i> (sheep face and body louse)	Usually found on hairy parts of the sheep's skin As populations increase, lice spread to other parts of body
<i>Linognathus africanus</i> (African blue louse)	Often found on flanks of sheep Forms clusters Slippage of wool is common

body louse. Despite its name, *L. africanus* is found outside Africa, including in the USA, Central America, and India. *L. africanus* has also been reported from a variety of hosts, including goats and several species of deer.

Goats can be parasitized by three types of chewing lice, namely *Damalinia caprae* (formerly *Bovicola caprae*), *D. limbata* (formerly *B. limbata*), and *D. crassipes* (formerly *Holokartikos crassipes*); and two types of bloodsucking lice, namely *Linognathus stenopsis* and *L. africanus*. *L. stenopsis* is found on both short-haired and Angora breeds of goats. *L. stenopsis* has occasionally been reported from sheep in various parts of the world. It is found mostly on the long-haired parts of the hindlegs and back. Severe infestations are rare. *D. caprae*, the goat biting louse, is most frequently found on short-haired goats. Both *D. crassipes* and *D. limbata* (the Angora goat biting louse) are serious pests of Angora breeds.

Pathogenesis and Disease Transmission: Affected animals often rub vigorously on fencing and pens, damaging the coat and causing excoriations. Pediculosis is one cause of "wool slip" in sheep.

Sheep and goat lice are not known to vector any disease agents within the USA.

Treatment: Pyrethrins and pyrethroids are labeled for control of lice in sheep and goats. Shearing may be necessary to achieve effective louse control on sheep and goats. Re-treatment is often necessary. Husbandry issues and individual health issues within the flock or herd should be addressed. Shearing must be done carefully, because clippers may carry lice from animal to animal.

Treatment of meat and dairy animals must be restricted to uses specified on the product label, and all label precautions should be carefully observed. Appropriate meat and milk withdrawal times must be observed.

HORSES AND DONKEYS

Horses and donkeys may be infested by two species of lice, *Haematopinus asini*, the horse bloodsucking louse, and *Damalinia equi*, the horse biting louse. *D. equi* is also called *Werneckiella equi* and was formerly known as *Bovicola equi*, *Trichodectes equi*, and *T. parumpilosus*. Both species are distributed worldwide. *D. equi* is a small louse, 1–2 mm long, and *H. asini* is 3–3.5 mm long. There have been reports of poultry chewing lice (see p 2876) infesting horses when poultry and horses are housed in the same facilities. This problem is exacerbated when the poultry are removed without concurrent animal or premise treatments, leaving horses as the only host available.

Stressors such as high stocking density, poor feed quality, gestational status, and underlying health issues are often contributing factors to susceptibility and degree of infestation. Longer body hair, whether a winter coat or feathering, appears to allow for higher densities of lice to be sustained, because they have greater surface area to infest. Infestations are most common in winter and early spring. For site predilection on host by species of louse, see TABLE 3.

Pathogenesis and Disease Transmission: *D. equi* and *H. asini* are not known to vector any disease agents in the USA.

Treatment: A variety of compounds effectively control lice on horses, including synergized pyrethrins, synthetic pyrethroids, and the organophosphate coumaphos. Diazinon is no longer labeled for use on horses in the USA.

Pyrethrin and pyrethroid sprays are the most popular method for lice control on horses in the USA. Pyrethrin or pyrethroid formulations also are available

TABLE 3 SITE PREDILECTION OF EQUINE LICE

Site Predilection	
CHEWING LICE	
<i>Damalinia equi</i> (also called <i>Werneckiella equi</i>)	Found most commonly on the finer hairs of the body Found on lateral aspects of the neck, flanks, and base of the tail
BLOODSUCKING LICE	
<i>Haematopinus asini</i>	Found most commonly at roots of the forelock and mane, around base of the tail, and on hairs just above the hoof (especially in breeds with feathering)

in wipe-on, pour-on, and powder applications. Coumaphos is available as a powder or spray. Caution is warranted in mares with foals at their side, because the foals may be exposed to larger amounts of the compound than intended, especially with powdered formulations. When using sprays, certain formulations require soaking the hair to the skin, including mane and tail, whereas others may require only a light, misting application. Label instructions should be read carefully, and the manufacturer consulted if necessary.

Depending on the severity of infestation, the coat may be clipped. Long hair such as feathers on certain breeds, winter coats, or resultant from endocrine disorder (eg, pituitary pars intermedia dysfunction, see p 547) may make treatment more difficult.

Husbandry issues (overcrowding, poor feed quality, etc) and underlying health conditions should be addressed. Treatment will be most effective if trailers, stalls, wash racks, and other areas where horses have contacted are cleaned and treated with an appropriate premise spray.

PIGS

Domestic pigs are infested with only one species of louse, *Haematopinus suis*, the hog louse. This very large (5–6 mm) sucking louse is common on domestic swine worldwide. Swine pediculosis is more common in smaller or backyard populations than in large, commercial operations. Nymphal lice are normally found on the inside of the ears (often in the ear canal), on the skin behind the ears, in the folds of the neck, and on the medial aspects of the legs. In severe infestations, *H suis* may be found elsewhere on the body.

H suis can cause severe anemia, especially in piglets, because of the amount of blood imbibed by this large louse species. Extreme pruritus and subsequent self-trauma (alopecia, erythema, excoriations, and crusting) can be seen as hogs alleviate the irritation associated with the lice feeding.

Pathogenesis and Disease Transmission

H suis is a vector of swine pox virus, and it has also been implicated as a vector of *Eperythrozoon suis* and *E parvum*, the causative agents of swine eperythrozoonosis and of African swine fever virus in regions where these agents are endemic. Except for swine pox virus, transmission of these agents by *H suis* is considered rare.

Treatment: A variety of compounds effectively control lice on swine, including synergized pyrethrins; pyrethroids; the organophosphates phosmet, coumaphos, and tetrachlorvinphos; and the macrocyclic lactones ivermectin and doramectin.

Amitraz is no longer available for use on swine in the USA. Although eprinomectin is used in cattle, this compound should not be used in unapproved animal species, because severe adverse reactions, including fatalities, may result.

For severe infestations in swine, dust formulations can be used to treat bedding. Husbandry and underlying health issues should be addressed.

DOGS AND CATS

Dogs can be infested with one species of bloodsucking lice, *Linognathus setosus*, and two species of chewing lice, *Trichodectes canis* and *Heterodoxus spiniger*. *H spiniger* is considered rare in North America. It is distributed worldwide but appears to be more common in warmer environments; infestations are heavier on animals in poor physical condition. *H spiniger* exhibits atypical behavior for a chewing louse—it is a blood-feeder. Dogs neglected or in poor health may become heavily infested with *L setosus*, which tends to prefer longhaired breeds. *T canis* prefers the head, neck, and tail of the host, and it may be found around wounds and body openings. Infestations may be heavy on very young and very old animals. Infested dogs rub, bite, and scratch the affected area and have a rough, matted coat.

Cats can be infested with one species of chewing lice, *Felicola subrostratus*, although there are rare reports of *H spiniger* on feral cats in other regions of the world. The louse may be seen more frequently on older, longhaired cats that are unable to groom themselves.

Practitioners should be able to distinguish *Phthirus pubis*, the human crab louse, from the lice of dogs and cats. This species may be presented for identification by owners who claim to have found them on an animal. *P pubis* does not typically infest dogs or cats; there have been only two reports of dogs infested with *P pubis*, both of which occurred from sharing bedding with a person who was severely infested.

With widespread use of monthly flea and tick preventives, pediculosis in dogs and cats has become rare in the USA. Infestation is usually seen on debilitated, feral, stray, or shelter animals.

Pathogenesis and Disease Transmission:

T. canis can serve as an intermediate host to the double-pored tapeworm, *Dipylidium caninum*. This parasite of dogs and cats can occasionally infect people. *H. spiniger* has been found to contain the filarial nematode *Acanthocheilonema reconditum* (formerly *Dipetalonema reconditum*), but its competence as a vector has not been demonstrated.

Treatment: A variety of compounds effectively control lice on dogs and cats, including many of the topical, monthly flea and tick control products. Pyrethrins and pyrethroids are very effective pediculicides. However, caution must be exercised when using these products on cats, because this species is highly sensitive to pyrethrins and pyrethroids, lacking the ability to metabolize high doses. Limited pyrethrin or pyrethrin products are labeled for use on cats; the products either contain very low concentrations of the active compound or are available in a slow-release formulation

(eg, flumethrin/imidacloprid collar). Selamectin, imidacloprid, and fipronil have all been used successfully to treat lice on dogs and cats.

Although carbamates are effective against lice, carbaryl-containing collars were removed from the USA market in 2010, and propoxur-containing collars will no longer be available for sale in the USA after April 1, 2016. Extra-label use of eprinomectin or doramectin may result in fatalities.

Currently, spot-on products are the most popular way to treat lice in dogs and cats. However, other formulations, such as collars, shampoos, sprays, or dusts, are available for insect control on pets.

If the animal is heavily matted or long-haired, treatment may be facilitated by clipping the coat. Bedding should be washed frequently in hot, soapy water or treated with an approved bedding or premise spray until the infestation is controlled. Certain fipronil products are labeled for this use. Nutritional deficiencies or concurrent health conditions should be addressed.

MANGE

(Cutaneous acariasis, Mite infestation)

Mange is a contagious disease characterized by crusty or scaly skin, pruritus, and alopecia. Mange is a general term for cutaneous acariasis and is the result of infestation with one of several genera of parasitic mites, including *Chorioptes*, *Demodex*, *Psorobia* (formerly *Psorergates*), *Psoroptes*, *Sarcoptes*, and others. The term “scabies” most appropriately refers to infestation with *Sarcoptes* sp mites (ie, sarcoptic mange); however, this term is commonly misused to refer to any type of mange.

Historically, mange in large animals was a reportable disease because of the severity of clinical signs and contagiousness. However, widespread use of macrocyclic lactones beginning in the 1990s has provided effective treatment and decreased the prevalence. As a result, mange is no longer a federally reportable disease in the USA. However, some types of mange in large animals remain reportable to certain state agencies, although this may change as the lists are revised.

Successful mange treatment is a multifactorial process, including treatment of the affected animal(s), treatment of contact animals, and environmental control. Isolation of affected animals for 2 wk is often recommended to prevent or limit spread of contagious mites. Care should be taken to prevent contact of naive animals with potentially infested fomites (eg, animal bedding, feed and water buckets, tack and other equipment). Specific treatments are discussed for each species below.

CATTLE

Sarcoptic Mange (Scabies): *Sarcoptes scabiei* var *bovis* is a highly contagious disease spread by direct contact between infested and naive animals or by contaminated fomites. Lesions caused by this burrowing mite start on the head, neck, and shoulders and can spread to other parts of the body. The whole body may be involved in 6 wk. Pruritus is intense, and papules

develop into crusts; the skin thickens and forms large folds. Diagnosis is made by deep skin scrapings, skin biopsy, or response to therapy. *S. scabiei* var *bovis* can be transmitted to people and result in a transient, self-limiting dermatitis.

The following compounds are approved for use against sarcoptic mange mites in cattle at the labeled injectable and pour-on dosages: doramectin, eprinomectin, and ivermectin. Hot lime sulfur dips or sprays may be used, following the label instructions for species-specific dilution, with treatment repeated at 12-day intervals as needed, usually for a maximum of three treatments. Phosmet is also labeled for use against sarcoptic mange mites in cattle; two treatments may be required. Label instructions for dilution (multiple dilutions are listed) should be followed as appropriate. Certain spray formulations of permethrin are labeled for use against sarcoptic mange mites, but it is generally not considered the compound of choice. If permethrin is used, the animals should be wet thoroughly with the product and re-treated in 10–14 days.

Practitioners and producers should take care to note whether the compound, dose, and formulation are appropriate for the age of the animal and the production system in use. Eprinomectin and moxidectin pour-on formulations, as well as hot lime sulfur, are approved for use on dairy animals in the USA.

Psoroptic Mange: Psoroptic mange in cattle is caused by infestation with *Psoroptes ovis*. Current taxonomic and systematic classification of *Psoroptes* spp indicates that *P. ovis* and *P. cuniculi* (ear canker in rabbits, ear mange in sheep and goats) are strains or variants of the same species, with *P. ovis* being found primarily on the backs and flanks of infested animals and *P. cuniculi* in the ears. *P. ovis* is not zoonotic.

P. ovis is a nonburrowing mite that lives on the skin surface. All stages of the mite are found on the host, and transmission is through direct contact of infested and susceptible hosts. Transmission is also possible through contact with contaminated environments or fomites, because *P. ovis* can survive off the host for ≥2 wk under the right conditions.

P. ovis is a common parasite of cattle with a distribution limited to continental Europe and parts of the USA. It can be found in range and feedlot beef cattle from the central and western states, with the largest numbers of outbreaks historically reported

from Texas, New Mexico, Oklahoma, Kansas, Colorado, and Nebraska. Clinical signs of *P. ovis* infestation are rare in dairy cattle. These mites pierce host tissue and feed on serum and other fluid secretions from the bite wound. Exudates coagulate to form thick, scabby crusts. Alopecia is common with exudative dermatitis. Infestations are intensely pruritic, with papules, crusts, excoriation, and lichenification on the shoulders and rump initially, spreading to cover almost the entire body. Secondary bacterial infections are common in severe cases. Death in untreated calves, weight loss, decreased milk production, and increased susceptibility to other diseases can occur.

Treatment can be done by spray dipping or vat dipping; topical application of nonsystemic acaricides; and oral, topical, or injectable formulations of systemic drugs. Spray dipping is time consuming but useful for small herds, whereas vat dipping has fallen out of favor in the USA because of expense and the difficulty in managing proper concentrations of therapeutic compounds and proper cleanup. Toxaphene spray (0.5%–0.6%) was used historically; however, all uses of toxaphene were banned in the USA in 2001 and prohibited internationally through the Stockholm Convention on Persistent Organic Pollutants, effective 2004.

In the USA, the following treatments are labeled for use against *P. ovis* in cattle at the labeled dosages: injectable doramectin, injectable ivermectin, and moxidectin (pour-on and injectable formulations). Hot lime sulfur dips or sprays may be used, following the species-specific dilution labeled on the package, with treatment repeated at 12-day intervals as needed, usually for a maximum of three treatments. Of these, only pour-on moxidectin and hot lime sulfur are approved for use on dairy animals. Certain spray formulations of permethrin are labeled for use against mange mites in cattle, but it is generally not considered the compound of choice. If permethrin is used, the animals should be thoroughly wet with the product and re-treated in 10–14 days. Outside the USA, other treatments are available and labeled for the control of mange, including flumethrin pour-on (2 mg/kg, repeated 10 days later), 0.3% coumaphos, 0.1% phoxim, 0.075% diazinon, and 0.025–0.05% amitraz. There are currently no amitraz products labeled for use on cattle in the USA. Diazinon is available for use on cattle only in an ear tag formulation in the USA; it is not labeled for treatment or prevention of

mange. Products labeled for treatment and control of sarcoptic mange in cattle are considered effective against *P ovis*.

Chorioptic Mange (Leg Mange, Foot and Tail Mange, Symbiotic Mange, Barn Itch):

Chorioptic mange in cattle is caused by infestation with *Chorioptes bovis* or *C texanus*. Species of *Chorioptes* are not host specific, and *C bovis* can be found on domestic ruminants and horses throughout the world. Chorioptic mange caused by infestation with *C bovis* is the most common type of mange in cattle in the USA. *C texanus* has been reported on cattle from Brazil, China, Germany, Israel, Japan, Malaysia, South Korea, and USA. *C bovis* and *C texanus* are not zoonotic.

C bovis live on the skin surface and do not burrow. Life cycle stages include egg, larval, two nymphal, two female, and one male stage. Eggs are deposited on the skin, and secretions from female mites help secure eggs to the surface of their hosts. Eggs require 5–6 days to hatch, whereas each larval and nymphal stage requires 3–5 days for development. The entire life cycle may be completed in 21–26 days and depends on temperature and humidity. Transmission is by direct contact of infested and naive hosts. *C bovis* can live off their host for up to 3 wk and can be transmitted to cattle through contact with contaminated fomites and housing.

C bovis likely feeds on sloughed skin cells and other surface debris. While feeding, *C bovis* irritates the host skin, causing abrasions that become contaminated with secretions and feces from the mites. Most cattle are subclinically infested with *C bovis*. However, *C bovis* may cause an allergic, exudative, mildly pruritic, flaky dermatitis. Lesions include nodules, papules, crusts, and ulcers that typically begin at the pastern and spread up the legs to the udder, scrotum, tail, and perineum. Self-trauma and alopecia may be evident. Lesions and clinical signs appear in late winter and spontaneously regress during summer months. Chorioptic mange is less pathogenic than sarcoptic or psoroptic mange in cattle. Diagnosis is by observation of mites in skin scrapings.

In the USA, the following treatments are approved for use against *C bovis* at the labeled dosages: pour-on doramectin, eprinomectin (both pour-on and injectable formulations), and pour-on moxidectin. Hot lime sulfur dips or sprays are labeled for use against chorioptic mites and may be used following the label directions for species-specific dilution. Lime sulfur treatment

should be repeated at 12-day intervals if needed. Of these, the pour-on formulations of eprinomectin and moxidectin as well as hot lime sulfur are approved for use on dairy animals in the USA.

Demodectic Mange (Follicular Mange, Bovine Demodicosis):

Three species of *Demodex* are known to infest cattle: *D bovis*, *D ghanensis*, and *D tauri*. *D bovis* is the most common and infests hair follicles of cattle worldwide. *D ghanensis* infests meibomian glands of cattle from Ghana, and *D tauri* has been recovered from hair follicles and sebaceous glands of cattle from Czechoslovakia. Species of *Demodex* are host specific and not zoonotic.

Demodex spp are unique among parasitic mites, because they are elongated with short, stumpy legs. Their distinct morphology is a presumed adaptation to living in hair follicles and sebaceous glands of their hosts. All life cycle stages are found on the host and include egg, larvae, two nymphs, and adults. These mites feed on sebum, protoplasm, and epidermal debris.

Transmission of *D bovis* occurs through close contact of infested and naive hosts, with the transfer of mites from infested dams to neonates being the primary route.

Lesions consist of follicular papules and nodules, especially over the withers, neck, back, and flanks. Invasion by *D bovis* results in chronic inflammation, with formation of ulcers, abscesses, and fistulae due to follicular rupture or secondary staphylococcal infection. Pruritus is absent. Infestation of *D bovis* may result in considerable damage to hides. Cattle of any age are susceptible to demodectic mange, although disease is more evident in the young. Most cases are seen in dairy cattle in late winter or early spring. Infestation with *D bovis* is usually subclinical, and infestation may

Demodex bovis, skin lesions. Courtesy of Dr Raffaele Roncalli.

extend for many months. Diagnosis is by observation of mites in deep skin scrapings. Recovery is usually spontaneous; consequently, treatment is rarely performed. If therapy is instituted, the macrocyclic lactones listed for treatment of *Sarcoptes scabiei* var *bovis* or *Chorioptes ovis* should be considered.

Psorergatic Mange (Itch Mite): *Psorobia bos* (formerly *Psorergates bos*) is a small mite that lives in the superficial layers of cattle skin. In most instances, *P bos* is nonpathogenic, and few cattle exhibit clinical signs of infestation. On rare occasions, mild pruritus, alopecia, and increased licking and rubbing have been attributed to infestation with *P bos*. This mite has been reported from cattle in the USA, Canada, the UK, and South Africa. *P bos* is not zoonotic. The disease does not cause significant economic losses; therefore, animals are usually not treated. The macrocyclic lactone products labeled for use for sarcoptic, chorioptic, and psoroptic mange likely control this infestation effectively.

SHEEP AND GOATS

It is the practitioner's duty to recommend a safe and effective treatment regimen, but this proves difficult when treating mange in sheep and goats. In the USA, ectoparasiticide are regulated by the Environmental Protection Agency (EPA) or the FDA Center for Veterinary Medicine. As a general rule, if a product is applied topically to an animal to treat ectoparasites, it likely falls under the jurisdiction of the EPA. If a topical product is used to treat both external and internal parasites, it likely falls under jurisdiction of the FDA. This distinction is important for practitioners to recognize, because there is no legal extra-label use of products regulated by the EPA. Label directions must be followed regarding species treated, product concentration, product dosage, individuals allowed to administer application, and re-treatment interval. Because products regulated by the FDA are approved animal drugs, extra-label drug use may be allowed under the Animal Medicinal and Drug Use and Clarification Act (AMDUCA). (See also p 2748 and see p 2637.) The Food Animal Residue Avoidance Databank (FARAD) can be consulted for extra-label drug use recommendations and calculated meat and milk withdrawal times.

Hot lime sulfur spray or dip is labeled for use against sarcoptic, psoroptic, and chorioptic mites in sheep. Treatment should

be repeated every 12 days if needed. Certain formulations of permethrin sprays are labeled for mange in sheep and goats. As with cattle, permethrin is generally not considered the compound of choice, but if used, the animals should be thoroughly wet with the product and re-treated in 10–14 days. Topical treatments are more likely to be effective if sheep are freshly shorn. Oral ivermectin sheep drench is not labeled for treatment or control of mange. Although single doses of oral ivermectin have been shown to reduce the number of *Psoroptes ovis* mites within 24 hr, a single oral dose is not considered curative. For these reasons, extra-label drug use of macrocyclic lactones in sheep and goats is common. However, practitioners should consider compounds labeled for a large range of species, the production system of the animals treated, and any warnings against use in species not listed on the label. Outside the USA, injectable ivermectin is approved to treat *P ovis* in sheep at the labeled dosage of 200 mcg/kg, two doses given 7 days apart.

Sarcoptic Mange: *Sarcoptes scabiei* var *ovis* infests sheep, and *S scabiei* var *caprae* infests goats, throughout the world. However, *S scabiei* var *ovis* is rare in the USA. This mite infests nonwooly skin, usually on the head and face. Typical of scabies, lesions manifest with formation of crusts and intense pruritus. Affected animals have decreased reproduction, meat gain, and milk yield. In goats, *S scabiei* var *caprae* is responsible for a generalized skin condition characterized by marked hyperkeratosis. Lesions start usually on the head and neck and can extend to the inner thighs, hocks, brisket, ventral abdomen, and axillary region. Both *S scabiei* var *ovis* and *S scabiei* var *caprae* are zoonotic. Consistent with other animal variants of *Sarcoptes*, zoonoses are initiated from direct contact with infested animals but are self-limiting infestations.

Chorioptic Mange: *Chorioptes bovis* infests sheep and goats worldwide. Prevalence of *C bovis* is more common in rams than ewes or lambs. Infestation of *C bovis* on goats is fairly common, with most of a herd infested. Distribution of lesions is the same as that in cattle, with papules and crusts seen on the feet and legs. Most sheep are subclinically infested with *C bovis*. However, *C bovis* can cause exudative dermatitis on the lower legs and scrota of rams (scrotal mange). Semen quality may be affected, presumably due to increased temperature of infested scrota.

Psoroptic Mange (Sheep Scab, Ear Mange): *Psoroptes ovis* is a highly contagious and severe infestation of sheep. This mite has been eradicated from sheep in Canada, New Zealand, and the USA. However, sheep scab persists in many countries, including some in Europe. Intense pruritus leads to large, scaly, crusted lesions that develop in more densely haired or woolly parts of the body. Lesions begin on the back and side but may become generalized and cover a large portion of the body. Animals bite, lick, and scratch in response to the pruritus, which results in wool loss and secondary bacterial infection. If affected sheep are not treated, infested animals may become emaciated and anemic and possibly die.

Psoroptic mange (ear mange) in goats and sheep is caused by *P. cuniculi*, which is likely a variant of *P. ovis*. *P. cuniculi* typically infests the ears of goats but can spread to the head, neck, and body. Infestation of *P. cuniculi* in goats can be common, with 80%–90% of a herd infested. Disease can range from subclinical to scaling, crusting, inflammation, alopecia, ear scratching, head shaking, and rubbing of ears and head to alleviate irritation. Although the course is chronic, the prognosis is good with appropriate treatment.

Demodectic Mange (Ovine Demodecticosis, Caprine Demodecticosis): *Demodex ovis* infests sheep, and *D. caprae* infests goats. Demodectic mange in sheep is not common, whereas *D. caprae* are relatively common in goats. Lesions are similar to those in cattle. In goats, nonpruritic papules and nodules develop, especially over the face, neck, shoulders, and sides or udder. Demodectic mange in goats occurs most commonly in kids, pregnant does, and dairy goats. The nodules contain a thick, waxy, grayish material that can be easily expressed; mites can be found in this exudate. The disease can become chronic. Historically, in some cases, localized lesions in goats have been managed by incision, expression, and infusion with Lugol's iodine or rotenone in alcohol (1:3). This practice should not be continued or condoned. Rotenone, a plant-derived ketone once a popular pesticide and ectoparasiticide approved for use in organic farming, is now available only as a piscicide in the USA and Canada.

Psorergatic Mange (Itch Mite, Australian Itch): *Psorobia ovis* (formerly *Psorergates ovis*) is a common skin mite of sheep in Africa, Australia, New Zealand, and South America. Most infested sheep are not

affected. However, intense generalized pruritus and scaliness, with matting and loss of wool can result from infestation with *P. ovis*. All breeds of domestic sheep are susceptible. Because of their small size, the mites are difficult to find in skin scrapings. This disease can cause significant economic losses through weight loss and wool damage. Treatments effective against sarcoptic, chorioptic, and psoroptic mange in sheep are expected to be efficacious for psorergatic mange.

HORSES

The last large animal mange reportable to the OIE was horse mange, but this was removed in 2006. Mange in horses was removed from the list of federally reportable diseases in the USA prior to this date, although it remains reportable to some state veterinary agencies.

Sarcoptic Mange: *Sarcoptes scabiei* var *equi* is rare but is the most severe type of mange in horses. The first sign of infestation is intense pruritus due to hypersensitivity to mite products. Early lesions appear on the head, neck, and shoulders. Regions protected by long hair and lower parts of the extremities are usually not involved. Lesions start as small papules and vesicles that later develop into crusts. Alopecia and crusting spread, and the skin becomes lichenified, forming folds. If infestations are not treated, lesions may extend over the whole body, leading to emaciation, general weakness, and anorexia. Negative skin scrapings do not exclude the disease; biopsy may establish a diagnosis.

Hot lime sulfur spray or dip is labeled for use against sarcoptic, psoroptic, and chorioptic mites in horses. Treatment should be repeated every 12 days if needed, following the species-specific dilution on the label. Although certain spray formulations of permethrin are labeled for use against mange in horses, it is generally not considered the compound of choice. If permethrin is used, the animals should be thoroughly wet with the product and re-treated in 10–14 days. Although not labeled for treatment of mange in horses, two doses of oral ivermectin at 200 mcg/kg given 14 days apart (field studies), or a single treatment of oral moxidectin at 400 mcg/kg, have effectively treated psoroptic, chorioptic, and sarcoptic mange in horses.

Psoroptic Mange: *Psoroptes ovis* (formerly *P. equi*) and *P. cuniculi* (likely a

variant of *P ovis*) both infest horses. *P ovis* is rare in horses. However, infestations can produce lesions on thickly haired regions of the body, such as under the forelock and mane, at the base of the tail, under the chin, between the hindlegs, on the udder, and in the axillae. *P cuniculi* can sometimes cause otitis externa in horses and may cause head shaking. Pruritus is characteristic. Lesions start as papules and alopecia and develop into thick, hemorrhagic crusts. Psoroptic mites are more easily recovered from skin scrapings than are sarcoptic mites. Topical and oral treatments recommended for other types of mange are effective. Hot lime sulfur is labeled for use against *Psoroptes* in horses (see above). Although not labeled for treatment of mange in horses, oral ivermectin at 200 mcg/kg given for two doses 14 days apart (field studies), or a single treatment with oral moxidectin at 400 mcg/kg, has effectively treated psoroptic, chorioptic, and sarcoptic mange in horses.

Chorioptic Mange (Leg Mange):

Chorioptic mange is caused by infestation with *Chorioptes bovis* (formerly *C equi*) and is the most common form of mange in horses. Draft horses are commonly infested, although all breeds are susceptible. Lesions caused by *C bovis* start as a pruritic dermatitis affecting the distal limbs around the foot and fetlock. Papules are seen first, followed by alopecia, crusting, and thickening of the skin. A moist dermatitis of the fetlock develops in chronic cases. Infested horses may stamp their feet or rub one foot against the opposite leg or object. Chorioptic mange is a differential diagnosis for "greasy heel" in draft horses. The signs subside in summer but recur with the return of cold weather. The disease course is usually chronic without treatment, but the prognosis is favorable when treated. Topical and oral treatments recommended for other types of mange are effective. Hot lime sulfur is labeled for use against *Chorioptes* in horses (see above). Treatment is aided by clipping long hair from infested areas. Although not labeled for treatment of mange in horses, oral ivermectin at 200 mcg/kg given for two doses 14 days apart (field studies), or a single treatment with oral moxidectin at 400 mcg/kg, has effectively treated psoroptic, chorioptic, and sarcoptic mange in horses.

Demodectic Mange (Equine Demodicosis): Demodectic mange in horses is caused by infestation with *Demodex equi*

or *D caballi*. *Demodex* mites infest hair follicles and sebaceous glands. *D equi* lives on the body, and *D caballi* on the eyelids and muzzle. Demodectic mange is rare in horses but can manifest as patchy alopecia and scaling or as nodules. Lesions appear on the face, neck, shoulders, and forelimbs. It has been reported in association with pituitary pars intermedia dysfunction (see p 547) and chronic corticosteroid treatment. Pruritus is absent; therefore, secondary infections due to excoriation are rare. Therapy is rarely done, although there is limited evidence that the macrocyclic lactones may be effective. Lesions have also been reported to resolve without treatment.

Trombiculidiasis (Chiggers, Harvest Mite):

Trombiculid mites can parasitize the skin of horses, especially during the late summer and fall. The adult mites live on invertebrates and plants; the larvae normally feed on small rodents, but they can opportunistically feed on people and domestic animals, including horses. Lesions consist of severely pruritic papules and wheals on the face, lips, and feet. At the time of diagnosis, a topical pyrethrin or pyrethroid labeled for horses can be used to kill any remaining larvae still feeding. Symptomatic treatment with a glucocorticoid for pruritus can be added to minimize further self-trauma and associated secondary infections. Any secondary infections should be treated. Repellents may help prevent infestation.

Straw Itch Mite (Forage Mite): These mites usually feed on organic material in straw and grain and can opportunistically infest the skin of horses. Papules and wheals appear on the face and neck if horses are fed from a hay rack, and on the muzzle and legs if fed from the ground. Pruritus is variable. Treatment for trombiculidiasis may be used for straw itch mite infestations.

PIGS

Mange in pigs is principally due to infestation with *Sarcoptes scabiei* var *suis*. Rarely, infestation with *Demodex phylloides* has been reported to cause clinical disease in pigs.

Sarcoptic Mange: Sarcoptic mange, caused by infestation with *Sarcoptes scabiei* var *suis*, is of primary importance in pigs worldwide. *S scabiei* var *suis* in a herd typically becomes established after introduction of infested breeding stock.

Transmission of *S. scabiei* var *suis* can occur rapidly through direct contact of infested and naive pigs. However, transmission to naive pigs is also possible through contact with fomites contaminated with *S. scabiei* var *suis*. Survival of the mite eggs away from the host is limited. However, exposure for as little as 24 hr to contaminated pens that were recently vacated by infested pigs resulted in transmission of the mite. Laboratory experiments indicated that *S. scabiei* var *suis* did not survive >96 hr at temperatures <25°C or >24 hr at 20°–30°C. Survival was <1 hr at temperatures >30°C. Unless pigs originated from SPF colonies or after mange eradication programs, all pig herds must be considered potentially infested even if acaricides are used routinely.

Lesions due to infestation with *S. scabiei* var *suis* usually start on the head, especially the ears, then spread over the body, tail, and legs. Itching can be intense and associated with a hypersensitivity reaction to the mites. As the hypersensitivity subsides, typically after several months, the thickened, rough, dry skin is covered with grayish crusts. Infestations are negatively correlated with daily weight gains and feed conversion in pigs.

Experimental studies of *S. scabiei* var *suis* in pigs have demonstrated that infestation alters the microbial community on the skin. Comparing the microbiome of bacteria on pigs without *S. scabiei* var *suis* versus that of infested pigs showed that noninfested pigs had low relative abundances of *Staphylococcus*, whereas the relative abundance of *Staphylococcus* increased significantly on pigs with *S. scabiei* var *suis* during the course of infestations. Specifically, the staphylococci population shifted from *S. hominis* to that of the more pathogenic *S. chromogenes* as scabies progressed.

■ Diagnosis is best performed by combining different approaches: dermatitis score recorded at slaughter, scratching index, observation of clinical signs of mange, ear or skin scrapings for microscopic examination, and ELISA for detection of specific antibodies. The usefulness of each criterion may vary according to the group age. This global approach is particularly useful during an eradication campaign.

Injectable doramectin and ivermectin are labeled for use against *S. scabiei* var *suis* and are considered highly effective treatments. In some instances, a second dose of macrocyclic lactone 14 days later may be necessary for complete resolution. Hot lime sulfur is labeled for use against

mange in swine. In swine, lime sulfur dips are repeated at intervals of 3–7 days to treat mange, unlike in other species in which they are repeated every 12 days. Label instructions must be followed closely, because there are three possible lime sulfur dilutions for use on swine. Unlike phosmet, lime sulfur spray can be applied to suckling pigs. Certain spray formulations of permethrin are labeled for use against mites on swine, but it is generally not considered the compound of choice. If permethrin is used, animals should be wet thoroughly with the product and re-treated in 14 days. Phosmet spray is approved for sarcoptic mange in swine at the species-specific dilution instructions on the label. A single treatment is usually effective, but a second treatment can be applied 14 days later if necessary. Phosmet should not be applied directly to suckling pigs. Coumaphos sprays are available for use on swine in the USA, but they are labeled only for control of lice.

Demodectic Mange (Swine Demodicosis):

Demodectic mange caused by infestation with *Demodex phylloides* is possible in pigs. Clinical signs of *D. phylloides* infestation include reddening of the skin, pustules, and alopecia. Although rare in domestic pigs, *D. phylloides* infestation can be common in wild boars without overt signs of clinical disease. In wild boars, the highest prevalence and greatest numbers of *D. phylloides* were found in sebaceous glands in eyelids and cheeks. *D. phylloides* can also be found around the eyes, mouth, snout, ventral neck, ventrum, and thighs. There is no reliable treatment.

DOGS AND CATS

Sarcoptic Mange (Canine Scabies):

Sarcoptes scabiei var *canis* infestation is a highly contagious disease of dogs found worldwide. The mites are fairly host specific, but animals (including people) that come in contact with infested dogs can also be affected. Adult mites are 0.2–0.6 mm long and roughly circular in shape; their surface is covered with small triangular spines, and they have four pairs of short legs. Females are almost twice as large as males. The entire life cycle (17–21 days) is spent on the dog. Females burrow tunnels in the stratum corneum to lay eggs. Sarcoptic mange is readily transmitted between dogs by direct contact; transmission by indirect contact may also occur. Clinical signs may develop anytime from 10 days to 8 wk after contact with an infected animal. Asymptomatic

carriers may exist. Intense pruritus is characteristic and probably due to hypersensitivity to mite products. Primary lesions consist of papulocrustous eruptions with thick, yellow crusts, excoriation, erythema, and alopecia. Secondary bacterial and yeast infections may develop. Typically, lesions start on the ventral abdomen, chest, ears, elbows, and hocks and, if untreated, become generalized. Dogs with chronic, generalized disease develop seborrhea, severe thickening of the skin with fold formation and crust buildup, peripheral lymphadenopathy, and emaciation; dogs so affected may even die. "Scabies incognito" has been described in well-groomed dogs; these dogs, infested with sarcoptic mites, are pruritic, but demonstrating the mites on skin scrapings is difficult because the crusts and scales have been removed by regular bathing. Atypical, including localized, clinical forms that are probably linked to extensive use of insecticides or acaricides are being increasingly seen.

Diagnosis is based on the history of severe pruritus of sudden onset, possible exposure, and involvement of other animals, including people. Making a definitive diagnosis is sometimes difficult because of negative skin scrapings. Concentration and flotation of several scrapings may increase chances of finding the mites, eggs, or feces. Several extensive superficial scrapings should be done of the ears, elbows, and hocks; nonexcoriated areas should be chosen. A centrifugation fecal flotation using sugar solutions may reveal mites or eggs. A specific and sensitive commercially available ELISA to detect specific antibodies has been developed and may be useful. Because mites can be difficult to detect, if *Sarcoptes* is on the differential diagnosis list but no mites are found, a therapeutic trial is warranted.

Systemic treatments of scabies are based on administration of macrocyclic lactones, some of which are FDA approved for this purpose. Among them, selamectin is given as a spot-on formulation at 6 mg/kg. This drug appears to be safe, even in ivermectin-sensitive breeds. Another is the imidacloprid-moxidectin formulation, which may be used on dogs as young as 7 wk of age. In some countries, moxidectin is also registered for treatment of scabies. It is available as a spot-on formulation in combination with imidacloprid and should be given in two doses of 2.5 mg/kg, 4 wk apart; additionally, oral uptake should be prevented in breeds at risk of avermectin sensitivity. Other endectocides, such as

milbemycin oxime and ivermectin, which are not registered for treatment of sarcoptic mange in dogs, have been reported to be effective depending on the dosage and route of administration. The recommended dosage for milbemycin oxime is 2 mg/kg, PO, weekly for 3–4 wk; potential toxicity should be considered in dogs with avermectin sensitivity. Ivermectin (200 mcg/kg, PO or SC, 2–4 treatments 2 wk apart) is very effective and usually curative. Ivermectin at this dosage is contraindicated in avermectin-sensitive breeds. Additionally, the microfilaremic (*Dirofilaria immitis*) status of the dog should be evaluated before treatment with a macrocyclic lactone. For topical treatment, hair can be clipped, the crusts and dirt removed by soaking with an antiseborrheic shampoo, and an acaricidal dip applied. Lime sulfur is highly effective and safe for use in young animals; several dips 7 days apart are recommended. Amitraz is an effective scabicide, although it is not approved for this use. It should be applied as a 0.025% solution at 1- or 2-wk intervals for 2–6 wk. In addition, the owner must observe certain precautions to avoid self-contamination. Fipronil spray was reported to be effective but should be considered an aid in control rather than a primary therapy. Treatment can be topical or systemic, and should include all dogs in contact.

Notoedric Mange (Feline Scabies):

This rare, highly contagious disease of cats and kittens is caused by *Notoedres cati*, which can opportunistically infest other animals, including people. The mite and its life cycle are similar to the sarcoptic mite. Pruritus is severe. Crusts and alopecia are seen, particularly on the ears, head, and neck, and can become generalized. Mites can be found quite easily in skin scrapings. Treatment consists of both topical and systemic therapies. Nonapproved but effective and safe treatments include selamectin (6 mg/kg, spot-on) and moxidectin (1 mg/kg, spot-on, in the imidacloprid-moxidectin formulation). Ivermectin (200 mcg/kg, SC) has also been used. Another effective topical therapy is lime sulfur dips at 7-day intervals.

Otodectic Mange: *Otodectes cynotis* mites are a common cause of otitis externa, especially in cats but also in dogs. Mites that belong to the family Psoroptidae are usually found in both the vertical and horizontal ear canals but are occasionally seen on the body. Clinical signs include head shaking, continual ear scratching, and ear droop.

Pruritus is variable but may be severe. Dark brown cerumen accumulation in the ear and suppurative otitis externa with possible perforation of the tympanic membrane may be seen in severe cases. Affected and in-contact animals should receive appropriate parasiticide treatment in the ears. Systemic therapies have been approved and include topically applied selamectin and moxidectin. Direct applications to the external ear canal of cats using approved ivermectin and milbemycin formulations are also effective. As a general rule, ear cleansing with an appropriate ceruminolytic agent is indicated with any therapy.

Cheyletiellosis (Walking Dandruff):

Cheyletiella blakei infests cats, *C yasguri* infests dogs, and *C parasitovorax* infests rabbits, although cross-infestations are possible. This disease is very contagious, especially in animal communities. Human infestation is frequent. Mite infestations are rare in flea-endemic areas, probably because of the regular use of insecticides. These mites have four pairs of legs and prominent hook-like mouthparts. They live on the surface of the epidermis, and their entire life cycle (3 wk) is spent on the host. Female mites can, however, survive for as long as 10 days off the host. Clinical disease is characterized by scaling, a dorsal distribution, and pruritus, which varies from none to severe. Cats can develop dorsal crusting or generalized miliary dermatitis. Asymptomatic carriers may exist. The mites and eggs may not be easy to find, especially in animals that are bathed often. Acetate tape preparations, superficial skin scrapings, and flea combing can be used to make the diagnosis.

Cheyletiella sp. Courtesy of Dr. Michael W. Dryden.

Both topical and systemic acaricides are effective against cheyletiellosis, although no drugs are currently licensed for this indication. In addition to treatment of the affected animals, it is necessary to treat all in-contact animals. Topical drugs include lime sulfur, fipronil spot-on and spray, permethrin, and amitraz (the latter two drugs are contraindicated in cats). Extra-label systemic drugs include selamectin spot-on, milbemycin oxime (PO), and ivermectin (SC). Care must be taken to avoid or minimize the risks of adverse reactions as described above (see p 920). The treatment period depends on the selected drug but must be long enough to eradicate the mites from both the animals and their environment, which can be difficult in animal communities (eg, breeding colonies, kennels). In practice, treatment lasts 6–8 wk and should continue for a few weeks beyond clinical cure until parasitologic cure is achieved.

Canine Demodicosis: Canine demodicosis occurs when large numbers of *Demodex canis* mites inhabit hair follicles and sebaceous glands. In small numbers, these mites are part of the normal flora of canine skin and usually cause no clinical disease. The mites are transmitted from dam to puppies during nursing within the first 72 hr after birth. The mites spend their entire life cycle on the host, and the disease is not considered to be contagious. The pathogenesis of demodicosis is complex and not completely understood; evidence of hereditary predisposition for generalized disease is strong. Immunosuppression, natural or iatrogenic, can precipitate the disease in some cases. Secondary bacterial deep folliculitis, furunculosis, or cellulitis may occur, leading to a guarded prognosis.

Three forms of demodicosis are seen in dogs: localized demodectic mange, juvenile-onset generalized demodicosis, and adult-onset generalized demodicosis. Localized demodicosis is seen in dogs usually <1 yr old, and most of these cases resolve spontaneously. Lesions often consist of one to five well-demarcated small areas of alopecia, erythema, and scaling. Lesions are usually confined to areas around the lips, periorbital area, and forelimbs but may be found in other locations. Pruritus is usually absent or mild. A small percentage of these cases, especially the diffuse localized forms, progress to a more severe generalized form. Juvenile-onset generalized demodicosis is the result of an inherited immunologic defect with functional abnormality associated with the cell-mediated immune

system. It is a severe disease of young dogs with generalized lesions (erythema, papules, alopecia, oily seborrhea, edema, hyperpigmentation, and crusts) that are usually aggravated by secondary bacterial infections (pyodermatitis). Accompanying pododermatitis is common. Dogs can have systemic illness with generalized lymphadenopathy, lethargy, and fever when deep pyoderma, furunculosis, or cellulitis is seen. Diagnosis is not difficult; deep skin scrapings or hair plucking typically reveal mites, eggs, and larval forms in high numbers. The third form is adult-onset generalized demodicosis and clinically appears similar to juvenile-onset generalized demodicosis but is seen in adult dogs. It is typically associated with or triggered by some neoplastic process or debilitating disease that may be producing immunosuppression, such as malignant lymphosarcoma, malignant melanoma, hyperadrenocorticism, hypothyroidism, diabetes mellitus, etc. However, in many cases an underlying immunosuppressive condition may not be found.

Localized demodicosis can generally be left untreated. The prognosis for this form is usually good, and spontaneous recovery is frequent. In contrast, treatment is required in cases of generalized demodicosis, for which prognosis is guarded. Hair clipping and body cleansing, especially with benzoyl peroxide shampoo used for its follicular flushing activity, may be required. Whole-body amitraz dips (0.025%) applied every 2 wk remains the only approved treatment in the USA for generalized demodicosis. Higher concentrations (0.05%) and shorter treatment intervals (1 wk) may be more efficient.

A number of other protocols are commonly used for refractory generalized demodicosis. Among macrocyclic lactones, milbemycin oxime (0.5–1 mg/kg/day, PO), moxidectin, and ivermectin have all demonstrated varying degrees of effectiveness. Moxidectin is available as a spot-on formulation in combination with a flea product (imidacloprid) and should be given at 2.5 mg/kg at 1–4 wk intervals. More frequent applications are associated with higher degrees of success. Other reportedly successful but unapproved systemic treatments include moxidectin (400 mcg/kg/day, PO) and ivermectin (300–600 mcg/kg/day, PO). For the latter, different therapeutic protocols have been proposed with a gradually increased dosage and thorough monitoring of treated animals to detect any potentially toxic effect. Ivermectin is contraindicated in Collies and Collie

crosses. However, idiosyncratic toxicity may be seen in any breed. Testing for mutation in the MDRI allele (ABCB1) may be required before initiating therapy. Local and systemic corticosteroids are contraindicated in any animal diagnosed with demodicosis. Secondary bacterial infections must be treated aggressively with an appropriate antibiotic. Antiparasitic therapy must be continued not only until clinical signs abate but also until at least two consecutive negative skin scrapings are obtained at 1-month intervals. Although some dogs respond rapidly, others may need several months of treatment. Recurrence within the first year of treatment is not uncommon. As the sole prophylactic measure, dogs developing juvenile-onset generalized demodicosis should not be used for breeding.

Feline Demodicosis: Feline demodicosis is an uncommon to rare skin disease caused by at least two species of demodectic mites. *Demodex cati* is thought to be a normal inhabitant of feline skin. It is a follicular mite, similar to but narrower than the canine mite, that can cause either localized or generalized demodicosis. One other species of *Demodex* (named *D. gatoi*) is shorter, with a broad abdomen, and is found only in the stratum corneum. It causes a contagious, transmissible, superficial demodicosis that is frequently pruritic and can be generalized. In follicular localized demodicosis, there are one or several areas of focal alopecia most commonly on the head and neck. In generalized disease, alopecia, crusting, and potential secondary pyoderma of the whole body are seen. The generalized form is often associated with an underlying immunosuppressive or metabolic disease such as feline leukemia virus infection, feline immunodeficiency virus infection, diabetes mellitus, or neoplasia. In some cases, ceruminous otitis externa is the only clinical sign.

Diagnosis is made by superficial (*D. gatoi*) and deep (*D. cati*) skin scrapings, although mite numbers are often small, especially with *D. gatoi*. Medical evaluation is indicated in cats with generalized disease. Dermatophyte cultures are essential, because dermatophytosis and demodicosis can be concomitant conditions. Prognosis of generalized demodicosis is unpredictable because of its potential relationship with systemic disease. Some cases spontaneously resolve. Weekly lime sulfur dips (2%) are safe and usually effective; amitraz (0.0125%–0.025%) has been used but is not approved for use in cats and can cause anorexia, depression, and diarrhea. The use

of antiparasitic macrocyclic lactones has been reported but their efficacy is unclear.

Trombiculosis: Trombiculosis is a common, seasonal, noncontagious acariasis caused by the parasitic larval stage of free-living mites of the family Trombiculidae (chiggers). It can affect domestic carnivores, other domestic or wild mammals, birds, reptiles, and people. Two common species found in cats and dogs, *Neotrombicula autumnalis* and *Eutrombicula alfreddugesi*, are reported in Europe and in America, respectively. Adults (harvest mites) and nymphs look like small spiders and live on rotting detritus. In temperate areas from summer to fall, dogs and cats can acquire the larvae as parasites when lying on the ground or walking in suitable habitat. In warmer regions, infestation occurs throughout the year. The larvae (0.25 mm long) attach to the host, feed for a few days, and leave when engorged. At that time, they are easily identified as ovoid, 0.7 mm long, orange to red, immobile dots, usually found clustering on the head, ears, feet, or ventrum. Pathogenicity is through traumatic and proteolytic activities. Hypersensitivity reactions are suspected in some animals, because pruritus may vary from none to severe. Lesions include erythema, papules, excoriations, hair loss, and crusts. When present, intense pruritus can persist for hours to several days even after the larvae have left the animal.

Diagnosis is based on history and clinical signs. The infestation is a seasonal threat to free-ranging dogs and cats. Differential diagnoses include other pruritic dermatoses. Diagnosis is confirmed by careful examination of the affected areas. Microscopic examination of samples obtained from skin scrapings may help to identify the larvae, which have an oval-shaped body densely covered with setae, six long legs, and curved pedipalps terminating in claws.

Management is difficult. The most useful approach, if feasible, consists of keeping pets away from areas known to harbor large numbers of mites to prevent reinfestation during periods of risk. The application of pyrethroids (dogs only) with repellent-like activity to prevent infestation has yielded variable results. Fipronil and permethrin (dogs only) can be used, both for prevention and treatment of infested animals. Symptomatic treatment may be required in cases of severe pruritus.

Straelensiosis: Canine straelensiosis is a rare, noncontagious, sporadic, but potentially emerging parasitic dermatitis caused by the temporary encystment in the

epidermis of the parasitic larval stage of *Straelensia cynotis*. This mite belongs to a family close to the family Trombiculidae. To date, the life cycle is largely unknown, and the disease has been reported only in France, Portugal, Spain, and Italy. Transmission occurs mainly in rural and small-sized hunting dogs, probably through contact with contaminated soil, litter, and other terrestrial habitat of foxes. No contagion has been reported to congeners and people. *S. cynotis* has distinct differences from other trombidoid mites, especially in clinical presentation, histopathologic features, and response to treatment.

Straelensiosis is sudden in onset and may be accompanied by systemic signs such as anorexia and prostration. Lesions are painful, variably pruritic, and either generalized or multifocal, most often affecting the dorsal regions of the head and trunk. The characteristic erythematous papules and nodules resemble small craters. Scaling, pustules, and crusts can be seen.

Differential diagnoses include bacterial folliculitis, sarcoptic mange, and gunshot. Microscopic examination of samples obtained from deep skin scrapings may help identify the larvae (0.7 mm long, 0.45 mm wide), each in a thick-walled cyst. The larvae, which resemble *Neotrombicula*, are more easily visualized by histopathology.

The prognosis is favorable; a self-cure generally occurs after several months if reinfestation is prevented. However, management of clinical signs is difficult. Anitraz may be somewhat effective.

Lynxacariasis: Feline lynxacariasis is a quite common but to date geographically restricted (Australia, Brazil, Hawaii, Florida, North Carolina, Texas) parasitic dermatitis caused by the fur mite *Lynxacarus radovskyi*, which belongs to the family Lishophoridae. The life cycle remains poorly described, and this species has not been reported from hosts other than cats. Infestation typically occurs by direct contact, but fomites may be important for transmission. Clinical signs include a salt-and-pepper appearance of the hair coat, variable pruritus, and alopecia. Diagnosis is based on visualization of mites (0.5 mm long) using a magnifying glass or on isolation of any parasitic stage in skin scrapings or acetate tape preparations. Treatment with acaricidal sprays, weekly lime sulfur dips, and ivermectin (300 mcg/kg, SC) are effective. The only case of contagion to people that has been reported involved a transient rash in an owner with a heavily infested cat.

TICKS

Ticks are obligate ectoparasites of most types of terrestrial vertebrates virtually wherever these animals are found. Ticks are large mites and thus are arachnids, members of the subclass Acari. They are more closely related to spiders than to insects. The ~850 described species are exclusively bloodsucking in all feeding stages. Ticks transmit a greater variety of infectious organisms than any other group of arthropods and, worldwide, are second only to mosquitoes in terms of their public health and veterinary importance. Some of these agents are only slightly pathogenic to livestock but may cause disease in people; others cause diseases in livestock that are of tremendous economic importance. In addition, ticks can harm their hosts directly by inducing toxicosis (eg, sweating sickness [see p 684], tick paralysis [see p 1314] caused by salivary fluids containing toxins), skin wounds susceptible to secondary bacterial infections and screwworm infestations, and anemia and death. International movement of animals infected with the tick-transmitted blood parasites *Theileria*, *Babesia*, and *Anaplasma* spp and *Ehrlichia* (*Cowdria*) *ruminantium* is widely restricted.

Movement of tick-infested livestock over great distances is an important factor in the extensive distribution and prevalence of many tick species and tickborne disease agents. A number of introduced tick species thrive in the vast grazing and browsing environments established during recent centuries of human and livestock population explosions. Conversely, introduction of livestock into areas with exotic tick species and tickborne agents to which they have no immunity or innate resistance often results in significant losses.

Two of the three families of ticks parasitize livestock: the Argasidae (argasids, "soft ticks") and the Ixodidae (ixodids, "hard ticks"). Although they share certain basic properties, argasids and ixodids differ in many structural, behavioral, physiologic, ecologic, feeding, and reproductive patterns. Tropical and subtropical species may undergo one, two, or rarely three complete life cycles annually. In temperate zones, there is often one annual cycle; in northern regions and at higher elevations in temperate regions, at least 2–4 yr are required by most species.

There are four developmental stages: egg, larva, nymph, and adult. All larvae have three pairs of legs; all nymphs and adults have four. Adults have a distinctive genital and anal area on the ventral body surface. The foreleg tarsi of all ticks bear a unique sensory apparatus—Haller's organ—to sense carbon dioxide, chemical stimuli (odor), temperature, humidity, etc. Pheromones stimulate group assembly, species recognition, mating, and host selection.

Certain tick species that parasitize livestock can survive several months, and occasionally a few years, without food if environmental conditions permit. Tick host preferences are usually limited to a particular genus, family, or order of vertebrates; however, certain ticks are exceptionally adaptable to a variety of hosts, so each species must be evaluated separately. The larvae and nymphs of most ixodids that parasitize livestock feed on small wildlife such as birds, rodents, small carnivores, or even lizards.

In the Argasidae, the leathery dorsal surface lacks a hard plate (scutum). Male and female argasids appear to be much alike, except for the larger size of the female and differences in external genitalia. The argasid capitulum (mouthparts) arises from the anterior of the body in larvae but from the ventral body surface in nymphs and adults.

In the Ixodidae, the male dorsal surface is covered by a scutum. The scutum of the ixodid female, nymph, and larva covers only the anterior half of the dorsal surface. The ixodid capitulum arises from the anterior end of the body in each developmental stage.

Argasid Parasitism

The world's argasid tick fauna comprises 185 species in four genera, namely *Argas*, *Carios*, *Ornithodoros*, and *Otobius*, in the family Argasidae. The Argasidae are highly specialized for sheltering in protected niches or crevices in wood or rocks, or in host nests or roosts in burrows and caves. Some argasid species are known to survive for several years between feedings. Most of these leathery parasites inhabit tropical or warm, temperate environments with long dry seasons. Hosts are those that

either rest in large numbers near the argasid microhabitat or return from time to time to rest or breed there. Soft ticks can be a serious pest in poultry and pig operations in tropical and subtropical countries. Blood loss and subsequent anemia can be significant and substantially affect weight gains and egg-laying performance. Massive infestations can cause numerous fatalities.

An argasid population typically parasitizes only a single kind of vertebrate and inhabits its shelter area. Argasids use multiple hosts, ie, the larvae feed on one host and drop to the substrate to molt; the several nymphal instars each feed separately, drop, and molt; adults feed several times (but do not molt). Argasid nymphs and adults feed rapidly (usually 30–60 min). Larvae of some argasids also feed rapidly; others require several days to engorge fully. Adult argasids mate off the host several times; afterward, females deposit a few hundred eggs in several batches and feed between ovipositions.

Most of the 57 described *Argas* spp parasitize birds that breed in colonies in trees or against rock ledges; others parasitize cave-dwelling bats. Few feed on reptiles or wild mammals, and none on livestock. Several species have become important pests of domestic fowl and pigeons; among these are the vectors of *Borrelia anserina* (avian spirochetosis) and the rickettsia *Anaplasma (Aegyptianella) pullorum* (aegyptianellosis). *Argas* spp also cause tick paralysis and transmit *Pasteurella multocida* (agent of fowl cholera), and many are vectors of a variety of arboviruses, some of which infect people.

Genus *Caros* includes 88 species, most of which are parasites of mammals, especially bats and rodents. Depending on the species, they inhabit dens or roosts of bats located in caves or tree holes or rodent burrows. Several species parasitize colonial nesting birds and dwell in the substrate or under stones and debris in ground-level bird colonies. Many of these ticks parasitize only a single host species or a group of closely related hosts. However, some *Caros* ticks will feed on people and domestic animals if the primary host is not available. *C kelleyi*, a tick associated with bats and bat habitats, has been reported to carry a novel spotted fever group *Rickettsia* and a relapsing fever spirochete closely related to *Borrelia turicatae*. The seabird tick *C capensis* has been shown to transmit West Nile virus to ducklings. The American *C puertoricensis* and *C talaje* are potential vectors of African swine fever virus.

The majority of nearly 37 species belonging to the genus *Ornithodoros* inhabit animal burrows and lairs in hot, arid climates and feed on most any potential hosts that enter their habitat. Larvae in this nidicolous genus do not feed, which may be related to the fact that these ticks dwell in burrows that may house hosts irregularly. A few species have adapted to living in crevices of walls and under fences where livestock are confined and also are pests of people. Certain species are vectors of relapsing fever spirochetes (*Borrelia* spp) and African swine fever virus; some species cause toxicoosis, and one species (*O coriaceus*) transmits a spirochete causing epizootic bovine abortion in the western USA. Numerous *Ornithodoros*-transmitted salivary toxins or arboviruses cause irritation or febrile illnesses in people.

The unique argasid genus *Otobius* (see p 939) has three species, which do not feed in the adult stage. *O megnini* (spinose ear tick) is exceedingly specialized biologically and structurally. It infests the ear canals of pronghorn antelope, mountain sheep, and Virginia and mule deer in low rainfall biotopes of the western USA, Mexico, and western Canada. Cattle, horses, goats, sheep, dogs, various zoo animals, and people are similarly infested. This well-concealed parasite has been transported with livestock to western South America, Galapagos, Cuba, Hawaii, India, Madagascar, and southeastern Africa. Notably, adults have nonfunctional mouthparts and remain nonfeeding on the ground but may survive for almost 2 yr. Females can deposit as many as 1,500 eggs in a 2-wk period. Larvae and two nymphal instars feed for 2–4 mo, mostly in winter and spring. There can be two or more generations per year. People and other animals may have severe irritation from ear canal infestations, and heavily infested livestock lose condition during winter. Tick paralysis of hosts and secondary infections by larval screwworms are reported. *O megnini* is infected by the agents of coxiellosis/Q fever, tularemia, Colorado tick fever, and Rocky Mountain spotted fever. Another species, *O lagophilus*, feeds on the heads of jackrabbits (hares) and rabbits in western USA.

Ixodid Parasitism

The Ixodidae number >600 species, occupy many more habitats and niches than do argasids, and parasitize a greater number of vertebrates in a wider variety of environments. Most ixodid species have a three-host life cycle, others have a two-host

cycle, and a few have a one-host cycle. Each ixodid postembryonic developmental stage (larva, nymph, adult) feeds only once but for a period of several days. Males and females of most species that parasitize livestock mate while on the host, although some mate off the host on the ground or in burrows. Males take less food than females but remain longer on the host and can mate with several females. During inactive seasons, few or no females are found feeding, even though males may remain attached to the hosts. Such males may contribute to transmission of pathogens to new susceptible animals by serial interhost transfer. Larval and nymphal population activity generally peaks during the "off seasons" of adults, although in some species there is overlap in the seasonal dynamics of immatures and adults.

The ixodid males, except those in the genus *Ixodes*, become sexually mature only after beginning to feed, after which they mate with a feeding female. Only after mating does the female become replete and proceed to develop eggs. She then detaches, drops from the host, and over a period of several days deposits a single batch of many eggs on or near the ground, usually in crevices or under stones, leaf litter, or debris. Depending on species and quantity of female nourishment, the egg batch usually numbers 1,000–4,000 but may be >12,000. The female dies after ovipositing. Notably, ixodids (except one- and two-host species, which use vertebrate host animals as habitat for much of their life cycle) spend >90% of their lifetime off the host, a fact of utmost significance in planning control measures. The several-day feeding process progresses slowly; the balloon shape characteristic of engorged larvae, nymphs, and females develops only during the final half day of feeding and is followed by detaching. The dropping time at certain hours of the day or night is governed by a circadian rhythm closely associated with the activity cycle of the principal host.

It is also important, especially in understanding the epidemiology of tickborne pathogens, to know whether immatures of an ixodid species feed on the same host species as do the adults, or on smaller vertebrates. Where acceptable smaller-sized hosts are scarce, immatures of some ixodid species can feed on the same livestock hosts as adults; immatures of other species seldom or never do so.

The proximity of acceptable hosts, air temperature gradients, and atmospheric humidity during resting and questing periods are among the factors that regulate

the development of each stage and, in the case of females, oviposition.

Three-host Ixodids: Most ixodids have a three-host cycle. The recently hatched larvae quest for a suitable host, usually from vegetation, feed for several days, drop, and molt to nymphs, which repeat these activities and molt to adults. Of the three-host species that parasitize livestock or dogs, a few have immatures and adults that parasitize the same kind of host; these often develop tremendous population densities. The success of ixodid species that require smaller-size hosts for immatures depends on the availability of those hosts in the livestock browsing and grazing grounds. The natural hazards inherent in the three-host cycle have been compensated for by the benefits afforded adaptable tick species by animal husbandry practices. Only certain ixodids specific for herbivores have adapted to coexistence with livestock, and therein lies the answer to numerous livestock tick problems in Africa, where hosts for adults and immatures are abundant.

Two-host Ixodids: Some ixodids, especially those that parasitize wandering mammals (and also birds in certain cases) in inclement environments of the Old World, have developed a two-host cycle in which larvae and nymphs feed on one host, and adults on another. As in three-host species, both hosts may be different or may be the same species. Two-host parasites of livestock thrive in both inclement and clement environments and are difficult to control. This is especially true of two-host species that feed in the ears and anal areas of livestock.

One-host Ixodids: Among the most economically important ticks are several one-host species. These parasites evolved together with herbivores that wandered in extensive ranges in the tropics (*Rhipicephalus* [*Boophilus*] spp, *Dermacentor nitens*, etc) or in temperate zones (*D albipictus*, *Hyalomma scupense*). Larvae, nymphs, and adults feed on a single animal until the mated, replete females drop to the ground to oviposit.

Feeding Sites: Each species has one or more favored feeding sites on the host, although in dense infestations, other areas of the host may be used. Some feed chiefly on the head, neck, shoulders, and escutcheon; others in the ears; others around the anus and under the tail; and some in the

nasal passages. Other common feeding sites are the axillae, udder, male genitalia, and tail brush. Immatures and adults often have different preferred feeding sites. Attachment of the large, irritating *Amblyomma* spp is regulated by a male-produced aggregation-attachment pheromone, which ensures that the ticks attach at sites least vulnerable to grooming.

IMPORTANT IXODID TICKS

The important ixodid ticks include *Amblyomma* spp, *Anomalohimalaya* spp, *Bothriocroton* spp, *Cosmiomma* sp, *Dermacentor* spp, *Haemaphysalis* spp, *Hyalomma* spp, *Ixodes* spp, *Margaropus* spp, *Nosomma* sp, *Rhipicentor* spp, and *Rhipicephalus* spp.

AMBLYOMMA SPP

More than half of the ~140 known *Amblyomma* species are endemic to the New World. *Amblyomma* ticks are large, three-host parasites. They have eyes and long, robust mouthparts. They are more or less brightly ornamented and generally confined to the tropics and subtropics. Adults and immatures of 37 species in this genus parasitize reptiles, which together with ground-feeding birds, are often hosts of immature *Amblyomma* ticks that have adapted, in the adult stage, to parasitizing mammals. Their long mouthparts make *Amblyomma* ticks especially difficult to remove manually and frequently cause serious wounds that may become secondarily infected by bacteria or screwworms and other myiasis flies.

Several African *Amblyomma* that infest livestock are vectors of *Ehrlichia* (*Cowdria*) *ruminantium*, the rickettsial agent that causes heartwater (see p 751), whereas New World *Amblyomma* spp carry agents of monocytic and granulocytic ehrlichioses as well as several *Rickettsia* spp, including *R. rickettsii*, the agent of Rocky Mountain spotted fever.

A. americanum, the lone-star tick, is abundant in the southern USA from Texas and Missouri to the Atlantic Coast and ranges northward into Maine. Southward, its distribution extends into northern Mexico. Because of the changing climate, the geographic range of this species continues to expand.

The scutum is distinctive because of pale ornamentation in males and a conspicuous, silvery spot ("star") near the posterior margin in females. Larvae, nymphs, and adults are indiscriminate in host choice and

parasitize a variety of livestock, pets, and wildlife as well as people. Activity in the USA continues from early spring to late fall. Feeding sites on domestic and wild mammals are usually skin areas with sparse hair; wounds at these sites predispose livestock to attack by the screwworm fly *Cochliomyia hominivorax*.

A. americanum is a vector of *Francisella tularensis*, the etiologic agent of tularemia; *Ehrlichia chaffeensis*, which causes monocytic ehrlichiosis in people; *E. ewingii*, which causes granulocytic ehrlichiosis in dogs and people; and a recently described Panola Mountain *Ehrlichia* closely related to the agent of heartwater, which is pathogenic to at least goats and people. This tick also transmits *Rickettsia amblyommii*, *Borrelia lonestari*, and the Heartland virus pathogenic to people. A *Coxiella* sp symbiotic bacteria, closely related to the agent of Q fever, can be present in the majority of ticks in a population but is unknown to cause infections in people or other animals. *A. americanum* may cause tick paralysis in people and dogs. In addition, Lone star virus (Bunyaviridae) has been isolated from a single *A. americanum* nymphal tick that had been removed from a woodchuck (*Marmota monax*) in Kentucky.

A. cajennense, the Cayenne tick, ranges from South America into southern Texas. This species is found most commonly in dry tropical habitats and lower elevations of subtropical highlands. As with *A. americanum*, each active stage is indiscriminate in host choice: livestock and a large variety of avian and mammalian wildlife serve as hosts. People are severely irritated by clusters of *A. cajennense* larvae ("seed ticks") in wooded and high-grass areas. Most adults attach on the lower body surface, especially between the legs; some feed elsewhere on the body. Activity continues throughout the year. *A. cajennense* is a vector of *R. rickettsii* in Central and South America from Panama to Argentina and has been experimentally shown to transmit *Ehrlichia ruminantium*. Wad Medani virus (an Orbivirus, Reoviridae), an African virus transported to Caribbean islands by *A. variegatum*-infested cattle from Senegal, has been isolated from *A. cajennense* in Jamaica.

A. maculatum, the Gulf Coast tick, is an important pest of livestock, particularly cattle, from South America to southern USA. Optimal habitats are warm areas with high rainfall, near seacoasts. Immatures usually parasitize birds and small mammals; adults parasitize deer, cattle,

horses, sheep, pigs, and dogs. Adult feeding activity is chiefly in late summer and early fall but may begin later after a dry summer. Most adults infest the ears, where the feeding wounds are initial sites of screw-worm infestations. Clustered feeding adults also cause much irritation to the upper parts of the neck of cattle and to the humps of Brahman cattle. *A. maculatum* is the primary vector of *R. parkeri*, and in some tick populations as many as 50% of individual ticks may be infected with this pathogen.

A. imitator parasitizes livestock from Central America to southern Texas; it has been shown to transmit *R. rickettsii* in Mexico. Occasional pests of livestock in tropical America are *A. neumanni* (Argentina), *A. ovale* and *A. parvum* (Argentina to Mexico), *A. tigrinum* (much of South America), and *A. tapirellum* (Colombia to Mexico).

A. testudinarius inhabits Asian tropical wooded environments from Sri Lanka and India to Malaysia and Vietnam, Indonesia, Borneo, Philippines, Taiwan, and southern Japan. Adults are particularly abundant on wild and domestic pigs and also infest deer, cattle, other livestock, and people. Immatures parasitize birds and small mammals as well as people. In India and Sri Lanka, adult *A. integrum* and *A. nudlari* also parasitize livestock, wild ungulates, and people.

A. hebraeum, the southern Africa bont tick, inhabits warm, moderately humid savannas of South Africa, Namibia, Botswana, Zimbabwe, Malawi, Mozambique, and Angola. Immatures feed on various small mammals, ground-feeding birds, and reptiles. Adults infest livestock, antelope, and other wildlife. Adults, attached chiefly to body areas with relatively little hair, cause serious wounds that become secondarily infected by bacteria and the screwworm *Chrysomya bezziana*. Like other African *Amblyomma* ticks (bont ticks) that parasitize livestock, *A. hebraeum* is an important vector of *Ehrlichia ruminantium* and the principal vector of *Rickettsia africae*, the agent of African tick bite fever, in southern Africa.

A. variegatum, the tropical African bont tick, is an easily visible, brightly colored parasite found throughout sub-Saharan savannas southward to the range of *A. hebraeum*, and also in southern Arabia and several islands in the Indian and Atlantic Oceans and the Caribbean. An eradication program is in progress in the Caribbean; St. Kitts, St. Lucia, Montserrat, Anguilla, Barbados, and Dominica qualified

for "provisionally free" certification by 2002 although St. Kitts was reinfested in 2004. Host preferences are similar to those of *A. hebraeum* but also include camels. The bites of the tropical bont tick are severe. They may result in septic wounds and abscesses, inflammation of the teats of cows, and considerable damage to hides and skins. Adults feed chiefly during rainy seasons, immatures during dry seasons. Most adults attach to the underside of the host body, on the genitalia, and under the tail.

A. variegatum injuries to hosts and transmission of *E. ruminantium* are similar to those of *A. hebraeum* but also include the spread of acute bovine dermatophilosis (see p 858). This tick is not considered to be an effective vector of Nairobi sheep disease virus but is a secondary vector of Crimean-Congo hemorrhagic fever virus. Dugbe virus has been isolated from *A. variegatum* in six countries north of the equator; the Thogoto and Bhanja viruses are also associated with this tick in various areas north of the equator. Notably, yellow fever virus has been isolated from *A. variegatum* collected from cattle in the Central African Republic and has been demonstrated to be transovarially transmitted to the progeny of infected females. Jos virus infects *A. variegatum* from Ethiopia to Senegal and has been transported in this tick to Jamaica.

A. lepidum, the East African bont tick, inhabits xeric savanna environments from northern Tanzania to central Sudan. *A. gemma*, the gem-like bont tick, occurs in similar environments of Tanzania, Somalia, Kenya, and Ethiopia. A small variety of the buffalo bont tick, *A. cohaerens*, is abundant on cattle in Ethiopian highlands, but from Zaire to Tanzania the larger variety of *A. cohaerens* parasitizes chiefly Cape buffalo. Other African *Amblyomma* ticks of Cape buffalo and various other large mammals, including livestock, are *A. pomposum* of humid highland forests in Angola, Zaire, Uganda, southern Sudan, Kenya, and Zimbabwe, and *A. astrion* of West Africa and Zaire.

In Central and South America, numerous *Amblyomma* spp parasitize livestock and dogs, often in large numbers. Among those, *Amblyomma* and *A. ovale* adults feed primarily on carnivores and *A. parvum* on carnivores and armadillos. *A. auricularium* has been found on wild hosts of the families Myrmecophagidae and occasionally Didelphidae, Caviidae, Chinchillidae, Hydrochaeridae, Muridae, Canidae, Mustelidae, and Procyonidae; it transmits *R. rickettsii* in Brazil. *A. pseudoconcolor* has

been found occasionally on wild hosts of the family Didelphidae. *A naponense* is common on peccaries, and *A oblongoguttatum* has been found on a variety of hosts in several South and Central American countries. The South American tapir (*Tapirus terrestris*) seems to be the primary host for the adult stage of *A latepunctatum*, *A scalpturatum*, and *A incisum*. *A dissimile* is a common parasite of reptiles and true toads of the genus *Bufo*, from Argentina northward to southern Mexico, the Caribbean islands, and southern Florida.

ANOMALOHIMALAYA SPP

The three *Anomalohimalaya* spp are found in mountains of Central Asia—Pamir, Tian Shan, Tibet, and Himalayas. All stages of these three-host ticks parasitize rodents, shrews, and less frequently hares.

BOTHRIOCROTON SPP

Genus *Bothriocroton* (formerly *Aponomma*) includes seven species of ticks indigenous to Australia and Papua New Guinea (*B oudemansi*). *Bothriocroton* spp resemble *Amblyomma* spp except they have no eyes. In this group, *B aruginans* is a parasite of wombats; *B concolor* and *B oudemansi* are ectoparasites of echidnas in Australia and Papua New Guinea, respectively. The other four species in this genus parasitize reptiles almost exclusively. *B hydrosauri*, the blue-tongued lizard tick, is the reservoir of *Rickettsia honei* on Flinders Island, Australia.

COSMIOMMA SP

Genus *Cosmiomma* contains a single species, *C hippopotamensis*, which is found in southwestern and eastern Africa. It feeds primarily on white and black rhinoceroses and less frequently on antelopes.

DERMACENTOR SPP

Of the 36 *Dermacentor* spp, 19 inhabit temperate zones. Of the tropical species, *D (Anocenter) nitens* is of major veterinary importance, although others may transmit zoonotic infections, and adults may be common on wildlife such as pigs, deer, and antelope. Imatures infest chiefly rodents and lagomorphs. *Dermacentor* spp in cold areas and *D nitens* in tropical America have specialized life cycles and seasonal dynamics of activity, each of which must be considered separately. Except for *D nitens*,

D albipictus, and *D dissimilis*, the *Dermacentor* life cycle is of the typical three-host pattern.

D nitens, the one-host tropical horse tick, is of considerable veterinary importance. It originally parasitized deer (*Mazama*) in the forests of northern South America. With the introduction of Equidae and other livestock into its habitat, it adapted to these animals. Spending its entire parasitic life deep in the hosts' ears, this parasite was easily spread by human activities to other areas of the Americas, including Florida and Texas. In addition to ear cavities, each active stage may infest nasal passages and the mane, ventral abdomen, and perianal area. *D nitens* transmits *Babesia caballi* transovarially to successive generations and is important in the horse-racing industry. It also is an experimental vector of *Anaplasma marginale* to cattle.

Another American one-host species, *D albipictus*, the winter or mouse tick, ranges from Canada and northern USA into western USA and Mexico. A brownish form, sometimes called *D nigrolineatus*, is distributed from New Mexico to southern and eastern USA and may merit subspecies, if not full-species, rank. The larval-nymphal-adult feeding period on a single host (moose, deer, elk, or domestic cattle or horses) extends from fall to spring. Heavily infested hosts may die. *D albipictus* causes the often fatal "phantom moose disease" of Canada, is a secondary vector of Colorado tick fever virus, and is an experimental vector of *B caballi*; it is a natural vector of *A marginale* in Oklahoma.

In Mexico and central America, *D dissimilis* parasitizes a variety of equine and ruminant hosts and may be a one-host tick on horses.

The Rocky Mountain wood tick, *D andersoni*, is found from Nebraska westward to the western mountains (Cascades and Sierra Nevadas), in northern New Mexico and Arizona, and in western Canada.

The American dog tick, *D variabilis*, is found west of the Cascades and Sierra Nevadas, in Mexico, from Montana to Texas and east to the Atlantic, and in eastern Canada. Both species may cause tick paralysis in livestock, wildlife, and people. They are the primary vectors of *Rickettsia rickettsii*, the agent of Rocky Mountain spotted fever (see p 806). *D andersoni* is also the chief vector of Colorado tick fever virus and transmits Powassan virus, *A marginale*, *A ovis*, and the agents of tularemia and coxiellosis/Q fever. *D variabilis* is an experimental vector of *A*

marginale, *B. caballi*, and *B. equi*. In addition, sawgrass virus, *Ehrlichia chaffeensis*, and *E. ewingii* have been detected in questing *D. variabilis* adults. Adults of both species parasitize livestock and wildlife, including deer, bison, and elk, but those of *D. variabilis* prefer skunk, raccoon, puma, etc, and domestic dogs. Immatures feed on rodents and other small wild mammals. A related, biologically similar species, *D. occidentalis*, is restricted to the Pacific lowlands and foothills from Oregon to Baja California and is a natural vector of *A. marginale*.

In western USA and Mexico, *D. parvum*, *D. hunteri*, and *D. halli* parasitize various hares and rabbits, mountain sheep, and peccaries, respectively. These ticks seldom make contact with livestock. *D. hunteri* is an experimental vector of *A. marginale* and *A. ovis*. In Costa Rica and Panama, *D. latus* infests tapirs.

In Eurasian steppes, forests, and mountains, *D. marginatus*, *D. reticulatus*, and *D. silvarum*, collectively, are vectors of *Rickettsia slovaca* and *R. raoultii* (the causative agents of tickborne lymphadenopathy), *R. sibirica* (the agent of Siberian tick typhus), *Babesia bovis*, *B. caballi*, *B. equi*, *B. canis*, *Theileria ovis*, and *A. ovis*, together with the agents of tularemia and coxiellosis/Q fever, and Russian spring-summer encephalitis. *D. marginatus* is found in forests, marshes, semideserts, and alpine zones from France to southwestern Siberia, Kazakhstan, Xinjiang Uygur Autonomous Region of China, Iran, and northern Afghanistan. *D. reticulatus* ranges from Ireland and Britain to northwestern Siberia and Xinjiang, China, in meadows, floodplains, and deciduous and deciduous-conifer forests. *D. silvarum* ranges from central Siberia and northeastern China to Japan in marshes, meadows, shrubby and secondary forests, and farmlands in taiga forest areas. Some males in populations of each of these three species remain attached to the host during winter. Adults and immatures may overwinter on the ground. Greatest adult activity is from early spring to summer with a lower peak in fall. Larvae and nymphs are active from spring through fall. The life cycle may be completed in 1 yr or extended by one or more summer or winter diapause to 2–4 yr.

About 12 other *Dermacentor* spp inhabit certain lowland, mountain steppe, and semidesert areas of temperate Asia. Their adults are commonly taken from camels, cattle, horses, sheep, and goats. In tropical Asia, the several species of the *Dermacentor* subgenus *Indocentor* are parasites of wild pigs; they also infest larger wildlife but seldom if ever feed on livestock.

HAEMAPHYSALIS SPP

Few of the 166 species of *Haemaphysalis* parasitize livestock, but those that do are economically important in Eurasia, Africa, Australia, and New Zealand. Some haemaphysaline parasites of wild deer, antelope, and cattle have adapted to domestic cattle and, to a lesser extent, to sheep and goats. Others, originally specific for various wild sheep and goats, have adapted chiefly to the domestic breeds of these animals. A few African species that evolved together with carnivores now parasitize domestic dogs. Immatures of species that parasitize livestock generally feed on small vertebrates, but there are a few notable exceptions. All *Haemaphysalis* spp have a three-host life cycle. They are small (unfed adults <4.5 mm long), brownish or reddish, and eyeless. Most have very short mouthparts. Different species cause tick paralysis and are vectors of the agents that cause coxiellosis/Q fever, tularemia, and brucellosis, and of *Theileria orientalis*, *T. ovis*, *Babesia major*, *B. motasi*, *B. canis*, *Anaplasma mesaeterum*, etc.

H. punctata, the red sheep tick, is widely distributed where sheep, goats, and cattle feed in certain open forests and shrubby pastures from southwestern Asia (Iran and former USSR) to much of Europe, including southern Scandinavia and Britain. It usually does not appear in large numbers. Immatures infest birds, hedgehogs, rodents, and reptiles. *H. punctata* can cause tick paralysis. In addition to transmitting *Anaplasma*, *Brucella*, *Theileria*, *Babesia* spp, and tularemia, different *H. punctata* populations are infected by Russian spring-summer encephalitis virus, Tribeca virus, Bhanja virus, and Crimean-Congo hemorrhagic fever virus. *H. concinna* is found in Central Europe, East and Southeast Asia, China, and Japan. It is found in humid scrubby forests as well as in meadows and peat-lands but avoids dense forests. *H. concinna* can transmit tularemia, several *Rickettsia* spp, including mildly pathogenic *R. heilongjiangensis*, and several encephalitis viruses.

H. sulcata adults parasitize livestock (chiefly sheep and goats) from northwestern India and southern former USSR to Arabia, Sinai, and southern Europe. *H. parva* adults parasitize these hosts from southwestern former USSR and the Near East to the Mediterranean area (but not Egypt). Immature *H. sulcata* are especially common on lizards, but the range of hosts of larvae and nymphs of both species is similar to that of *H. punctata*.

H longicornis is a parasite of deer and livestock in Japan and northeast Asia; there is a bisexual form (race) in southern areas and a parthenogenetic race in northern areas. The latter has been introduced into Australia, New Zealand, and the Pacific islands, where it preserves this unusual reproductive ability. Immatures usually parasitize small mammals and birds but may also feed on livestock; heavy population densities may become serious pests of deer and livestock. This tick is the chief vector of *Theileria orientalis* and also transmits *Babesia ovata*, *B gibsoni*, and the agents of coxiellosis/Q fever, Powassan encephalitis, and Russian spring-summer encephalitis. Larval feeding causes acute dermatitis in people.

H inermis is found in lowlands from northern Iran and southwestern former USSR to central and southeastern Europe to Italy, where it prefers deciduous and mixed forests as well as grasslands. It can cause tick paralysis. Other Eurasian haemaphysalines of livestock are *H pospellovashtroniae* (mountains of southern former USSR and Mongolia), *H kopetdaghicus* (Caspian Sea area, mountains of former USSR, and Iran), and *H tibetensis*, *H xinjiangensis*, and *H moschisuga* (China).

Of the several *Haemaphysalis* spp parasitizing livestock in southeast Asia, three are especially noteworthy: *H bispinosa* ranges to Pakistan, Bangladesh, Nepal, Bhutan, Sri Lanka, and Malaysia, and transmits *Babesia* spp to cattle, sheep, and dogs; *H spinigera* is the chief vector of Kyasanur Forest disease virus in people in Karnataka state, India; and *H anomala* ranges from the Nepal lowlands to Sri Lanka and the mountains of northwestern Thailand.

In temperate Asia, 18 other haemaphysalines parasitize livestock: 9 high in the Himalayas and outlying mountains, and 9 in northeastern Russia, Korea, and Japan. Yak and yak-cattle hybrids are among the livestock hosts of Himalayan haemaphysalines. Several Himalayan species appear to prefer sheep and goats.

H leachi, the yellow or African dog tick, is found in tropical and southern Africa. It can transmit canine and feline babesiosis, Mediterranean spotted fever, coxiellosis/Q fever, and Boutonneuse fever. Other haemaphysalines that infest livestock in highland forests or lowland, humid, secondary or riparian forests in sub-Saharan Africa are *H parmata* (Ethiopia and Kenya, Central and West Africa, to Angola), *H aciculifer* (Ethiopia to Cameroon and Zimbabwe, introduced into South Africa), *H rugosa* (southern Sudan and Uganda to Ghana and Senegal), and *H silacea* (Zululand and eastern South Africa).

HYALOMMA SPP

Hyalomma ticks are often the most abundant tick parasites of livestock, including camels, in warm, arid, and semiarid, generally harsh lowland and middle altitude biotopes, and those with long dry seasons, from central and southwest Asia to southern Europe and southern Africa. Of the ~30 known *Hyalomma* spp, at least half are important vectors of infectious agents to livestock and people. The three-host life cycle predominates in this genus, but some species have either a one- or two-host cycle. Some three-host species can develop in one- or two-host cycles, a facultative ability unique to this ixodid genus. *Hyalomma* spp are mostly moderately large to large ticks with long mouthparts.

In the subgenus *Hyalommast*, immatures of the single species, *H aegyptium*, parasitize tortoises and small wildlife and livestock from Pakistan to both sides of the Mediterranean basin. Adults are specific for tortoises.

The subgenus *Hyalomm* is found on the Indian subcontinent and in Somalia. Each of the six species has a three-host cycle. Immatures parasitize small mammals, especially rodents. Adult host preferences among livestock reflect the wild gazelle, bovine, caprine, or ovine group with which each species evolved. Two species infest chiefly cattle and the domestic buffalo: *H brevipunctata* (India and Pakistan) and *H kumari* (India, Pakistan, Afghanistan, northwestern Iran, and Tadzhikistan). Three usually parasitize sheep and goats: *H hussaini* (India, Pakistan, Burma), *H rhinopicephaloides* (Dead Sea and Red Sea areas), and *H arabica* (Yemen and Saudi Arabia). *H punt* (Somalia and Ethiopia) feeds on antelope, camels, cattle, sheep, and goats.

The subgenus *Hyalomma* contains ticks of veterinary and public health importance that affect cattle, sheep, goats, horses, camels, dromedaries, dogs, cats, and people. Chief among these is the two-host *H anatolicum anatolicum*, which ranks high among the world's most damaging ticks and has been widely distributed by camels, cattle, and horses in steppe and semidesert environments from central Asia to Bangladesh, the Middle and Near East, Arabia, southeastern Europe, and Africa north of the equator. Immatures and adults generally infest the same kinds of hosts. Nymphs and unfed adults spend the dry and winter season in crevices in stone walls, stables, and weedy or fallow fields. When

immatures infest smaller mammals, birds, or reptiles, the life cycle type is three-host. In addition to significantly weakening affected animals, causing weight loss, reduced fertility, and decreased milk production, *H. anatolicum* transmits *Theileria annulata*, *Babesia equi*, *B. caballi*, *Anaplasma marginale*, *Trypanosoma theileri*, and at least five arboviruses; it is a significant vector of Crimean-Congo hemorrhagic fever virus to people.

Immatures of the subspecies *H. anatolicum excavatum* (a three-host parasite) infest chiefly burrowing rodents in somewhat different biotopes in the same environments as *H. anatolicum anatolicum*. Adults of both species may infest the same animal. Distribution of *H. anatolicum excavatum* is somewhat more limited than that of *H. anatolicum anatolicum*, but its winter season population densities are often greater. A closely related species, *H. lusitanicum*, replaces *H. anatolicum anatolicum* from central Italy to Portugal, Morocco, and the Canary Islands; it is associated with equine and bovine babesiosis. In addition to livestock, deer and rabbits serve as hosts.

The *H. marginatum* complex consists of four species, each apparently invariably two-host. Adults parasitize livestock and wild herbivores. Immatures primarily parasitize birds. Rodents are rarely, if ever, parasitized. Hares and hedgehogs are secondary hosts. This group includes *H. marginatum marginatum* (Caspian area of Iran and former USSR to Portugal and northwestern Africa), *H. marginatum rufipes* (south of the Sahara to South Africa, also Nile Valley and southern Arabia), *H. marginatum turanicum* (Pakistan, Iran, southern former USSR, Arabia, parts of northeastern Africa—introduced with sheep from Iran to Karoo), and *H. marginatum isaaci* (Sri Lanka to southern Nepal, Pakistan, northern Afghanistan). Ticks belonging to the *H. marginatum* complex are major vectors of the Crimean-Congo hemorrhagic fever virus. They also transmit *Rickettsia aeschlimannii* and several *Babesia*, *Anaplasma*, *Theileria*, and *Trypanosoma* spp that infect wildlife, livestock, and people. *H. truncatum* can cause paralysis in livestock, pets, and people.

The *H. asiaticum* complex includes three species with three-host life cycles and inhabits deserts, semideserts, and steppes from southwestern China, Mongolia, and the southern former USSR into the Middle East as far as Iraq. Rodents are the chief hosts of

immatures; hares also may be infested. Adults parasitize livestock, particularly camels. The subspecies from east to west, *H. asiaticum kozlovi*, *H. asiaticum asiaticum*, and *H. asiaticum caucasicum*, are of veterinary and medical importance.

Three additional three-host *Hyalomma* spp that parasitize camels and other livestock are *H. dromedarii* (India to Africa north of the equator), *H. schulzei* (eastern Iran to Arabia and northern Egypt), and *H. franchinii* (Syria to Tunisia). Immatures parasitize rodents and other small mammals, birds, and reptiles; those of *H. dromedarii* also infest livestock. *H. dromedarii* is of veterinary and medical importance; the other two species have been little investigated.

H. detritum, an important vector of *Theileria annulata*, is a three-host species; both adults and immatures parasitize livestock. Its biotopes are humid areas in steppes, deserts, and semideserts from southern China, Mongolia, and Nepal lowlands to southern Europe and northern Africa. *H. impellatum* ranges from Iran and Arabia to northern Tanzania and Chad. Adults parasitize livestock; immatures feed on rodents and other small mammals, birds, and reptiles.

H. scupense, a one-host parasite of cattle and horses in southwestern former USSR and southeastern Europe, is unusual (like Canadian strains of *Dermacentor albipictus*) in that it overwinters on the host, which often suffers greatly from the long feeding period of numerous larvae (late fall), nymphs (winter), and adults (spring). *H. scupense* is a vector of *T. annulata* and *B. equi*.

In addition to the several species already mentioned, the African savannas harbor five other *Hyalomma* spp of livestock and wildlife: *H. (Euhyalomma) glabrum truncatum* (southeastern Egypt to southern Africa), *H. albiparvum* (southern Kenya, northern Tanzania), *H. erythræum* (eastern Somalia and Ethiopia, Yemen), *H. impressum* (western Sudan, West Africa), and *H. nitidum* (Central African Republic, West Africa). The preferred hosts of its adults are large herbivores such as zebras, gemsbok, and eland. Immatures of these three-host species generally infest small mammals, less often ground-frequenting birds and reptiles. *H. truncatum glabrum*, which causes bovine sweating sickness and lameness and also human and ovine tick paralysis, is a vector of Crimean-Congo hemorrhagic fever virus, *Coxiella burnetii* (Q fever), and *Rickettsia conorii* (African tick typhus, Boutonneuse fever).

IXODES SPP

Ixodes spp, the largest genus of the family Ixodidae, contains 249 species and is highly specialized both structurally and biologically. So far as is known, all *Ixodes* spp have a three-host life cycle. Almost all inhabit temperate or tropical forest zones or wooded or shrubby grasslands; fewer are adapted to humid areas in semideserts or to arctic or sub-Antarctic nesting colonies of marine birds. Hosts are a wide variety of birds and mammals and a few reptiles. Most species parasitize burrowing hosts or those that return regularly to caves, dens, or terrestrial or arboreal nesting colonies. The few *Ixodes* spp that parasitize wandering artiodactyls or perissodactyls are exceptionally adaptable; they also parasitize livestock and are important pests or vectors of agents that infect livestock and people.

The *I ricinus* group of Eurasia, northwestern Africa, and North and South America is especially important. *I ricinus*, the so-called sheep tick and prototype of this group, inhabits relatively humid, cool, shrubby and wooded pastures, gardens, windbreaks, floodplains, and forest through much of Europe to the Caspian Sea and northern Iran, and also northwestern Africa. Its life cycle is 2–4 yr, depending on environmental temperature. (In drier, warmer, eastern Mediterranean biotopes, *I ricinus* is replaced by *I gibbosus*, which completes its life cycle in 1 yr.) *I ricinus* larvae feed on small reptiles, birds, and mammals. Nymphs feed on small and medium-sized vertebrates, and adults feed chiefly on herbivores and livestock. All stages, especially nymphs and adults, parasitize people. Male *I ricinus* take little or no food and can mate either on or off the host. Unfed adults often mate while on vegetation. Adult activity peaks in spring; in some populations, there is a lower peak of adult activity in the fall. Chief among the numerous arboviral diseases transmitted by *I ricinus* are louping ill, tickborne encephalitis, and Crimean-Congo hemorrhagic fever. Other agents transmitted to livestock are *Coxiella burnetii*, *Anaplasma marginale*, *Babesia divergens*, and *A phagocytophilum*, various strains of which cause bovine, ovine, and human granulocytic anaplasmoses.

I persulcatus, the taiga tick, is closely related to *I ricinus* and has similar host preferences. It ranges from the central and eastern mountains of Europe through the lowland forests from the Baltic Sea and Karelia eastward through the Siberian taiga to the Seas of Japan and Okhotsk and the

northern islands of Japan. The life cycle can be completed in 3–4 yr but can last up to 7 yr in regions with a short summer season. It is one of the main vectors of Russian spring-summer encephalitis virus and *Borrelia burgdorferi*. In addition, it transmits *Babesia* spp, *Ehrlichia muris*, and the agents of human and ovine anaplasmoses and tularemia.

Other Asian representatives of the *I ricinus* group are *I sinensis* of China; *I kashmiricus* of mountainous northern India, Pakistan, and Kyrgyzstan; *I pavlovskyi* of the southern Siberian mountains of Russia; and *I kazakstani* of mountain taiga and deciduous forest in Kazakhstan, Kyrgyzstan, and Turkmenistan.

In the Americas, representatives of the *I ricinus* group include *I scapularis*, *I pacificus*, *I affinis*, *I jellisoni*, *I minor*, and *I muris*. *I scapularis* is distributed throughout the eastern and northcentral USA and southern Canada. It is a vector of *Borrelia burgdorferi*, the agent of Lyme disease, and *A phagocytophilum*, which causes granulocytic anaplasmosis in people, horses, and dogs. It also transmits *Babesia microti*, the agent of human babesiosis in coastal areas from Rhode Island to Virginia, and an *E muris*-like agent causing granulocytic ehrlichiosis in people and rodents in the midwestern USA. The chief hosts of adult *I scapularis* are deer; livestock seldom graze in the wooded zones inhabited by this tick. Adults of *I pacificus* parasitize livestock from Baja California to British Columbia and in inland pockets of Idaho, Nevada, and Oregon. *I pacificus* and *I neotomae* transmit the agents of Lyme disease, tularemia, and a rickettsia of the Rocky Mountain spotted fever group; *I pacificus* also transmits *A phagocytophilum*. The tick bites cause slowly healing ulcers. A related species, *I affinis*, ranges from South Carolina and Florida to Argentina. It is recorded chiefly from wildlife and has not been shown to be a vector.

In Africa, only four *Ixodes* spp have adapted to livestock. Chief among these is the South African paralysis tick, *I rubicundus*, of humid hill and mountain karoo vegetation in South Africa. Its salivary toxins cause a flaccid tetraplegia in livestock, people, dogs, and jackals. Immatures parasitize the rock hare, other hares, and elephant shrews. Other parasites of livestock in African highlands are *I drakenbergensis* (Natal), *I lewisi* (Kenya), and *I cavipalpus* (southern Sudan to Zimbabwe and Angola).

I holocyclus, the Australian paralysis tick, is considered the most medically important of the Australian tick fauna. Although most cases of tick bite are uneventful, some can result in life-threatening illnesses, including paralysis, tick typhus, and severe allergic reactions. The species is found throughout the year in a variety of habitats, particularly wet sclerophyll forests and temperate rainforest areas, across the humid coastal regions of eastern Australia. Adults are more abundant in the spring and early summer, larvae in mid to late summer, and nymphs during winter. Natural hosts include bandicoots, kangaroos, possums, birds, and sometimes even reptiles, but it regularly attaches to domestic animals, including dogs, cats, cattle, and horses, and occasionally people. The tick injects a neurotoxin that causes progressive motor paralysis, respiratory depression, and death in animals that have no immunity to the toxin. Most cases of tick paralysis seen by veterinarians are in dogs and cats, but other species can be affected. The condition has been recorded in sheep, cattle, goats, llamas, and Muscovy ducks. Fatal cases have occurred in people. In the larger species, the younger and smaller animals are likely to be affected.

I rubicundus, the karoo paralysis tick, may cause paralysis in sheep and goats in southern Africa. The immature stages of *I rubicundus* can be found on scrub hares and elephant shrews. The life cycle of the tick is ~2 yr. The ticks can often be found along the lower line of the neck, chest, and belly. The active period for adult ticks begins usually late in summer and reaches peak levels in autumn and early winter (April/May) and declines thereafter. The paralysis commonly occurs from February and reaches a peak in April and May.

MARGAROPUS SPP

Ticks of the genus *Margaropus* resemble *Rhipicephalus* (*Boophilus*) ticks but do not have festoons or ornamentations. They are characterized by greatly enlarged posterior legs and a prolonged median plate. The three highly specialized beady-legged, one-host *Margaropus* spp are restricted to limited areas of Africa. *M reidi* and *M wileyi* are recorded from giraffes in the Sudan and in Kenya and Tanzania, respectively. *M wileyi* is also known to parasitize zebras and gnu. *M winthemi*, a winter-feeding parasite of zebras, horses, and less often other livestock and antelope, is confined to mountains of South Africa and may contribute to loss of condition during winter.

NOSOMMA SP

Adults of the single species in this genus, *N monstrosus*, particularly parasitize wild and domestic buffalo, and also people, livestock, and wildlife, through much of India, Nepalese lowlands, Bangladesh, Thailand, and Laos. Inmatures parasitize chiefly murid rodents.

RHIPICENTOR SPP

The genus *Rhipicentor* is composed of two species, namely *R bicornis* and *R nuttalli*, and both are found only in Africa south of the Sahara. *R bicornis* feeds on goats, cattle, horses, dogs, and carnivores in southern and central Africa. *R nuttalli* has a widespread distribution in South Africa. Immature stages feed on elephant shrews. The preferred hosts of the adults are domestic dogs, leopards, and South African hedgehogs. The life cycle of these ticks probably takes a year to complete in the field.

RHIPICEPHALUS SPP

Approximately 60 of the 81 rhipicephalid species are found in sub-Saharan Africa. The other rhipicephalid species have their origins in Eurasia and northern Africa, with *R sanguineus* and *R (Boophilus) microplus* being spread by human activities into Asia, Australia, and the Americas. Adults of most species parasitize wild and domestic artiodactyls, perissodactyls, or carnivores. Immatures feed mostly on smaller mammals; however, of those that parasitize rodents or hyraxes, and of those that parasitize artiodactyls, a few feed on the same host as the adults. The rhipicephalid life cycle is typically three-host, but in the Mediterranean climatic zone (long, warm summer with low rainfall) *R bursa* has a two-host cycle. In sub-Saharan Africa with long dry seasons, *R evertsi* and *R glabroscutatum* also have two-host cycles. In contrast, each of the five species in subgenus *Boophilus* has a one-host life cycle that may be completed in 3–4 wk (see below).

A number of *Rhipicephalus* spp have long been difficult to identify or have been incorrectly identified. Current concepts of tick phylogeny, taxonomy, and nomenclature are based on molecular analyses.

Subgenus *Boophilus* spp

Each of the five *Rhipicephalus* (*Boophilus*) spp has a one-host life cycle that may be completed in 3–4 wk and results in a

heavy tick burden. Under these conditions, acaricide resistance becomes a major problem in control efforts. Zebu cattle, which have served for centuries as hosts of *R (B) microplus* in the Indian region, have developed resistance to feeding by large numbers of ticks and are used (purebred or crossbred) in integrated control programs. *R (B) microplus*, considered the world's most important tick parasite of livestock, has been introduced from the bovid- and cervid-inhabited forests of the Indian region to many areas of tropical and subtropical Asia, northeastern Australia, Madagascar, the coastal lowlands of southeastern Africa to the equator, and much of South and Central America, Mexico, and the Caribbean. *R (B) microplus* and *R (B) annulatus* were eradicated from the USA after a long, costly control program. Constant surveillance is maintained to prevent their reintroduction. *R (B) annulatus* of southern former USSR, the Middle East, and the Mediterranean area, was introduced with livestock of the early Spanish colonialists into northeastern Mexico but has not spread into Central America. In Africa, south of the Sahara and north of the equator, cattle movements probably account for the many *R (B) annulatus* populations.

R (B) decoloratus, which ranges from southern Africa to the Sahara, is being replaced in the southeastern part of this area by *R (B) microplus*. In more humid West African zones, *R (B) annulatus* mixes with or is totally replaced by *R (B) geigyi*. Scattered *R (B) geigyi* populations are found as far east as southern and central Sudan. The only boophilid restricted to sheep and goats (and occasionally horses) is *R (B) kohlisi* of Syria, Iraq, Israel, Jordan, western Saudi Arabia, and Yemen. *R (B) microplus* is an experimental vector of *Babesia equi* and has been collected from the nasal passages of equids in Panama. This tick and *R (B) annulatus* are major vectors of *Babesia bigemina*, *B bovis*, and *Anaplasma marginale*. *R (B) decoloratus* is an efficient vector of *B bigemina* and *A marginale* but does not transmit *B bovis* or *B equi*.

Subgenus *Rhipicephalus* spp

Tropical Asia is the home of five *Rhipicephalus* (*Rhipicephalus*) spp; adults of two species parasitize domestic animals. *R haemaphysaloides* infests all types of livestock, and wild antelope, deer, carnivores, and hares in continental southeast Asia (and Taiwan and the

Philippines) westward to India, Sri Lanka, Nepal, Pakistan, and western Afghanistan. *R pilans* infests livestock and wildlife in Indonesia and Borneo. Immatures of both species feed chiefly on rodents, also on shrews, hares, and smaller carnivores.

From central Europe to Kazakhstan, *R rossicus*, *R schulzei*, and *R pumilio* are of medical and veterinary importance. In southwestern Europe, *R pusillus* infests dogs as well as European rabbits, foxes, and wild pigs. *R turanicus*, as presently recognized, ranges from China, southern former USSR, India into southern Europe, and Africa as far south as South Africa. A member of the taxonomically difficult *R sanguineus* group, "*R turanicus*" and its various populations, which may represent separate species, requires further studies of its abilities as a vector.

An easily recognized two-host species, *R bursa*, ranges from the western Mediterranean area of Europe to Iran and Kazakhstan. Adults and inmmatures parasitize livestock, hares, deer, wild sheep and goats, people, and infrequently dogs. It causes ovine paralysis and transmits Crimean-Congo hemorrhagic fever virus and other viruses to people, and numerous microbial diseases of livestock such as various species of *Babesia*, *Anaplasma*, and *Theileria* (notably *Theileria parva*, the agent of East Coast Fever, often fatal for cattle), *Ehrlichia* (*Cowdria*) *ruminantium* (the agent of heartwater), and *Trypanosoma vivax* (an agent of sleeping sickness).

The best known African rhipicephalid, *R sanguineus*, the kennel tick or brown dog tick, has spread worldwide with domestic dogs. It is now established in buildings as far north as Canada and Scandinavia and as far south as Australia. In Africa, the Near East, and parts of southern Europe, adults parasitize wild and domestic carnivores, sheep, goats, camels, other livestock, and various wild mammals, especially hares and hedgehogs. Immatures in nature in this area feed on small mammals. However, in urban situations everywhere, dogs are virtually the only hosts of inmmatures and adults. People are attacked infrequently, more often in situations when children play and sleep in close contact with heavily infested dogs. Strains of adult *R sanguineus* that feed on cattle are recorded in parts of Mexico and in Tahiti. This tick is active throughout the year in the tropics and subtropics but only from spring to fall in temperate zones. Newly active adults and nymphs are frequently seen climbing walls from floor-level cracks. *R sanguineus* is a vector of *Babesia canis*, *Ehrlichia canis*, *Rickettsia conorii*,

R. massiliae, *R. rickettsii*, and *R. rhipicephali*, Crimean-Congo hemorrhagic fever virus, and Thogoto virus. In southcentral USA, *R. sanguineus* is associated with scattered foci of *Leishmania mexicana*. Certain American populations have become resistant to insecticides. The hymenopteran (chalcid) parasite of ticks, *Hunterellus hookeri*, frequently infests nymphal *R. sanguineus* in East Africa.

R. appendiculatus, the brown ear tick, is a major pest in cool, shaded, woody and shrubby savannas from southern Sudan and eastern Zaire to Kenya and South Africa. Adults and immatures feed in the ears of cattle, other livestock, and antelope, but also on other areas when the infestation is massive. Immatures may infest small antelope and carnivores, and occasionally rodents. Engorged females lay as many as 5,000 eggs. The life cycle lasts 3–9 mo. Seasonal activity is closely associated with temperature and rain periods. As many as three generations a year can follow in regions with two rainy seasons. *R. appendiculatus* is the major vector of the *Theileria parva* group of diseases (East Coast fever, Corridor disease, Zimbabwe malignant theileriosis) and Nairobi sheep disease virus, and is also a vector of *T. taurotragi*, *Ehrlichia bovis*, *R. conorii*, and Thogoto virus. Heavy infestations on susceptible *Bos taurus* cattle cause a sometimes fatal toxemia, loss of resistance to various infections, and severe damage to the host's ears.

The closely related *R. zambeziensis*, with similar host preferences, is found in drier lowland savannas in Tanzania, Zimbabwe, Zambia, Botswana, and Transvaal; it also is a vector of East Coast fever. Other species closely related to *R. appendiculatus* include *R. nitens* in the Cape Province of South Africa and *R. duttoni* in Angola and Zaire.

The ivory-ornamented *R. pulchellus*, a parasite of zebras, also infests livestock and game animals in savanna habitats east of the Rift Valley from southern Ethiopia to Somalia and northeastern Tanzania. Adults and immatures generally infest the same host; however, immatures also feed on hares, and larvae ("seed ticks") are notoriously annoying pests of people. *R. pulchellus* feeds in the ears and on the lower abdomen, chiefly during wet seasons. This tick is a vector of *Babesia equi* (among zebra), *Theileria* spp., *Trypanosoma theileri*, *Rickettsia conorii*, several Bunyaviridae (Crimean-Congo hemorrhagic fever virus; Nairobi sheep disease; and Kajiado, Kismayo, and Dugbe viruses), and Barur virus.

The two-host African rhipicephalids are *R. evertsi* subspecies and *R. glabroscutatum*. *R. evertsi evertsi*, a large, beady-eyed, red-legged tick, a parasite of the East African zebra, parasitizes all types of herbivorous wildlife and livestock (but seldom pigs). Immatures and adults infest the same hosts; immatures are also recorded from hares. It ranges from South Africa through eastern Africa east of the Nile to southern Sudan and is established in the mountains of Yemen. Scattered foci, introduced by domestic animals, are found west of the Nile. Immatures feed in the ear canal; adults feed mostly around the anus and under the tail but also in the axillae and groin and on the sternum. Large numbers on a single host are common on Equidae and are difficult to control because of their concentrations in difficult-to-reach feeding sites. Adult females lay as many as 7,000 eggs. The life cycle takes 36 mo to complete, depending on weather conditions. *R. evertsi evertsi* transmits *Babesia equi*, *Theileria parva* (secondary vector), *Borrelia theileri*, *Rickettsia conorii*, and Kerai, Wad Medani, and Thogoto viruses. The banded-legged (*Hyalomma*-like) western subspecies, *R. evertsi mimeticus*, found from western Botswana to Namibia, Angola, and Zaire, is like the nominate subspecies in host preferences, feeding sites, and life cycle.

The tiny *R. glabroscutatum* has become a common pest of sheep, goats, and other livestock in the arid, small-shrub savanna of southeastern Cape Province, South Africa. Kudu and other small antelope are also infested. The few records of immatures are from rodents.

The *R. pravorum* group, currently under taxonomic study, consists of four or more species of which the adults feed on livestock and herbivorous wildlife (including hares); immatures feed on elephant shrews (insectivores), hares, and other small mammals. *R. pravorum*, a brown, convex-eyed tick, is found in shrubby and wooded savannas in east Africa. It is infected by *Kadam virus*. The closely related *R. occulatus*, a parasite of hares, and another related, unnamed parasite of livestock are found in southern Africa.

The difficult-to-classify *R. punctatus* group of parasites of livestock and wild artiodactyls consists of *R. punctatus* (Angola, Mozambique, Tanzania), *R. kochi (neavi)* (Botswana to Kenya and Zaire), and an as yet unnamed species from Zimbabwe and South Africa.

The *R. capensis* group is also under study. Originally parasites of the Cape buffalo, these species now parasitize livestock and wildlife in Namibia and South Africa (*R. capensis* and *R. gertrudae*), East Africa (*R. compositus* and *R. longus*), and West Africa to southwestern Sudan (*R. pseudolongus*).

Above 5,900 ft (1,800 m) altitude in East African forest and shrub zones, *R. hirti* and *R. jeanelli* infest livestock and Cape buffalo and other large game animals. *R. hirti* also inhabits mountains in Zaire. Both species feed chiefly in the hosts' ears; *R. jeanelli* also feeds in the tailbrush.

R. simus, the prototype of the *R. simus* group and long considered to be a well-established species, is divided into several species. *R. simus sensu stricto* is found through central and southern Africa, roughly south of latitude 8°S, where it is a competent experimental vector of *Anaplasma marginale* and *A. centrale*. In eastern and northern Africa, *R. simus* is replaced by a less punctate species, *R. praetextatus*, which ranges from central Tanzania to Egypt. Adults of both species parasitize livestock, dogs, wild carnivores, large and medium-sized game animals, and people. Occurrence and densities on livestock are inexplicably erratic. Immature stages feed on the common burrowing rodents in savannas. Both species cause tick paralysis of people and transmit *Rickettsia conorii* and *Coxiella burnetii*. In Kenya, *R. praetextatus* is a vector of Thogoto virus and may be a secondary vector of Nairobi sheep disease virus. West of the Nile, these species are replaced by *R. senegalensis* and *R. muhsamae*.

Much literature regarding *R. tricuspis* (Tanzania to South Africa) and *R. lunulatus* (West Africa to Ethiopia and Tanzania) has been incorrect. The chief feeding site of both on livestock and wildlife is the tailbrush, but other parts of the host may also be feeding sites.

R. sanguineus and *R. turanicus* of the *R. sanguineus* group are described above. Related species are *R. camicasi* and *R. bergoni* of northeastern Africa, *R. guilhoi* and *R. moucheti* of West Africa, and two widely distributed "forms" of *R. sulcatus*, which are under study.

Two quite distinctive species often confused with *R. appendiculatus* are *R. supertritus* (Natal to southern Sudan) and *R. muhlensi* (Kenya and southern Sudan to Central Africa). Adults of both species parasitize cattle, Cape buffalo, antelope,

and big game animals; *R. supertritus* also is found on carnivores.

IMPORTANT ARGASID TICKS

The important argasid ticks include *Argas* spp, *Carios* spp, *Ornithodoros* spp, and *Otobius* spp.

ARGAS SPP

Most of the 57 known *Argas* spp are specific for birds or bats; a few parasitize wild terrestrial mammals or Galapagos giant tortoises. *A. persicus* (the fowl or poultry tick) is an important poultry pest worldwide in warm climates. *A. miniatus* (the South American chicken tick) and *A. radiatus* (the North American bird tick) can present a problem for traditional or outdoor poultry operations from Caribbean to Central America and from Caribbean to North America, respectively. The species of importance in transmitting *Aegyptianella pullorum* and *Borrelia anserina* to poultry are *A. persicus* (many tropical and subtropical areas of the world), *A. arboreus* (much of Africa, including Egypt), *A. afri-columbae* (tropical Africa), *A. walkerae* (southern Africa), and *A. miniatus* (South and Central America). Other species that infest poultry appear to transmit both *A. pullorum* and *B. anserina*. (See also p 2876.) Tick paralysis is caused by feeding *A. persicus*, *A. arboreus*, *A. walkerae*, *A. miniatus*, *A. radiatus*, and *A. sanchezi* (USA). These and other *Argas* spp can cause great irritation when feeding on people.

CARIOS SPP

Most of the 88 *Carios* spp are species-specific parasites of bats and rodents. Several species infest birds nesting in rocks and caves. These ticks normally live alongside their hosts in caves, hollow trees, and rock crevices, and therefore rarely come in contact with domestic animals. However, in locations where bats occupy roof cavities, their parasites may present a problem for people and their pets. Ticks *C. kelleyi* in North America and *C. vespertilionis* in Europe, which in nature feed almost exclusively on rock- and tree-roosting bats, have been found in massive numbers in homes with associated bat colonies and have been reported to attach to people. Nest parasites of colonial birds such as *C. amblus*, *C. capensis*, and *C. denmarki* may pose a distinct threat to breeding colonies and are known to cause the death of chicks.

ORNITHODOROS SPP

Most of the 37 *Ornithodoros* spp inhabit protected niches in burrows, caves, dens, cliffsides, and bird colonies. Among the few that parasitize livestock, *O savignyi* and *O coriaceus* are exceptional, because they have eyes and because they rest just below or above ground level under the shade of trees and rocks where livestock and game animals rest and sleep. *O savignyi*, the sand tampan, lives in semiarid areas from Namibia to India and Sri Lanka and is often tremendously abundant. It can cause fatal tick paralysis in calves. People and tethered livestock suffer severe irritation, allergy, and toxicosis from sand tampan bites, and paralysis and death of animals are recorded. *O coriaceus*, the "pajaroello" of hillside scrub oak habitats from northern California and Nevada to Chiapas, Mexico, occupies deer beds under trees and near large rocks. It is well known for irritating deer and cattle, and in people, its bite causes a severe skin reaction. Epizootic bovine abortion, caused by an unnamed bacterium (in the order Myxococcales), is transmitted by *O coriaceus*. *O gurneyi* shelters in tree-shaded soil in arid zones of Australia where kangaroos and people rest; livestock are rare or absent in these habitats.

Among the numerous *Ornithodoros* spp that inhabit burrows, several species are either naturally infected with African swine fever (ASF) virus in Africa or have the laboratory-confirmed ability to harbor and transmit the agent in Europe and the Americas. The natural reservoir and vector of ASF virus is *O porcinus*, which is abundant in burrows of tropical African pigs and also of antbears and porcupines. It has secondarily adapted to human dwellings and domestic animal shelters, where it lives in the cracks of walls and floors. Domestic pig populations in the vicinity of infected wild pigs can be decimated by ASF. Wild and domestic pigs are not involved in the epidemiology of *Borrelia duttoni*, the agent of human African relapsing fever, which is transmitted by *O moubata*. ASF virus has been transported in infected meat to Spain where *O maroccanus*, an inhabitant of rodent burrows and pig sties, is an efficient vector. *O maroccanus* is also a reservoir and vector of *Borrelia hispanica*, the agent of Spanish-northwest African human relapsing fever. ASF has likewise been introduced in Brazil, Haiti, the Dominican Republic, and Cuba. The American *O turicata*, *O dugesi*, and *O coriaceus* are potential vectors of ASF virus.

O tholozani (*O papillipes*, also *O crossi*) infests burrows, caves, stables, stone and clay fences, and human habitations in semidesert, steppe, and long dry-season environments from China, southern former USSR, northwestern India, and Afghanistan to Greece, northeastern Libya, and eastern Mediterranean islands. Numerous rodents, hedgehogs, porcupines, and domestic animals support *O tholozani* populations. People develop severe, sometimes fatal, Persian relapsing fever when bitten by *O tholozani* infected with *Borrelia persica*.

O lahorensis, originally a parasite of wild sheep resting in the lee of cliffsides, is an important pest of stabled livestock in lowlands and mountains of Tibet, Kashmir, and southern former USSR to Saudi Arabia and Turkey, Greece, Bulgaria, and Yugoslavia. The two-host life cycle and long wintertime attachment of *O lahorensis* is biologically remarkable. It is deleterious to livestock held for much of the winter in heavily infested stables; it may cause paralysis, anemia, and toxicosis, and it transmits the agents of piroplasmosis, brucellosis, coxiellosis/☉ fever, tularemia, and possibly *Borrelia persica*, the agent of Persian relapsing fever.

O turicata parasitizes rodents that live in burrows, crevices, or caves; owls; snakes; tortoises; and also domestic pigs and other livestock in southern USA and Mexico. Contrary to most *Ornithodoros* feeding patterns, immature *O turicata* engorge in <30 min, but adults may attach for as long as 2 days. *O turicata* has been associated with diseases of pigs, and serious toxic reactions and secondary infections can result when people are bitten.

O furcosus parasitizes people and livestock in houses and stables in northwestern South America. Other South American pests of livestock and people, probably originally parasites of the peccary, are *O braziliensis* and *O rostratus*.

OTOBIOUS SPP

Otobius megnini, which is exceedingly specialized biologically and structurally, infests the ear canals of pronghorn antelope, mountain sheep, and Virginia and mule deer in low rainfall biotopes of western USA and in Mexico and western Canada. Cattle, horses, goats, sheep, dogs, and people are similarly infested. This well-concealed parasite has been transported with livestock to western South America, Galapagos, Cuba, Hawaii, India, Madagascar, and southeastern Africa. Notably, adults have nonfunctional

mouthparts and remain nonfeeding on the ground but may survive for almost 2 yr. Females can deposit as many as 1,500 eggs in a 2-wk period. Larvae and two nymphal instars feed for 2–4 mo, mostly in winter and spring. There can be two or more generations per year. In contrast with most other ticks, the bites of *O. megnini* are painful for the hosts. People and other animals may suffer severe irritation from ear canal infestations, and heavily infested livestock lose condition during winter. Tick paralysis of hosts and secondary infections by larval screwworms are reported. *O. megnini* is infected by the agents of coxiellosis/Q fever, tularemia, Colorado tick fever, and Rocky Mountain spotted fever, although its ability to transmit these pathogens to the hosts is uncertain. The second *Otobius* sp, *O. lagophilus*, feeds on the heads of jackrabbits (hares) and rabbits in western USA.

TICK REMOVAL

Ticks found attached to people or domestic animals should be removed immediately. The longer a tick remains attached to the skin, the more pathogen- and/or toxin-containing saliva is being injected into the host. Therefore, prompt removal is imperative. Several tick removal devices are on the market, but ticks are most effectively removed by a plain set of fine-tipped tweezers.

The CDC recommends the following method of tick removal: 1) Use tweezers to grasp the tick as close to the skin surface as possible. 2) Pull upward with steady, even pressure. 3) Do not twist the tick, because this will cause the mouthparts to break off and remain in the skin. If this happens and the mouthparts cannot easily be removed with clean tweezers, leave it alone and let the skin heal. Chances of a local infection being caused by remaining tick mouthparts are insignificant compared with the risk of pathogen transmission by an attached tick. 4) Avoid crushing the tick. Do not squash the tick with your fingers; the contents of the tick can transmit disease through skin abrasions. 5) After removing the tick, thoroughly clean the bite area and your hands with rubbing alcohol, an iodine scrub, or soap and water.

Avoid folklore remedies such as "painting" the tick with nail polish or petroleum jelly or using a hot match to make the tick detach from the skin. The goal is to remove the tick as quickly as possible, not to wait for it to detach. Using irritants such as petroleum jelly, a hot match, or alcohol

will *not* cause the tick to "back out" and in fact, may cause more disease-carrying tick saliva to be deposited in the wound.

TICK CONTROL

The main reasons for tick control are to protect hosts from irritation and production losses, formation of lesions that can become secondarily infested, damage to hides and udders, toxicosis, paralysis, and of greatest importance, infection with a wide variety of disease agents. Control also prevents the spread of tick species and the diseases they transmit to unaffected areas, regions, or continents.

Cultural and Biologic Control: These measures can be directed against both the free-living and parasitic stages of ticks. The free-living stages of most tick species, both ixodid and argasid, have specific requirements in terms of microclimate and are restricted to particular microhabitats within the ecosystems inhabited by their hosts. Destruction of these microhabitats reduces the abundance of ticks. Alteration of the environment by removal of certain types of vegetation has been used in the control of *Amblyomma americanum* in recreational areas in southeastern USA and in the control of *Ixodes rubicundus* in South Africa. Control of argasid ticks such as *Argas persicus* and *A. walkerae* in poultry can be achieved by eliminating cracks in walls and perches, which provide shelter to the free-living stages.

The abundance of tick species can also be reduced by removal of alternative hosts or hosts of a particular stage of the life cycle. This approach has occasionally been advocated for control of three-host ixodid ticks such as *Rhipicephalus appendiculatus*, *Amblyomma hebraeum*, and *Ixodes rubicundus* in Africa, and *Hyalomma* spp in southeastern Europe and Asia.

Rotation of pastures or pasture spelling has been used in control of the one-host ixodid tick *Rhipicephalus (Boophilus) microplus* in Australia. The method could also be applied to other one-host ticks, in which the duration of the spelling period is determined by the relatively short life span of the free-living larvae. However, it has minimal application to multihost ixodid ticks or argasid ticks because of the long survival periods of the unfed nymphs and adults.

Predators, including birds, rodents, shrews, ants, and spiders, play a role in some areas in reducing the numbers of free-living ticks. In the New World, fire ants

(*Pheidole megacephala*) are noteworthy tick predators. Engorged ticks may also become parasitized by the larvae of some wasps (Hymenoptera), but these have not significantly reduced tick populations.

Zebu (*Bos indicus*) and Sanga (a *B. taurus*, *B. indicus* crossbreed) cattle, the indigenous breeds of Asia and Africa, usually become very resistant to ixodid ticks after initial exposure. In contrast, European (*B. taurus*) breeds usually remain fairly susceptible. The tick resistance of Zebu breeds and their crosses is being increasingly exploited as a means of control of the parasitic stages. The introduction of Zebu cattle to Australia has revolutionized the control of *R. microplus* on that continent. Use of resistant cattle as a means of tick control is also becoming important in Africa and the Americas. In Africa, infestations of ixodid ticks on livestock and wild ungulates may also be reduced by oxpeckers (*Buphagus* spp), which are birds that feed on attached ticks.

Chemical Control: See also **ECTOPARASITICIDES**, p 2748.

Control of ticks with acaricides may be directed against the free-living stages in the environment or against the parasitic stages on hosts. Control of ixodid ticks by acaricide treatment of vegetation has been done in specific sites (eg, along trails) in recreational areas in the USA and elsewhere, to reduce the risk of tick attachment to people. This method has not been recommended for wider use because of environmental pollution and the cost of treatment of large areas. Dog kennels, barns, and human dwellings may also require periodic treatment with acaricides to control the free-living stages of ixodid ticks such as the kennel tick, *Rhipicephalus sanguineus*.

The free-living stages of argasid ticks, which infest specific foci such as fowl runs, pigeon lofts, pig sties, and human dwellings, are more frequently and more effectively treated with acaricides.

Treatment of hosts with acaricides to kill attached larvae, nymphs, and adults of ixodid ticks and larvae of argasid ticks has been the most widely used control method. In the first half of the century, the main acaricide was arsenic trioxide. Subsequently, organochlorines, organophosphates, carbamates, amidines, pyrethroids, and avermectins have been used in different parts of the world. The introduction of new compounds, such as the phenylpyrazoles, has been necessary because of the development of resistance in tick populations.

Acaricides are most commonly applied to livestock by use of dips or sprays, with dips being considered the more effective. In recent years, several other means of acaricide application have been developed, including slow release of systemics from implants and boluses, slow release of conventional acaricides from impregnated ear tags, pour-ons (which are applied on the back and spread rapidly over the entire body surface), and spot-ons (which are similar but have less ability to spread). Acaricides are usually applied as dusts or washes on cats, and as dusts on dogs and fowl.

For many years, pyrethroids and organophosphates formulated as dusts, dips, or collars were used on dogs and cats to control ticks. With the advent of the phenylpyrazoles, long-lasting spray and convenient spot-on formulations were introduced. Pyrethroids are available as highly concentrated spot-on products that are labeled only for dogs because of their toxicity in cats. Use of these concentrated pyrethroids is not advised on dogs if a cat is even in the same household.

Vaccines: An advance of potentially great importance has been the production, using biotechnology, of a promising vaccine against *R. microplus*. The immunizing agent is a concealed tick antigen, not normally encountered by the host. The immune mechanism it stimulates is different from that stimulated by exposure to ticks (ie, tick feeding). The antigen was derived from a crude extract of partially engorged adult female ticks. It stimulates the production of an antibody that damages tick gut cells and kills the ticks or drastically reduces their reproductive potential.

Prospects of developing similar vaccines against other ixodid tick vectors of cattle diseases of major veterinary importance are not clear. *Rhipicephalus* ticks are good candidates for such vaccines in that they are one-host ticks and show a marked preference for bovine hosts, which act as the principal reservoir of perhaps the most important group of disease agents (*Babesia* spp) these ticks transmit. By contrast, most other tick vector species of agents that cause important cattle diseases (eg, anaplasmosis, heartwater, theileriosis) are three-host ticks, which infest not only cattle but also wild ungulate species, for which vaccination is not feasible. Moreover, many wild ungulate hosts of the vector ticks serve as reservoirs of these disease agents. For these reasons, vaccines against nonboophilid vector ticks may be unable either to

eradicate the ticks or to eliminate important sources of the disease agents they transmit.

Control Strategies: Initially, the main uses of acaricides were for tick eradication, prevention of spread of ticks and tickborne diseases (quarantine), and eradication and control of tickborne diseases. The eradication programs were successful in some ecologically marginal subtropical areas, such as southern USA and central Argentina where *Rhipicephalus* spp and babesiosis were eradicated, and southern Africa where East Coast fever (caused by *Theileria parva parva*) was eradicated. The programs were less successful in the ecologically more favorable tropical areas of northeastern Australia, Central America, the Caribbean Islands, and East Africa.

In the areas where eradication was not achieved, costs of maintaining intensive tick control programs often have become prohibitive. For this reason, integrated biologic and chemical control strategies are being adopted. The effectiveness of these

cost-containment strategies requires better knowledge of the dynamic associations among the disease agents, their vertebrate hosts, the tick vectors, and the environment. Strict quarantine measures to prevent reintroductions are enforced in countries from which ticks and tickborne diseases have been eradicated. Climate-matching models, geographic information systems, and expert systems (models based on expert knowledge and artificial intelligence) are being used to identify unaffected areas in which tick pests could become established if introduced.

Control of these diseases will require use of the principles of endemic stability and development of improved recombinant vaccines. A current, promising strategy is the identification of receptor sites on the midgut of vector ticks and the development of antibodies that bind with these sites, thereby blocking tick-ingested tickborne pathogens from infecting the tick. Cattle injected with receptor site antigens may produce antibodies that feeding ticks ingest.

TUMORS OF THE SKIN AND SOFT TISSUES

Cutaneous tumors are the most frequently diagnosed neoplastic disorders in domestic animals, in part because they can be identified easily and in part because the constant exposure of the skin to the external environment predisposes this organ to neoplastic transformation. Chemical carcinogens, ionizing radiation, and viruses all have been implicated, but hormonal and genetic factors may also play a role in development of cutaneous neoplasms.

The skin is a complex structure composed of various epithelial (epidermis, adnexa), mesenchymal (fibrous connective tissues, blood vessels, adipose tissue), and neural and neuroectodermal tissues (peripheral nerve, Merkel cells, melanocytes), all with the potential to develop distinctive tumors. Because cutaneous tumors are so diverse, their classification is difficult and often controversial. There is also controversy regarding the criteria used to define whether a lesion that arises in the skin or soft tissues is neoplastic and, if so, whether it is benign or malignant. To avoid confusion, the following terms are used in this discussion: A

hamartoma (nevus) is a localized developmental defect associated with enlargement of one or more elements of the skin. A sebaceous hamartoma, for example, refers to a localized region of the skin where sebaceous glands are extremely prominent and sometimes malformed. Although by strict definition hamartomas are present at birth, they may occasionally take a long time to reach a clinically apparent size and may not be diagnosed until an animal is mature. To confuse matters further, some lesions with clinical and histologic features of congenital hamartomas may develop in adult animals. Such "acquired" hamartomas are difficult to separate from benign epithelial and mesenchymal neoplasms. In human medical literature and some veterinary texts, the term "nevus" is used synonymously with hamartoma. A **benign neoplasm** is localized, noninfiltrative, and because it is surrounded by a capsule, easily excisable. A **neoplasm of intermediate malignancy** is locally infiltrative and difficult to excise but does not metastasize. A **malignant neoplasm** is infiltrative with metastatic potential.

Although cutaneous neoplasms characteristically are nodular or papular, they also can occur as localized or generalized alopecic plaques, erythematous and pigmented patches and plaques, wheals, or nonhealing ulcers. The variability in clinical presentation can make distinguishing a neoplasm from an inflammatory disease difficult; furthermore, distinguishing a benign tumor from a malignant tumor is even more subjective because sarcomas or carcinomas early in their development may palpate as discrete, encapsulated masses. To establish a definitive diagnosis, histopathology is generally required. Cytologic evaluation is very useful and should be used to exclude mast cell tumor before surgery so that wide adequate margins are planned as appropriate. For some neoplasms (eg, round cell tumors), cytology can rival or even surpass the value of histologic examination.

Therapy depends largely on the type of tumor, its location and size, and signalment of the animal. For benign neoplasms associated with neither ulceration nor clinical dysfunction, no therapy may be the most prudent option, especially in aged companion animals.

Fine-needle aspiration cytology should be performed initially on all tumors to determine the type of tumor and treatment planning. For more aggressive neoplastic diseases or for benign tumors that inhibit normal function or are cosmetically unpleasant, there are several therapeutic options. For most, surgical intervention with complete excision provides the best chance of a cure with the least cost and often with the fewest adverse events.

Histologic assessment of margin status is useful to predict local recurrence of cutaneous malignant tumors in dogs and cats treated by means of excision alone. However, method accuracy varies among tumor types and grades. Recurrence times suggest postsurgical follow-up should continue for ≥ 2 yr. Careful postsurgical management is recommended for animals with both infiltrated and close tumor margins.

Lumpectomy is adequate for benign lesions, but if a malignancy is suspected, the lesion should be removed with wide (3 cm) surgical margins. For tumors that cannot be completely excised, partial removal or debulking may prolong the life of the animal and increase the effectiveness of radiation or chemotherapy. Cryosurgery is also an option, although it is more effective for benign, superficial lesions than for malignant cutaneous neoplasms. Radiation therapy is of most value for infiltrative

neoplasms not surgically resectable, or when surgical intervention would cause unacceptable physical impairment. Chemotherapy can be used either systemically (and if appropriate, intralesionally) as a primary method for treatment of malignant neoplasms or as an adjunct to surgery or radiation therapy. In the skin, radiation is most commonly used to treat round cell tumors (eg, lymphosarcomas, mast cell tumors, transmissible venereal tumors, etc) or solid tumors that cannot be excised completely. Although generally palliative, long remissions may sometimes be obtained with radiation therapy. Other forms of therapy include hyperthermia, laser therapy, photodynamic therapy, antiangiogenic therapy, metronomic therapy, gene therapy, immunotherapy, and multimodal therapy using a combination or sequencing of various therapies.

EPIDERMAL AND HAIR FOLLICLE TUMORS

Ceruminous gland tumors are discussed in TUMORS OF THE EAR CANAL (see p 535).

Benign, Nonvirus-associated Papillomatous Lesions

For a discussion of papillomas (viral warts), the most common, viral-induced neoplasms of the skin, see p 952. Benign, proliferative lesions not associated with papilloma virus infection can have a gross morphology similar to that of papillomas.

Epidermal hamartomas (nevi) are rare proliferations identified only in dogs, most often in the young. The disease may be heritable in Cocker Spaniels. Grossly, epidermal nevi appear as pigmented, hyperkeratotic, vaguely papillated papules and plaques that are occasionally arranged in a linear pattern. Some forms are associated with pustules and acantholytic cells. They are benign, but their appearance is unpleasant, and the extensive hyperkeratosis is prone to secondary bacterial infection. Localized lesions can be excised; dogs with multiple lesions or lesions too large to be surgically removed may be responsive to isotretinoin or etretinate. Hyperkeratosis may be transiently controlled by use of topical keratolytic shampoos and emollients.

Congenital papillomas of foals are rare and probably a developmental defect rather than a result of papilloma virus infection. They are found anywhere on the body but most commonly on the head. Thoroughbreds

may be predisposed. Present at birth, the lesions are often several centimeters in diameter, hairless, pedunculated, and exophytic, with a papillated surface reminiscent of a cauliflower. They are benign, and excision is curative.

Canine warty dyskeratomas are rare, benign neoplasms of uncertain derivation but with histologic features of follicular or apocrine neoplasms (or both). They appear grossly as verrucous papules or nodules with a keratotic, umbilicated center. Excision is curative.

Basal Cell Tumors and Basal Cell Carcinomas

(Basal cell epitheliomas, Basaliomas, Trichoblastomas, Basosquamous cell carcinomas)

Basal cell tumors represent a heterogeneous group of cutaneous epithelial neoplasms recognized most commonly in cats, less commonly in dogs, occasionally in horses and sheep, and seldom in other domestic animals. These neoplasms are composed of a proliferation of small basophilic cells that exhibit morphology reminiscent of the progenitor cells of the epidermis and adnexa. As these tumors have been examined more closely, evidence of differentiation (follicular, sebaceous, etc) has been discovered, giving justification for reclassification. For example, in dogs, what in the past was called a basal cell tumor is best characterized as a **trichoblastoma**, a tumor of hair bulb (the site of the follicle that produces the hair shaft) origin.

Some reclassification schemes have suggested that the use of the term basal cell tumor be restricted to a benign neoplasm in cats (the derivation of which has yet to be defined). Because this revised terminology is being adopted slowly, traditional terminology will be used herein. That is, a benign proliferation of basal cells will be called a basal cell tumor; a malignant proliferation will be called a basal cell carcinoma. In domestic animals, most basal cell tumors are benign and originate in the mid to deep dermis, indicating probable adnexal derivation. These features distinguish basal cell tumors in domestic animals from those in people, the latter being locally invasive (ie, they are true carcinomas) and originating in the epidermis. In addition, solar injury is a common cause of neoplasms derived from basal cells in people, but its role in inducing basal cell tumors of other animals is unknown.

Canine basal cell tumors generally develop in middle-aged to older dogs of

predisposed breeds such as Wirehaired Pointing Griffons, Kerry Blue Terriers, and Wheaton Terriers. These tumors are found most commonly on the head (especially the ears), the neck, and forelimbs. Older domestic longhair, Himalayan, and Persian cats are the breeds most at risk. Feline basal cell tumors may develop almost anywhere on the body. In both dogs and cats, these tumors generally appear as firm, solitary, encapsulated, and often hairless or ulcerated nodules that may be pedunculated; they vary in size from <1 cm to >10 cm in diameter. In cats more often than dogs, these tumors are often densely pigmented, and on cut section, they can be difficult to distinguish from dermal melanocytomas. Cystic variants are also more common in cats. Although basal cell tumors are benign, they are expansive neoplasms and may be associated with extensive ulceration and secondary inflammation. Complete excision is curative.

Basal cell carcinomas are more frequently recognized in aged cats than in dogs. Persian-type breeds are predisposed. They often appear as ulcerated plaques on the head, extremities, or neck. Unlike benign basal cell tumors, these carcinomas generally have continuity with the epidermis, are locally invasive, and may be multicentric. Although evidence of vascular invasion may be identified on histologic sections, local or systemic metastasis rarely occurs. Consequently, surgical excision is the treatment of choice.

In dogs, most basal cell carcinomas have histologic evidence of cornification, a feature they have in common with squamous cell carcinomas. Therefore, they are generally called **basosquamous cell carcinomas**. These tumors are generally recognized in older dogs. Saint Bernards, Scottish Terriers, and Norwegian Elkhounds are most at risk. Unlike canine basal cell tumors, basosquamous cell carcinomas do not tend to develop on the head and can be found almost anywhere on the body where they have continuity with the epidermis and appear as exoendophytic nodules or plaques. These tumors are locally invasive but seldom metastasize. Surgical excision is the treatment of choice.

Intracutaneous Cornifying Epitheliomas

(Keratoacanthoma, Infundibular keratinizing acanthoma)

Intracutaneous cornifying epitheliomas are benign neoplasms of dogs and possibly cats. As in human keratoacanthomas, these

lesions most likely arise from the hair follicle and not from the interfollicular epidermis. They can develop anywhere on the body, with the back, tail, and extremities the most common sites affecting middle-aged dogs. Norwegian Elkhounds, Belgian Sheepdogs, Lhasa Apsos, and Bearded Collies are most likely to develop these tumors, with Norwegian Elkhounds and Lhasa Apsos at risk of developing generalized lesions. The most characteristic presentation is a papule or nodule with a central cornified pore that may protrude above the epidermal surface, giving the appearance of a horn; however, many of these tumors never have continuity with the epidermis and may appear solely as cornified cysts. These tumors are benign and treatment is optional, provided a definitive diagnosis has been established and there is no self-trauma, ulceration, or secondary infection. Tumor wall rupture releases keratin into surrounding tissues, evoking a pyogranulomatous and granulomatous inflammatory response. Excision is curative; however, dogs are prone to develop additional tumors over time. For animals with a generalized form of the disease, oral retinoids (eg, isotretinoin or etretinate) may be of therapeutic benefit.

Squamous Cell Carcinomas

(Epidermoid carcinomas, Prickle cell carcinomas)

Thought to arise from either the epidermis or the epithelium of the superficial (infundibular) regions of the outer root sheath of the hair follicle, squamous cell carcinomas have been recognized in all domestic animals. Although most arise without prior cause, in many species,

especially in the face and ear tips of white cats and in the ventral nonpigmented skin of dogs, prolonged exposure to sunlight on sparsely haired, minimally pigmented areas of the body is a major predisposing factor. The grooming habits of cats also expose them to particulate carcinogens from cigarette smoke and flea collars. In addition, a unique form of feline squamous cell carcinoma associated with papilloma virus infection has been described (see below).

In dogs, squamous cell carcinomas are the most frequently diagnosed carcinomas arising in the skin. Two forms are recognized: cutaneous and subungual. **Cutaneous squamous cell carcinomas** are tumors of older dogs, with Bloodhounds, Basset Hounds, and Standard Poodles at greatest risk. Lesions commonly arise on the head, distal extremities, ventral abdomen, and perineum. Most cutaneous squamous cell carcinomas appear as firm, raised, frequently ulcerated plaques and nodules; sometimes they can be extremely exophytic and have a wart-like surface. The etiology of most of these tumors is undefined; however, some are induced by prolonged solar injury. These usually develop on ventral abdominal, preputial, scrotal, and inguinal skin in white-skinned, shorthaired breeds such as Dalmatians, Bull Terriers, Pit Bulls, and Beagles. Lesions develop in a ventral location because the poorly haired skin has minimal shielding from ultraviolet radiation, many animals sun themselves lying on their backs, and perhaps because solar radiation reflects from the ground. Before a carcinoma develops, animals acquire focal zones of lichenification, hyperkeratosis, and erythema known as **solar keratosis** (solar dermatosis, actinic keratosis, senile keratosis).

Subungual squamous cell carcinomas are most commonly found in older Giant and Standard Schnauzers, Gordon Setters, Briards, Kerry Blue Terriers, Standard Poodles, and Scottish Terriers. Generally, all are darkhaired breeds, and a dark coat color has been associated with development of subungual squamous cell carcinomas that arise from the nailbed epithelium and invade the medullary and cortical bone of P3. They may arise on multiple digits, often appear on different extremities, and may metastasize via lymphatics to regional lymph nodes and lungs in as many as 13% of cases. Females have a slight predilection, and both fore- and hindlimbs are equally predisposed to tumor development.

In cats, cutaneous squamous cell carcinomas most commonly develop in conjunction with chronic solar injury.

Solar-induced squamous cell carcinoma in the white skin of a Dalmation dog. Courtesy of Dr. Alice Villalobos.

Consequently, they usually develop on the pinnae, frontal ridges, eyelids, nose, or lips of cats that have white skin in these regions. There is no breed or sex predilection. As in dogs, solar keratosis or carcinoma *in situ* (early superficial stage) often precedes development of a malignant tumor.

Recently, coat-associated particulate carcinogens from exposure to cigarette smoke and flea collars have been identified as risk factors for cats with oral squamous cell carcinoma. Lesions not caused by sun exposure may develop on the digits and are presumed to be metastatic from primary squamous cell carcinomas of the lung, but primary subungual forms are uncommon in cats.

Cutaneous squamous cell carcinomas are the most common malignant neoplasm in horses. They generally develop in adult or aged horses with white or part-white coats; breeds at risk include Appaloosa, Belgian, American Paint, and Pinto. Although they can arise anywhere on the body, these tumors most commonly arise in nonpigmented, poorly haired areas near mucous membranes. Thus, the periorbital regions, lips, nose, anus, and external genitalia (especially the penile sheath) are sites most likely to be affected.

In cattle, these tumors are most common in breeds with white hair and poorly pigmented skin (especially Holsteins and Ayrshires) and, as in horses, develop around the mucous membranes, usually at the mucocutaneous junctions, particularly the periocular and vulvar regions. In India, squamous cell carcinomas of the horn core are common in aged bullocks. The most common cause is actinic injury. Solar keratoses often precede development of an invasive tumor; genetic factors, immunodeficiency, and viruses may also play a role.

In sheep, squamous cell carcinomas are of economic significance in some parts of the world. In a study in Australia, they were responsible for more than one-third of all condemnations before slaughter. The Merino breed is most at risk, and females more so than males. The most common sites are the poorly haired skin of the ears, lips, muzzle, and the vulvar lips after they have been externalized by a Mules operation to prevent fly strike. Tumors at these sites develop in conjunction with solar injury, which is heightened when animals ingest photosensitizing plants. Tumors of the ears also develop more frequently after a procedure such as ear tagging. Squamous cell carcinomas can develop from follicular cysts on sites not commonly exposed to sunlight.

In goats, squamous cell carcinomas develop most frequently in females, in which tumors develop on the perineal and vulvar regions and on the skin of the teats and udders. Both males and females can develop sun-induced tumors on the ears. Although Angoras are most at risk, Saanen goats occasionally develop squamous cell carcinomas on the udder in association with papillomas. The role papilloma viruses play in tumor progression is considered contributory.

Squamous cell carcinomas are extremely uncommon in swine.

Most squamous cell carcinomas are solitary lesions; however, multiple tumors may develop in conjunction with solar injury in the "field cancerization" model. They appear as endophytic or exoendophytic lesions, the former as raised, irregular dermal masses with an ulcerated surface, and the latter as raised, irregular dermal masses covered by a papillated epidermis. Cats initially exhibit small crusting facial sores that do not heal. The lesions often persist for months before defects appear on the ear tips, nares, and eyelids. Subungual squamous cell carcinomas of dogs are first identified by lameness or nail malformation, an infection that mimics chronic osteomyelitis, or loss of the claw of the affected digit. In cattle with involvement of the horn, the first sign is distorted growth.

Squamous cell carcinomas are characteristically invasive into adjacent soft and bony tissues. Infrequently, in cattle, they regress spontaneously. In small animals, longterm survival and the likelihood of metastasis are correlated with histologic differentiation. Well-differentiated tumors are slowly progressive or remain localized; undifferentiated tumors are more likely to metastasize or recur within 20 wk of excision. In general, failure of treatment is due to late diagnosis and lack of control of local disease rather than metastasis.

For dogs and cats, surgical excision, such as amputation of the involved digit or pinnae or nosectomy, is the treatment of choice, and margins of at least 2 cm are recommended. One review of 117 digit masses in dogs found that 25% of the lesions were squamous cell carcinomas and 66% were subungual lesions. These dogs had a 95% 1-yr survival after amputation; however, if the lesion originated in other parts of the digit, 1-yr survival was 60%. Excision may be combined with radiation or chemotherapy. Feline squamous cell carcinomas are more radiosensitive than their canine counterparts. Still, the 1-yr survival rate is <10%

for invasive neoplasms. Cryosurgery and hyperthermia can be very helpful for local therapy especially in early (carcinoma in situ) lesions, but controlled studies have not been done to determine their effectiveness. Intralesional implant chemotherapy with 5-fluorouracil (dogs only), cisplatin (dogs only), or carboplatin along with retinoids and photodynamic therapy has been used with variable success. Intratumoral injection of nasal planum squamous cell carcinomas in cats using carboplatin in a water-sesame seed oil emulsion resulted in a 70% general response with 1-yr progression-free survival rate of ~50%. In dogs with multiple ventral actinic keratoses, topical dinitrochlorobenzene or 5-fluorouracil (5%) may be of benefit. Cats should not be given any form of 5-fluorouracil therapy. More recently, the use of topical immunomodulating antineoplastics such as imiquimod cream applied topically on lesions twice daily for 2 wk creates a local application site inflammatory reaction and often resolves lesions. Imiquimod stimulates Toll-like receptor 7 and dendritic cells, modifying immune responses to destroy the targeted carcinoma cells. The response may be enhanced by the application of 6 joules of cold laser therapy to the lesions every 2 wk until regression. Limiting exposure to ultraviolet radiation may help prevent solar-induced squamous cell carcinomas in dogs and cats. This may be accomplished by using UV window screens, sunscreen, and keeping companion animals indoors during hours of peak sunlight between 10 AM and 2 PM. Tattoos, magic markers, and sunscreen are used with variable success.

In horses, radiotherapy using surface or interstitial brachytherapy is the treatment of choice for squamous cell carcinomas. Other options include ^{90}Sr or ^{192}Ir implants, wide surgical excision (especially for neoplasms of the third eyelid, penis, and prepuce), and cryosurgery. Immunotherapy, with either an autogenous vaccine made from the tumor tissue suspended in Freund's adjuvant, or nonspecific immunomodulation using *Corynebacterium parvum*, has had some success in treating ocular or horn core squamous cell carcinomas in cattle.

Feline multicentric squamous cell carcinoma in situ (feline Bowen disease) is a disease of aged (>10 yr old) cats and may be associated with immunosuppression. There is no defined breed or sex predilection. Clinically, lesions appear as multiple discrete, erythematous, black or brown hyperkeratotic plaques and papules. Lesions are nonpruritic, and ulceration is uncommon. Their development is

associated with the presence of a papilloma virus. The term in situ refers to a malignant proliferation of epidermal and follicular outer sheath cells that are not invasive into the underlying dermis. Unfortunately, lesions may progress over time into an invasive carcinoma. Metastasis is extremely uncommon. These lesions usually develop in systemically ill or immunosuppressed cats and are believed to be virally induced. They have not been amenable to therapy; however, cryotherapy of local lesions and topical imiquimod as described above may increase time to progression.

Keratinized Cutaneous Cysts

Most keratinized cutaneous cysts are malformations of the hair follicle. They are common in dogs; occasionally identified in cats, horses, goats, and sheep; and rare in cattle and pigs. Excision is the treatment of choice. Vigorous squeezing of these lesions is contraindicated, because it often incites a severe foreign body inflammatory response due to the release of keratin into surrounding tissues.

Infundibular follicular cysts

(epidermoid cysts, epidermal inclusion cysts, erroneously called sebaceous cysts) are the most common. They are a cystic dilatation of the upper portion of the outer sheath of the hair follicle (the infundibulum) lined by a layer of stratified cornifying epithelial cells indistinguishable from the epidermis. These cysts vary in size from 2 mm to >5 cm (lesions <5 mm in diameter are often called milia). The only domestic animals identified at risk are Merino sheep, in which these cysts are often multiple and may progress to squamous cell carcinomas. As with all follicular cysts, these are usually solitary, papular to nodular lesions that are freely movable. They are generally partially compressible on palpation and occasionally have a small opening through the epidermis from which the cystic contents can be extruded. On cut surface, they are filled with a gray, brown, or yellowish, granular, "cheesy" material that is luminal keratin.

Isthmus catagen cysts (trichilemmal cysts, pilar cysts, cystic intracutaneous cornifying epithelioma) are follicular cysts that have the keratinization pattern of the lower portion of the outer root sheath. They have been definitively identified only in dogs and (rarely) in cats.

Matrix cysts are follicular cysts in which the wall resembles the epithelium of the hair bulb (the matrix portion of the hair follicle) and the inner root sheath. They

occur predominantly in dogs and cats. Many progress to pilomatricomas (*see* p 948).

Hybrid cysts (panfollicular cysts) are follicular cysts that have a combination of the characteristics of epidermal inclusion, trichilemmal, and matrix cysts and that are found predominantly in dogs and cats. Many progress to trichoepitheliomas (*see* below).

Dermoid cysts are congenital malformations found most commonly on the dorsal midline of the head or along the vertebral column. They are most commonly identified in Boxers, Kerry Blue Terriers, and Rhodesian Ridgeback dogs; Thoroughbred horses; and possibly Suffolk sheep. Typically multiple, they differ from other follicular cysts in that on cut surface they contain fully formed hair shafts. They are arguably the only true epidermal inclusion cysts, because they most likely represent an embryonal invagination of the epidermis with associated adnexa. These adnexa are responsible for the hair shafts within the cyst lumens.

Keratomas are cystic lesions in the hoof wall of the toe or, less frequently, the quarter or heel in simple or cloven-hoofed animals. They often develop secondary to a traumatic injury. Although often asymptomatic, they commonly induce lameness and deformity of the hoof wall or sole and may be associated with distal phalangeal lysis. Keratomas are seldom >5 cm in diameter and contain white to brown laminated keratin, often with a necrotic center associated with secondary inflammation. When lameness is present, surgical excision and curettage of the underlying bone, if affected, is the treatment of choice.

Dilated pores of Winer are rare, hair-follicle neoplasms recognized only in aged cats. Males may be predisposed. These lesions most often develop on the head. Clinically, they appear as solitary, dome-shaped lesions with the appearance of a giant comedo. Compact keratin may protrude through (above) the surface, giving them the appearance of a cutaneous horn. These lesions are benign, and complete excision is curative.

Tumors of the Hair Follicle

The hair follicle is a complex structure composed of eight different epithelial layers. Hair-follicle tumors display a similar complexity, and much work needs to be done to characterize them further. They are most common in dogs, less frequent in cats, and rare in other domestic animals.

Tricholemmomas are rare, benign, hair-follicle neoplasms of dogs, most

commonly found on the head. Poodles may be predisposed. These tumors are derived from the lower portion of the outer root sheath and often have areas of transition into basal cell tumors. They have little in common with a tumor of the same name in people that represents an old wart. They appear as firm, ovoid masses, 1–7 cm in diameter, that are encapsulated but expand over time. Excision is curative.

Trichofolliculomas are extremely rare follicular tumors of dogs composed of the inferior and isthmic regions of multiple abortive follicles that extrude their luminal contents into a dilated abnormal cystic infundibulum. Too few have been recognized to determine age, breed, or sex predilection. Considered by some to be more a hamartoma than a true neoplasm, these tumors are benign, and complete surgical excision is curative.

Trichoepitheliomas are cystic hair follicle neoplasms of dogs and, less commonly, cats, in which all elements of the hair follicle (infundibulum, isthmus, and inferior portions) and the patterns of cornification they produce are represented. The epithelium and cornification of the infundibular and isthmic portions predominate. Benign and malignant forms are recognized. In dogs, these lesions can be seen at any age but are found most commonly during late middle age. Many breeds are predisposed, including Basset Hounds, Bull Mastiffs, Irish Setters, Standard Poodles, English Springer Spaniels, and Golden Retrievers. There is no defined sex predilection. Tumors can develop anywhere on the body but are most common on the trunk in dogs and on the head, tail, and extremities in cats. Benign forms appear as palpably encapsulated cystic nodules (1–5 cm in diameter) in the dermis and subcutaneous fat. Expansion of cysts or self-trauma may induce ulceration associated with extrusion of luminal keratin that appears as a condensed, yellow, granular, “cheesy” material. Excision is curative; however, animals that develop one such tumor are prone to develop additional lesions at other sites. This is especially true for Basset Hounds and English Springer Spaniels.

Malignant trichoepitheliomas are much less common than benign trichoepitheliomas and are differentiated by their local invasiveness; continuity with the epidermis; and association with extensive inflammation, necrosis, and fibrosis. Metastasis is uncommon. Wide surgical excision is the treatment of choice and is often curative in those tumors that are invasive but have minimal metastatic potential.

Pilomatricomas (hair matrix tumors, calcifying epitheliomas of Malherbe) are cystic hair-follicle neoplasms recognized almost exclusively in dogs. Unlike trichoepitheliomas, in which all elements of the follicle are represented, in pilomatricomas only the cells of the matrix region of the inferior part of the hair follicle and the cornification patterns they produce (hair shaft and inner root sheath) are present. Benign and malignant forms are recognized. Benign tumors are most common on the trunk of middle-aged dogs. Kerry Blue and Wheaten Terriers, Bouviers des Flandres, Bichons Frises, and Standard Poodles are most at risk. Grossly, these tumors are indistinguishable from trichoepitheliomas, but their cystic contents are often gritty because of mineralization. Excision is the treatment of choice. As in trichoepitheliomas, when one such lesion develops, additional lesions often develop over time.

Malignant pilomatricomas (malignant hair matrix tumor, matrical carcinoma) are rare and have been identified most often in dogs. They are a tumor of old dogs and grossly characterized as solitary or multinodular, variably cystic tumors that are often firmly attached to subjacent soft tissues. Because they are invasive, they are difficult to excise, and recurrence is common after attempts at surgical excision. They often metastasize to draining lymph nodes and internal organs, especially the lungs. Aggressive surgery is recommended. It is unknown whether they respond to radiation or chemotherapy.

Cutaneous Apocrine Gland Tumors

Sweat glands are of two types: apocrine and eccrine. Apocrine glands are tubular glands with a coiled secretory portion and a long,

straight duct that flows into the follicular infundibulum. In domestic animals, all hair follicles have apocrine glands. Apocrine glands in dogs and cats are also present in association with the anal sac, and modified apocrine glands, known as ceruminous glands, are present in the external auditory meatus. In most mammals, apocrine glands produce an odiferous, oily compound that is a sexual attractant, a territorial marker, and a warning signal. In horses and cattle, these glands play a role in thermoregulation by producing sweat.

Apocrine gland tumors and malformations are most common in dogs and cats. Three diseases of apocrine glands of haired skin have been characterized.

Cystic apocrine gland dilations (apocrine gland cysts, cystic apocrine gland hyperplasia, apocrine cystomatosis) are best characterized as hamartomas. Two forms exist: a cystic form in which one or more cysts develop in the mid to upper dermis with a poor association with hair follicles, and a more diffuse form characterized by cystically dilated apocrine glands associated with multiple hair follicles in nontraumatized skin. Both are found in middle-age or older dogs and, less commonly, cats. The head and neck are the most common sites where these lesions develop. In both species, lesions appear as fluctuant dermal cysts or as translucent bullae. Complete excision is curative; however, this may be difficult to accomplish in the more diffuse form.

Apocrine gland adenomas are diagnosed almost exclusively in dogs, cats, and rarely horses. Two types are recognized based on whether their histologic appearance primarily resembles the secretory or ductular portion of the apocrine gland.

Apocrine adenomas resemble the secretory region of the apocrine glands. They are found in older dogs and cats. Great Pyrenees, Chow Chows, and Alaskan Malamutes are the most commonly affected breeds. The head, neck, and extremities are the most frequent sites of development. In cats, apocrine adenomas are more likely to be seen in males, and no breed appears at greater risk than any other. The vast majority of apocrine adenomas occur on the head, especially the pinnae. In horses, no age, sex, or breed association is known. The pinnae and vulva are the most likely regions to develop these tumors. In all species, these tumors appear as firm to fluctuant cysts, seldom >4 cm in diameter. They contain varying amounts of clear to brownish fluid. In cats, the luminal fluid may be darkly pigmented, and apocrine cysts can be

Ceruminous gland carcinoma, right ear of a cat. Courtesy of Dr. Alice Villalobos.

confused clinically with melanocytomas, especially when present on the inner aspect of the ears. **Apocrine ductular adenomas** are less common. They are found in older dogs and cats and are putatively derived from or show differentiation toward apocrine ducts. In dogs, these tumors are most commonly recognized in Peekapoos, Old English Sheepdogs, and English Springer Spaniels. They are often smaller, firmer, and less cystic than apocrine adenomas. Because they often consist of a large population of basal cells and because evidence of ductular differentiation can be extremely subtle, these tumors are often diagnosed histologically as basal cell tumors (see p 944). Apocrine adenomas and apocrine ductular adenomas are benign, and complete surgical excision is curative.

Apocrine gland adenocarcinomas of haired skin are rare in all domestic animals but most frequently identified in older dogs and cats. In dogs, Treeing Walker Coonhounds, Norwegian Elkhounds, German Shepherds, and mixed-breed dogs are most at risk; in cats, Siamese may be predisposed. In both species, this tumor most commonly arises in axillary and inguinal regions—sites that allow it to be easily confused clinically and histologically with mammary gland ductular adenocarcinomas. Apocrine gland adenocarcinomas generally are larger than adenomas and have a variable clinical appearance ranging from fibrotic dermal nodules to ulcerated plaques. They are locally invasive and frequently metastasize to draining lymph nodes. Less commonly, skin and lung metastasis may occur. Complete surgical excision is the treatment of choice. Little is known about response to adjunct chemotherapy.

Apocrine Gland Tumors of Anal Sac Origin

Apocrine gland tumors of anal sac origin have been definitively identified only in dogs, although anecdotal reports suggest they may also be seen in cats. Older English Cocker and Springer Spaniels, Dachshunds, Alaskan Malamutes, German Shepherds, and mixed-breed dogs are most at risk. Unlike hepatoid gland tumors (see p 951), these apocrine gland tumors have no sex predilection. They most commonly appear as deep, firm, nodular masses near the anal sac. As these lesions grow, they may compress the rectum and induce constipation. Some of these tumors are associated with paraneoplastic hypercalcemia, which causes anorexia, weight loss, polyuria and polydipsia, and mineralization of renal

tissue with increased BUN and creatinine values. These tumors are often highly infiltrative into the pelvic canal and commonly (90%) metastasize to the sublumbar lymph nodes or to distant internal organs (40%). Wide surgical excision, including involved lymph nodes, is the treatment of choice. Even if the tumor cannot be totally resected, debulking can be of value in dogs with pseudohyperparathyroidism, because the hypercalcemia is related to the production of parathormone-like hormone from the total tumor volume. Adjunct chemotherapy along with tyrosine kinase inhibitors, metronomic chemotherapy, and radiation therapy may also be of benefit to increase time to progression, but few dogs are reported to live >1 yr after the tumor has been recognized.

Eccrine Gland Tumors

Eccrine glands are the coiled, tubular, sweat glands present on the footpads of carnivores, the frog of ungulates, the carpus of pigs, and the nasolabial region of ruminants. Tumors derived from these glands are extremely rare and have been identified only on the footpads of dogs and cats. Most are malignant and invasive. These tumors are reported to have a high potential to metastasize to draining lymph nodes.

Sebaceous Gland Tumors

Tumors and tumor-like conditions of sebaceous glands are common in dogs, infrequent in cats, and rare in other domestic animals. Based on morphologic more than on behavioral features, four categories of benign sebaceous gland proliferations have been described. In people, in which a roughly similar classification scheme is traditionally used, it has been proposed that all benign sebaceous gland tumors be called sebaceomas.

Sebaceous gland hamartomas are solitary lesions reported only in dogs. These lesions are distinguished from sebaceous gland hyperplasias and adenomas because they are linear or circumscribed, several centimeters in length or diameter, and usually identified shortly after birth.

Sebaceous gland hyperplasias (senile sebaceous hyperplasias) represent a senile change in dogs and cats. In dogs, Manchester, Wheaton, and Welsh Terriers are at greatest risk. In cats, there is no breed predilection, but females develop these lesions more frequently than males. In both species, the skin of the head and abdomen are affected most commonly. Sebaceous hyperplasias commonly appear as papillated

masses seldom >1 cm in diameter, often with a shiny, keratotic surface.

Sebaceous gland adenomas are seen in all domestic animals but are so common in older dogs and cats they can be considered primarily a small animal neoplasm. Coonhounds, English Cocker Spaniels, Cocker Spaniels, Huskies, Samoyeds, and Alaskan Malamutes are the canine breeds most likely to develop these tumors; Persians are the feline breed most predisposed. In dogs, these tumors frequently are clinically indistinguishable from sebaceous hyperplasias, but they tend to be larger (typically >1 cm). They are often multiple and may develop anywhere on the body but are commonly found on the head. Sebaceous adenomas may be covered with a serocellular crust and exhibit pleocellular inflammation and superficial pyoderma.

Sebaceous gland epitheliomas are a variant of sebaceous adenoma distinguished by lobules composed primarily of basal progenitor cells rather than mature sebocytes. Because they often have irregular lobules that extend into the deep dermis, they can occasionally be confused with sebaceous carcinomas. These tumors are found in older dogs and rarely in cats. They appear as ulcerated nodules that may be several centimeters in diameter. A papillated epidermal surface and pigmentation are variable findings.

Sebaceous gland adenocarcinomas are rare in domestic animals. They are recognized almost exclusively in dogs and cats, generally in middle-aged or older animals. Cavalier King Charles Spaniels; Cocker Spaniels; and Scottish, Cairn, and West Highland White Terriers are most at risk. Male dogs and female cats may be predisposed. These lesions are often ulcerated and may be indistinguishable from sebaceous epitheliomas or other cutaneous carcinomas. They are locally infiltrative and may metastasize to regional lymph nodes late in the disease.

Once a diagnosis is established, treatment is optional for benign sebaceous gland tumors unless they are secondarily inflamed and infected. For malignant adenocarcinomas, excision is the treatment of choice, but complete removal can be difficult because of the infiltrative nature of this tumor; adjunct radiotherapy may be required. Even benign sebaceous gland growths recur if remnants are left at the surgical site. In addition, animals that develop one sebaceous gland hyperplasia or adenoma often develop new lesions at other sites over time. No established protocol of

chemotherapy for any of these lesions has been defined. Oral retinoids may prevent recurrence of sebaceous hyperplasia, but their use remains poorly defined, and consultation with a veterinary oncologist or dermatologist is strongly recommended.

Hepatoid Gland Tumors

(Perianal gland tumors, Circumanal gland tumors)

These common neoplasms arise from modified sebaceous glands that are most abundant in the cutaneous tissues around the anus but may also be present along the ventral midline from the perineum to the base of the skull, the dorsal and ventral tail, and in the skin of the lumbar and sacral regions. Because androgens stimulate the development of hepatoid glands, the incidence of proliferative lesions of hepatoid glands in intact, male dogs is three times that in females.

Benign hepatoid gland tumors are divided into hepatoid gland hyperplasias and adenomas; however, as with benign sebaceous gland tumors, there is a continuum from hyperplasia to adenoma. Here, they will be considered as a single entity. Hepatoid gland adenomas are most common in aged dogs. Siberian Huskies, Samoyeds, Pekingese, and Cocker Spaniels are most commonly affected. Tumors may develop at any site where hepatoid glands are present, but 90% are found in the perianal region. Grossly, they appear as one or (more commonly) multiple intradermal nodules 0.5–10 cm in diameter. Larger lesions commonly ulcerate, and hemorrhagic, proteinaceous material can often be extruded with local pressure. Large tumors can compress the anal canal and make defecation difficult. Up to 95% of male dogs respond completely to castration; in those that do not, the pituitary-adrenal axis should be evaluated and, if no abnormality is detected, the dog should be reevaluated for the presence of a low-grade hepatoid gland adenocarcinoma. Excision may be used concurrently to remove extremely large or ulcerated tumors that have become secondarily infected. Surgery is the treatment of choice for females with hepatoid gland adenomas but may need to be repeated, because recurrence is common. Radiation therapy is also an option and has a 2-yr cure rate of 69% for benign tumors. Cryosurgery is another therapeutic alternative, but because of the complication of fecal incontinence, should be used only when tumors are not amenable to surgical intervention. Diethylstilbestrol has been

used in the past as an alternative to castration, but because of severe adverse effects, including aplastic anemia and cystic prostatic hyperplasia, it should be used with extreme caution, if at all. Antiandrogens may have a role as an alternative to castration.

Hepatoid gland adenocarcinomas are uncommon canine neoplasms that generally appear as nodular lesions affecting the perianal region. These tumors are found in male dogs 10 times more commonly than in females. Siberian Huskies, Alaskan Malamutes, and Bulldogs are most likely to develop this tumor. Histologic evaluation is the best means of diagnosis; however, there is debate about how to distinguish low-grade malignant tumors from hepatoid adenomas, because well-differentiated forms can be confused with adenomas, and anaplastic forms can be confused with apocrine gland adenocarcinomas of anal sac origin. These tumors have metastatic potential and often spread to regional lymph nodes. Treatment consists of wide surgical excision including involved lymph nodes and, possibly, subsequent radiation. These tumors are generally not responsive to castration or to estrogen therapy; however, some studies show that the use of masitinib and other tyrosine kinase inhibitors may overcome chemoresistance, inhibit the proliferation of tumor cells, and prevent the emergence of metastasis. These findings may increase the benefit of combining targeted agents with various forms of chemotherapy such as oral piroxicam and capecitabine or with metronomic chemotherapy to prevent or treat local recurrence and metastatic disease. The overall prognosis is guarded.

Primary Cutaneous Neuroendocrine Tumors

(Merkel cell tumors, Atypical histiocytomas, Trabecular carcinomas, Extramedullary plasmacytomas)

In veterinary medicine, the diagnosis of tumors derived from Merkel cells (tactile, neurosecretory cells of epithelial derivation present in the basal cell layer of the epidermis) has fallen in disfavor, and most pathologists consider this tumor to be an extramedullary plasmacytoma. Merkel cell tumors most likely develop in animals but are not recognized as such.

Papillomas

(Warts)

Papilloma viruses are small, double-stranded DNA viruses of the Papovaviridae family. Some mammals have several distinct

papilloma viruses: people have >20; cattle, 6; dogs, 3; and rabbits, 2. Different papilloma viruses often have considerable species, site, and histologic specificity. The virus is transmitted by direct contact, fomites, and possibly by insects. Papillomas have been reported in all domestic animals, birds, and fish. Multiple papillomas (**papillomatosis**) of skin or mucosal surfaces generally are seen in younger animals and are usually caused by viruses. Papillomatosis is most common in cattle, horses, and dogs. Single papillomas are more frequent in older animals, but they may not always be caused by viral infection.

When lesions are multiple, they may be sufficiently characteristic to confirm the diagnosis; however, there are many simulants of warts, and a definitive diagnosis requires identification of the virus or its cytopathic effects on individual cells—a change known as koilocytic atypia or koilocytosis.

In cattle, warts commonly are found on the head, neck, and shoulders, and occasionally on the back and abdomen. The extent and duration of the lesions depend on the type of virus, area affected, and degree of susceptibility. Warts appear ~2 mo after exposure and may last ≥1 yr. Papillomatosis becomes a herd problem when a large group of young, susceptible cattle becomes infected. Immunity usually develops 3–4 wk after initial infection, but papillomatosis occasionally recurs, probably due to loss of immunity.

Although most warts appear as epidermal proliferations that have a keratotic surface resembling a cauliflower (*verruca vulgaris*), some bovine papilloma viruses (bovine papilloma types 1 and 2) involve dermal fibroblasts and keratinocytes and appear as a papulonodule with a warty surface. Such fibropapillomas may involve the venereal regions, where they can cause pain, disfigurement, infection of the penis of young bulls, and dystocia when the vaginal mucosa of heifers is affected.

A form of persistent cutaneous papillomatosis with smaller numbers of papillomas may be seen in herds of older cattle. A bovine papilloma virus has been demonstrated in bladder tumors associated with bracken fern ingestion (*see* p 3089) and in upper GI tract papillomas of cattle in Scotland. It is believed that the papilloma virus acts as a co-carcinogen. When bovine papilloma virus type 1 or 2 is injected into the skin of horses, a dermal tumor similar to equine sarcoid develops.

In horses, small, scattered papillomas develop on the nose, lips, eyelids, distal legs,

penis, vulva, mammary glands, and inner surfaces of the pinnae, often secondary to mild abrasions. They can be a herd problem, especially when young horses are kept together, but regress in a few months, as a foal's immune system matures. When they develop in older horses, they often persist for >1 yr. So-called aural plaques are also thought to be a flat form of papilloma (*verruca planum*). Equine papillomas are disfiguring but benign. They should be distinguished from verrucous equine sarcoid (*see p 954*).

In dogs, three clinical presentations of canine papilloma virus infection have been described. The first is **canine mucous membrane papillomatosis**, which primarily affects young dogs. It is characterized by the presence of multiple warts on oral mucous membranes from lips to (occasionally) the esophagus and on the conjunctival mucous membranes and adjacent haired skin. When the oral cavity is severely affected, there is interference with mastication and swallowing. A viral etiology has been clearly established for these lesions. Azithromycin therapy has been shown to speed up regression in dogs. The second presentation is **cutaneous papillomas**, which are indistinguishable from the warts that develop on or around mucous membranes. However, they are more frequently solitary and develop on older dogs. Cocker Spaniels and Kerry Blue Terriers may be predisposed. A definitive viral etiology has not been established, and lesions may be confused with cutaneous tags. A syndrome characterized by papillomatosis of one or more footpads has also been described. Clinically, lesions appear as multiple, raised keratin horns. A viral etiology has been suggested but not proved. The third presentation is **cutaneous inverted papillomas**, which have more in common clinically with intracutaneous cornifying epitheliomas. In this disease of young, mature dogs, lesions most commonly develop on the ventral abdomen, where they appear as raised papulonodules with a keratotic center. Infrequently, viral papillomas in dogs may progress to invasive squamous cell carcinomas.

In cats, papilloma virus infection appears most commonly as a multicentric squamous cell carcinoma (*see p 945*). The typical warty lesions associated with papilloma virus infection in most species are not present. Papillomas may affect the skin of goats, and infection on the teats has been reported to induce malignant transformation. In sheep, papillomas are rare and most commonly appear as fibropapillomas. In

pigs, they are very rare and when present are identified as solitary or multiple lesions on the face or genitalia. (For discussion of papillomatosis in rabbits, *see p 1950*.)

A cutaneous fibroma occurs in white-tailed, black-tailed, and mule deer, and in antelope, moose, and caribou. It is caused by a papilloma virus that resembles a bovine papilloma virus and is found only in the epithelium that covers the tumors.

Infectious papillomatosis is a self-limiting disease, although the duration of warts varies considerably. A variety of treatments have been advocated without agreement on efficacy. Surgical removal is recommended if the warts are sufficiently objectionable. However, because surgery in the early growing stage of warts may lead to recurrence and stimulation of growth, the warts should be removed when near their maximum size or when regressing. Affected animals may be isolated from susceptible ones, but with the long incubation period, many are likely to have been exposed before the problem is recognized.

Vaccines are of some value as a preventive but are of little value in treating cattle that already have lesions. Because wart viruses are mostly species-specific, there is no merit in using a vaccine derived from one species in another. An intralesional lymphocyte T-cell immunomodulator, which stimulates T cells and endogenous interleukin 2 levels, may benefit individual animals that develop multiple or persistent warts. In addition to azithromycin, topical imiquimod cream may also help the immune system to resolve these warts in dogs.

When the disease is a herd problem, it can be controlled by vaccination with a suspension of ground wart tissue in which the virus has been killed with formalin. Autogenous vaccines may be more effective than those commercially available. It may be necessary to begin vaccination in calves as early as 4–6 wk of age with a dose of ~0.4 mL intradermally given at two sites. The vaccination is repeated in 4–6 wk and at 1 yr of age. Immunity develops in a few weeks but is unrelated to whatever mechanism is involved in spontaneous regression. If the animal was exposed to the virus before vaccination, immunity may develop too late to prevent warts. A vaccination program must be in effect for ~3–6 mo before its preventive value will be evident. Vaccination should be continued for ≥1 yr after the last wart disappears, because the premises may still be contaminated. Stalls, stanchions, and other inert materials can be disinfected by fumigating with formaldehyde.

EQUINE SARCOIDS

Equine sarcoids are the most commonly diagnosed tumor of equids, representing 20% of all equine neoplasms and 36% of all skin tumors in horses. Studies suggest there is no significant gender or age predisposition.

Equine sarcoids are rarely life threatening but can compromise function and be a major economic concern. Sarcoids may also cause significant welfare dilemmas, particularly in developing countries where equids, principally donkeys, are widely used as work animals (eg, brick-carrying donkeys in India).

Sarcoids can occur as single or multiple lesions in different forms, ranging from small, wart-like lesions to large, ulcerated, fibrous growths. Six distinct clinical entities are recognized: 1) Occult—flat, gray, hairless, and persistent; often circular or roughly circular. 2) Verrucose—gray, scabby, or warty in appearance and may contain small, solid nodules; possible surface ulceration; well-defined or cover large, ill-defined areas. 3) Nodular—multiple, discrete, solid nodules of variable size; may ulcerate and bleed. 4) Fibroblastic—fleshy masses, either with a thin pedicle or a wide, flat base that commonly bleed easily; may have a wet, hemorrhagic surface. 5) Mixed—variable mixtures of two or more types. 6) Malevolent—an extremely rare, aggressive tumor that spreads extensively through the skin; cords of tumor tissue intersperse with nodules and ulcerating fibroblastic lesions.

Lesions can develop anywhere on the body but are most common in the paragenital region, the ventral thorax and abdomen, and the head. They frequently are seen at sites of previous injury and scarring. Equine sarcoids can resemble other skin tumors such as benign fibropapillomas and also other cutaneous conditions such as exuberant granulation tissue (proud flesh). An individual lesion on a horse can be difficult to diagnose, but multiple tumors (often of more than one type) with characteristic features on an individual horse make the clinical diagnosis reasonably straightforward. A definitive diagnosis can be made by biopsy; however, acquiring the sample carries the risk of triggering a considerable and uncontrollable expansion of the lesion.

Bovine papillomavirus (BPV), primarily types 1 and 2, is now considered the main etiologic agent of equine sarcoids. There may also be a genetic predisposition associated with equine leukocyte antigens;

particular breeds and bloodlines appear to be more susceptible to the disease.

The mode of transmission has not been confirmed. BPV-1 has recently been detected in several common fly species (eg, house fly and stable fly), and because there is an apparent predilection for sarcoid development at wound sites, it has been proposed that flies may act as vectors as they move between wound sites on different horses. Alternatively, BPV infection may be transmitted via stable management practices, such as the sharing of contaminated tack, or be passed into existing wounds from contaminated pasture.

There is a wide range of therapies for sarcoids, and many tumors recur. Pedunculated sarcoids with a discernible neck are ideally suited to ligation with rubber bands or elasticized suture material, usually in combination with a topical preparation once the tumor is detached. Other commonly used treatments include cryotherapy, surgical or laser excision, and local immune modulation (Bacillus Calmette-Guérin [BCG] therapy). Surgical excision with margins of at least 0.5–1 cm is recommended. Preplaced sutures or releasing incisions are often needed for primary closure. Local radiotherapy (interstitial brachytherapy), using permanently implanted radon-222 or gold-198 seeds or removable needles of radium-226, cobalt-60 or, more often, iridium-192 (^{192}Ir) implants, is a highly effective treatment for tumors less amenable to traditional therapy (eg, those on the limbs or around the eye). However, ^{192}Ir implants and other radioisotopes are expensive and not widely available but may be the best option for recurrent aggressive lesions. Sarcoids have a 15%–82% recurrence rate if treated by surgical excision alone. Excised sarcoids often regrow more aggressively within 6 mo, which may be due to activation of latent BPV in apparently normal tissue surrounding the lesion. Larger tumors may require a combination of therapies (eg, surgical debulking or CO_2 laser vaporization followed by topical or intracavitary chemotherapy or local electrochemotherapy).

Several promising treatments now available or in the final stages of clinical trials include the use of intra-tumoral bioabsorbable cisplatin beads/emulsion (9% recurrence rate), the application of topical imiquimod every other day for 32 wk or until resolution (60%), autologous implantation, and topical acyclovir creams for treatment of flat, occult sarcoids (68% response rate) or applied to the wound bed of larger

tumors removed by surgical excision. Acyclovir is relatively inexpensive and has a wide safety margin, but its method of action is unknown. Other products used to treat sarcoids are topical ointments that contain heavy metals, thiouracils, and 5-fluorouracil; an escharotic salve containing bloodroot powder extract and zinc chloride; and an IV immunostimulant of nonviable *Propionibacterium acnes* and BCG. The development of preventive and/or therapeutic vaccines may form a significant part of disease control strategies in the future, but trials so far have shown limited success.

A novel therapeutic approach using small interfering RNA molecules to target viral gene expression is being investigated. This technique has been shown to selectively destroy BPV1-infected equine skin cells in vitro.

CONNECTIVE TISSUE TUMORS

Benign Fibroblastic Tumors

Collagenous nevi are benign, focal, developmental defects associated with increased deposition of dermal collagen. They are common in dogs, uncommon in cats, and rare in large animals. They generally are found in middle-aged or older animals, most frequently on the proximal and distal extremities, head, neck, and areas prone to trauma. They are sessile to raised, dermal nodules, often with a papillated surface. Two forms are seen: one develops in the interfollicular dermis or subcutaneous fat that is not accompanied by adnexal involvement, and one incorporates adnexa and induces enlarged, often malformed follicles, sebaceous glands, and apocrine glands. This latter form has been called **focal adnexal dysplasia**. Excision of both forms is generally curative although, infrequently, expansive forms have been identified that may grow too large to be surgically removed.

Generalized nodular dermatofibrosis (dermatofibromas), recognized rarely in German Shepherds (believed to be an inherited, autosomal dominant trait) and even less commonly in other canine breeds, is a syndrome in which multiple collagenous nevi are associated with renal cystadenocarcinomas and, in females, multiple uterine leiomyomas. Skin lesions, first recognized when animals are 3–5 yr old, are characterized by the development of multiple collagenous nevi varying from barely palpable to large and nodular, generally on the limbs, feet, head, and trunk. They may be symmetrically distributed. Renal disease

develops ~3–5 yr after the skin lesions are recognized. No known therapy can prevent development of the renal and uterine neoplasms.

Acrochordons (cutaneous tags, soft fibromas, fibrovascular papillomas) are distinctive, benign, cutaneous lesions of older dogs. These lesions are common, may be single or multiple, and can develop in any breed, although large breeds may be at increased risk. Most commonly, they appear as pedunculated exophytic growths, often covered by a verrucous epidermal surface. Treatment is optional, but a biopsy is recommended to confirm the diagnosis. Acrochordons are amenable to excision, electrosurgery, and cryosurgery, but dogs that develop one are prone to develop others over time.

Fibromas are discrete, generally cellular proliferations of dermal fibroblasts. Histologically, they resemble collagenous nevi or cutaneous tags. Fibromas occur in all domestic species but are primarily a tumor of aged dogs. Doberman Pinschers, Boxers (predisposed to developing multiple tumors), and Golden Retrievers are most at risk. The head and extremities are the most likely sites. Clinically, the lesions appear as discrete, generally raised, often hairless nodules originating in the dermis or subcutaneous fat. They palpate as either firm and rubbery (**fibroma durum**) or soft and fluctuant (**fibroma molle**). These lesions are benign, but complete excision is recommended if they change appearance or grow large.

Soft-tissue Sarcomas

This group of malignancies includes equine sarcoids, fibromatoses, fibrosarcomas, malignant fibrous histiocytomas, neurofibrosarcomas, leiomyosarcomas, rhabdomyosarcomas, and variants of liposarcomas, angiosarcomas, synovial cell sarcomas, mesotheliomas, and meningiomas. As a group, sarcomas are widely recognized, yet poorly characterized neoplasms. The confusion stems in part from the fact that spindle-cell sarcomas demonstrate much greater morphologic heterogeneity than carcinomas; often, features of one sarcoma are intermixed with features of another. Consequently, it is widely accepted that the cell of origin of all soft-tissue sarcomas is a primitive mesenchymal cell that can differentiate in many different directions. This makes it difficult to define histopathologic criteria necessary for making an unequivocal diagnosis of specific spindle-cell sarcomas.

In addition, comparing neoplastic mesenchymal cells with the normal cell they most closely resemble does not imply origin from those cells.

A second cause for the confusion stems from the difficulty in determining whether these are benign or malignant or what their biologic behavior will be in certain locations or breeds. Most spindle-cell sarcomas of domestic animals are locally infiltrative, difficult to excise, and yet seldom metastasize. Because, by definition, only malignant tumors have metastatic potential, these tumors should be considered benign; however, again by definition, benign neoplasms are not infiltrative, and those tumors should be considered malignant and treated aggressively from the start. In human pathology, infiltrative but nonmetastasizing mesenchymal spindle-cell tumors have been defined as sarcomas of intermediate malignancy, a concept used below.

Clinically, four general principles relate to spindle-cell sarcomas and soft-tissue sarcomas: The more superficial the location, the more likely the tumor is to be benign (deep tumors tend to be malignant). The larger the tumor, the more likely it is to be malignant. A rapidly growing tumor is more likely to be malignant than one that develops slowly. Benign tumors are relatively avascular, whereas most malignancies are hypervascular. The type of sarcoma, its size, location, stage and histologic grade (low, intermediate, high [or I, II, III]), which depends on the degree of differentiation, the number of mitotic figures per 10 high-power fields, and percent that is necrotic, will help guide treatment planning.

Surgical excision is the treatment of choice. Wide excision or amputation should be performed when anatomically feasible because spindle-cell sarcomas often infiltrate along fascial planes, making it difficult to determine from gross examination the peripheral margins of the tumor. The best, if not only, opportunity to completely remove a spindle-cell sarcoma is during the first surgical attempt. A presurgical biopsy should be performed and, if possible, tumor imaging with CT or MRI or ultrasound to provide a clear surgical plan that includes the intention of complete removal, with biopsy samples submitted for margin determinations. Those sarcomas that recur have a greater potential for metastasis, and the time to recurrence often shortens with each subsequent attempt at excision. In addition, many soft-tissue tumors have a pseudocapsule, which on gross examination gives the

impression of complete encapsulation; these tumors should not be "shelled out," because neoplastic cells are usually present in the pericapsular connective tissues. Many sarcomas are shaped like an octopus, with tentacles that extend deeply into the tumor bed. Except for equine sarcoids, cryosurgery is usually not used for these tumors because some types, most notably fibrosarcomas, are resistant to freezing. Spindle-cell sarcomas generally do not respond well to conventional doses of radiation; however, higher doses have been reported to control ~50% of them for 1 yr. Surgical debulking followed by intraoperative placement of carboplatinum-containing biodegradable beads, intracavitary chemotherapy with follow-up intratumor bed chemotherapy, and/or follow-up radiation therapy are options to enhance local control.

Chemotherapeutic protocols for sarcomas that include targeted therapy agents such as tyrosine kinase (T-K) inhibitors have become more accepted as a means of treatment. Most older protocols involve the use of adriamycin often in combination with other agents, including cyclophosphamide, vincristine, dacarbazine, and methotrexate. Some clinicians prefer to use a combination of carboplatin, T-K inhibitors, and metronomic chemotherapy, whereas others rotate carboplatin with adriamycin. Although chemotherapy may cause temporary adverse events, it can improve the length and overall quality of life; it is seldom curative.

Fibromatosis (aggressive fibromatosis, extra-abdominal desmoids, desmoid tumors, low-grade fibrosarcomas, nodular fasciitis) is a sclerosing and infiltrative proliferation of well-differentiated fibroblasts derived from aponeuroses and tendon sheaths. They are generally seen on the heads of dogs, especially Doberman Pinschers and Golden Retrievers, where they are commonly diagnosed as nodular fasciitis. In veterinary medicine, the term nodular fasciitis is applied to two different diseases: one that behaves as a fibromatosis and one that commonly affects the periocular tissues (known as canine fibrous histiocytoma [see p 957]). Fibromatoses are infrequently diagnosed in cats and horses. Grossly, fibromatoses are generally indistinguishable from infiltrative fibrosarcomas; however, they can be differentiated on histologic examination. Focal lymphoid nodules are scattered throughout the tissues. The fibromatoses are locally infiltrative, with essentially no metastatic potential. If feasible, wide, complete

excision with local control techniques as described above is the treatment of choice at diagnosis. Recurrence is common, and radiation therapy may be of value for local control.

Fibrosarcomas are aggressive mesenchymal tumors in which fibroblasts are the predominant cell type. They are the most common soft-tissue tumors in cats and are also common in dogs but rare in other domestic animals. In dogs, these tumors are most common on the trunk and extremities. Gordon Setters, Irish Wolfhounds, Brittany Spaniels, Golden Retrievers, and Doberman Pinschers may be predisposed. Fibrosarcomas vary markedly in their appearance and size. Neoplasms arising in the dermis may appear nodular. Those arising in the subcutaneous fat or subjacent soft tissues may require palpation to identify. They appear as firm, fleshy lesions involving the dermis and subcutaneous fat and often invade musculature along fascial planes. When tumors are multiple, they are usually found within the same anatomic region. Fibrosarcomas with abundant interstitial proteoglycans (connective tissue mucins) are called **myxosarcomas** or **myxofibrosarcomas**. Myxosarcomas remain poorly defined in veterinary medicine, and many of them could be characterized as variants of liposarcomas or malignant fibrous histiocytomas. Fibrosarcomas in dogs are invasive tumors; ~10% metastasize. Factors that affect whether a fibrosarcoma can be completely excised include the skill of the surgeon; rate of growth (as defined by the mitotic index and quantity of necrosis); degree of cellular atypia; and the tumor's infiltrative nature, size, and location (which may require imaging to define properly).

Three forms of fibrosarcoma are recognized in cats: a multicentric form in the young (generally <4 yr old) caused by the feline sarcoma virus (FSV); a solitary form in the young or old, in which FSV has not been implicated; and a fibrosarcoma that develops in the soft tissues where cats are commonly vaccinated (see p 2169). An association with rabies and feline leukemia virus vaccinations is better defined than with vaccinations for other viral or bacterial diseases. Aluminum hydroxide (commonly used in adjuvants) has been identified in vaccine-induced fibrosarcomas, and a prolonged proliferation of fibroblasts in response to the adjuvant may predispose these cells to undergo neoplastic transformation. These tumors appear as nodules or plaques between the shoulder blades, in the soft tissues of the proximal hindlimbs, or less commonly,

over the lumbar areas. Although commonly classified as fibrosarcomas, vaccination-site sarcomas are extremely heterogeneous and may be appropriately called malignant fibrous histiocytomas (giant cell tumors), liposarcomas, osteosarcomas, or chondrosarcomas.

Wide and deep surgical excision is the treatment of choice for fibrosarcomas, but because the necessary margin extent is commonly underestimated, recurrence is common (>70% within 1 yr of the initial surgery). The rate of recurrence is >90% for vaccine-associated sarcomas. Even when surgical excision is clinically and histologically complete, recurrence is still the rule. Therefore, multimodal therapy combining presurgical imaging, aggressive surgery, intracavitary chemotherapy with carboplatin, followed by radiation therapy and IV carboplatin every 21 days for 4–6 treatments with tyrosine kinase (T-K) inhibitors as adjunctive therapy may yield the best results. Chemotherapy with carboplatin, doxorubicin and cyclophosphamide, or dacarbazine, along with T-K inhibitors, has been recommended for nonresectable tumors. Initial results using a biologic response modifier (used intratumorally before excision and followed by radiation therapy) appear promising. Further work suggests that its effectiveness as an adjunct to surgery and radiation may increase tumor-free intervals up to 20% compared with historical controls.

Fibrohistiocytic Tumors

These pleomorphic, mesenchymal tumors composed of fibroblasts and histiocytic cells (often present as multinucleated giant cells) remain poorly defined in veterinary medicine. A lesion called **canine fibrous histiocytoma** (nodular granulomatous episclerokeratitis, nodular fasciitis, proliferative keratoconjunctivitis, conjunctival granuloma, Collie granuloma) is recognized at the episcleral junction and cornea primarily in young to middle-aged (2–4 yr old) Collies, but the histologic features are more suggestive of a granulomatous inflammatory response than a neoplasm. As might be expected for a noninfectious inflammatory process, these are generally responsive to sublesional injections of 10–40 mg of methylprednisolone.

Malignant fibrous histiocytomas (extraskelatal giant cell tumors, giant cell tumors of soft parts, dermatofibrosarcomas) are most frequently found in the skin and soft tissues of cats, occasionally found

in horses and mules, and rarely in the skin of other domestic species, including dogs. In cats, malignant fibrous histiocytomas are most common on the distal extremities or ventral cervical regions of the aged but may also be diagnosed at vaccination sites. In horses and mules, these have been described as giant cell tumors of soft parts. Seen in young adult to middle-aged Equidae, they are firm, nodular to diffuse swellings that are white on cut surface, with variable hemorrhage. Malignant fibrous histiocytomas are sarcomas of intermediate malignancy. They are locally invasive and tend to recur after attempts at complete excision but seldom metastasize. Radical excision is recommended.

Peripheral Nerve Sheath Tumors

Amputation neuromas (traumatic neuromas) are non-neoplastic, disorganized proliferations of peripheral nerve parenchyma and stroma that form in response to amputation or traumatic injury. They are most commonly identified after tail docking in dogs or neurectomy in the distal extremities of horses. The most common clinical presentation is a young dog that continuously traumatizes its docked tail. In horses, such a lesion appears as a firm, often painful swelling at a neurectomy surgery site. Excision is curative.

Neurofibromas and neurofibrosarcomas (perineuromas, neurilemmomas, nerve sheath tumors, hemangiopericytomas, neurothekomas, schwannomas) are spindle-cell tumors that arise from the connective tissue components of the peripheral nerve. They are believed to arise from Schwann cells, but they could also arise from mesenchymal cells, which produce the nonmyelinated connective tissues that surround the myelinated nerve fiber. In dogs, forms of this tumor can be virtually indistinguishable from hemangiopericytomas and may be the same tumor.

In dogs and cats, peripheral nerve sheath tumors of the skin are found in older animals. In cattle, they have a suspected genetic basis, may be multiple, can develop in both the young and old, and are generally an incidental finding at slaughter; they arise from the deep nerves of the thoracic wall and viscera, and cutaneous involvement is rare. Regardless of the species, these tumors appear as white, firm, nodules. Attachment to a peripheral nerve may occasionally be noted. Both benign and intermediate-grade malignant variants are recognized. Benign tumors are most common in cattle in which, because of their

indolent nature, treatment is optional; also, additional tumors often develop spontaneously at other sites over time. In dogs, cats, and horses, most are locally infiltrative but do not metastasize. Complete excision is the treatment of choice. When margins are narrow or insufficient, followup radiation therapy, postoperative intralesional tumor bed chemotherapy (using the patient's serum mixed with the chemotherapy agent), electrochemotherapy, or systemic chemotherapy with carboplatin or metronomic chemotherapy may increase the tumor-free interval.

Adipose Tissue Tumors

Lipomas are benign tumors of adipose tissue, perhaps more accurately characterized as hamartomas. They are common in dogs, occasionally identified in cats and horses, and rare in other domestic species. In dogs, they generally develop in older, obese females, most commonly on the trunk and proximal limbs. The breeds most at risk are Doberman Pinschers, Labrador Retrievers, Miniature Schnauzers, and mixed-breed dogs. Older, neutered male Siamese cats are predisposed, and tumors are most commonly found on the ventral abdomen. Obesity does not appear to be a factor in the development of lipomas in cats. Affected horses are generally <2 yr old. Lipomas typically appear as soft, occasionally pedunculated, discrete nodular masses, and most are freely movable. In dogs and cats, >5% are multiple. In general, these tumors float when placed in formalin.

A rare variant of this tumor, **diffuse lipomatosis**, has been identified in Dachshunds. Virtually the entire skin is affected, resulting in prominent folds on the neck and truncal skin. Many lipomas merge imperceptibly with the adjacent non-neoplastic adipose tissue, making it difficult to determine when the entire lesion is excised. Lipomas with an abundant connective tissue stroma (fibrolipomas), cartilaginous stroma (chondrolipomas), or a prominent vascular component (angiolipomas) are also recognized. Despite their benign nature, lipomas should not be ignored because they tend to enlarge over time, and their gross presentation may be indistinguishable from that of infiltrative lipomas or liposarcomas (see below). Excision is curative. In dogs, dietary restriction to 70% of normal intake for several weeks before surgery may allow for better definition of the surgical margins of the tumor.

Infiltrative lipomas (intra- and intermuscular lipomas) are rare in dogs and

even less common in cats and horses. In dogs, they are most common in middle-aged females, usually on the thorax and limbs. The breeds (dogs) most at risk are the same as those for lipomas. These tumors are poorly confined, soft, nodular to diffuse swellings that typically involve the subcutaneous fat and underlying muscle and connective tissue stroma. Infiltrative lipomas, which dissect along fascial planes and between skeletal muscle bundles, are considered sarcomas of intermediate malignancy. They rarely metastasize. Aggressive excision is recommended, and amputation may be necessary.

Liposarcomas are rare neoplasms in all domestic animals. Most are recognized in older male dogs in which they usually develop on the trunk and extremities; Shetland Sheepdogs and Beagles may be predisposed. In cats, feline leukemia virus infection has been infrequently associated with their development; whether this is a coincidence or such infections play a causative role remains unclear. Liposarcomas are nodular and soft to firm. They may exude a mucinous fluid when sectioned. Many have palpable, partially encapsulated areas, but these zones should not be construed as evidence of a benign tumor. Liposarcomas are malignant neoplasms that have a low metastatic potential but are frequently pseudoencapsulated. Wide excision is recommended. Recurrence is common, so followup radiation therapy is indicated in cases with insufficient margins.

Vascular Tumors

Hemangiomas of the skin and soft tissues are benign proliferations that closely resemble blood vessels. Whether these are neoplasms, hamartomas, or vascular malformations remains undefined, and no clear criteria exist that allow for their separation. They are most commonly identified in dogs, occasionally in cats and horses, and rarely in cattle and pigs; they are an exceptional finding in other domestic animals. In dogs, they are tumors of adult dogs and most commonly develop on the trunk and extremities. Many canine breeds (including Gordon Setters; Boxers; and Airedale, Scottish, and Kerry Blue Terriers) are considered to be at risk. Cats most frequently develop hemangiomas when they are adults. Lesions are most common on the head, extremities, and abdomen. In horses, they are most common on the distal extremities of young (<1 yr old) animals. In cattle, they may be seen as congenital lesions or in older animals. Dairy cattle are

predisposed to developing disseminated hemangiomas (angiomatosis) in the skin and internal organs. In pigs, these lesions generally develop in the scrotal or perineal skin of Yorkshire, Berkshire, and less commonly Chester White boars. In the first two breeds, the disease is believed to be genetically transmitted. Hemangiomas are single to multiple, circumscribed, often compressible, red to black nodules. The lining epidermis may be unaffected or ulcerated or papillated. Small, superficial hemangiomas that often appear as a "blood blister" are known as angiokeratomas. When erythrocytes are sparse or absent within vascular lumens, the term lymphangioma is applied. Hemangiomas are benign, but their tendency to ulcerate and grow quite large, along with the importance of confirming the diagnosis to make a prognosis, indicate removal. Excision is the treatment of choice; however, in large animals in which the lesions may be large and involve the distal extremities, this may be difficult. In these cases, cryosurgery or radiation therapy may be necessary. Except in dairy cattle with angiomatosis, development of additional tumors at new sites after complete excision is uncommon.

Hemangiopericytomas (canine spindle-cell sarcoma, canine malignant fibrous histiocytoma, canine neurofibrosarcoma, canine perineuroma) are common in dogs and rare in cats (if they occur at all). This tumor was initially named because it was thought to be derived from fibroblastic cells that surround small vessels; however, the appropriateness of the name remains a topic of debate. These tumors develop most commonly on the distal extremities and thorax of older dogs. Females appear to be predisposed, and Siberian Huskies, mixed-breed dogs, Irish Setters, and German Shepherds are most at risk. Hemangiopericytomas typically present as firm, multilobulated, solitary lesions with irregular borders, most commonly in the subcutaneous fat but sometimes in the dermis. They are of intermediate malignancy and have limited metastatic potential. Complete excision with adequate margins is the treatment of choice but, because of the infiltrative nature of these tumors, excisions are incomplete or margins are narrow in most surgeries; therefore, ~30% recur. If the first excision of any sarcoma does not have adequate margins, ie, clean, wide surgical margins ("complete" may include narrow margins not considered adequate for local tumor control), followup surgery to remove the tumor bed and increase the margins is indicated. At surgery, intracavitary

chemotherapy with carboplatin or 5-fluorouracil mixed with the patient's serum, and/or intraoperative radiation therapy with followup intratumor bed chemotherapy, and/or followup radiation therapy may increase the tumor-free interval.

Angiosarcomas, arguably the most aggressive of all soft-tissue tumors, are composed of cells that have many functional and morphologic features of normal endothelium. Although these tumors are often divided into hemangiosarcomas (of purported blood vessel origin) and lymphangiosarcomas (of lymphatic vessel origin), such a distinction is arbitrary. The term **angioendothelioma** is also used. These tumors generally arise spontaneously. In the nonpigmented skin of dogs with short, often white coats, chronic solar injury may induce transformation in the superficial vascular plexus, which initially appears as a hemangioma and then progresses to a malignant vascular tumor. The light-skinned breeds prone to actinically induced dermal angiosarcomas are Whippets, Italian Greyhounds, White Boxers, and Pit Bulls. Pathologists often diagnose these lesions as cutaneous hemangiosarcomas. Because histogenesis of dermal hemangiosarcoma is often related to that of chronic solar irritation, predisposed breeds should be protected from sun exposure. Dermal hemangiosarcomas have a moderately high potential for malignancy; therefore, wide surgical excision is the treatment of choice for tumors >0.5 cm. Cryosurgery or laser surgery can effectively control multifocal, small, early lesions. When metastasis occurs, it is by the hematogenous route to the lungs and spleen. Up to one-third of splenic hemangiosarcomas arise in the skin or peripheral tissue and end up in the spleen because of splenic filtering of cells in the bloodstream.

Angiosarcomas of the skin and soft tissues are seen in all domestic animals but are most common in dogs, generally in adult or aged animals. In dogs, they most frequently develop on the trunk, hip, thigh, and distal extremities. In addition to the breeds prone to actinically induced angiosarcomas, Irish Wolfhounds, Vizslas, Golden Retrievers, and German Shepherds are also at risk. In cats, this tumor is seen most commonly in older, neutered males, on the extremities and trunk. Cats with skin, subcutaneous, or visceral involvement develop distant metastasis. Angiosarcomas can vary markedly in appearance. Most commonly, they appear as one or more erythematous nodules present anywhere in

the skin or underlying soft tissues. Less frequently, they appear as a poorly defined bruise. All grow rapidly, often are associated with large zones of necrosis and thrombosis, and typically are red to black on cut section. Tumors often diagnosed as lymphangiosarcomas may have much less luminal blood, and the vascular spaces are typically filled with serum. Characteristically, angiosarcomas create their own vascular space by dissecting through soft tissues. Distant metastasis, especially to the lungs and liver, is common. In other domestic animals, these tumors do not appear to behave as aggressively, and postexcisional recurrence rather than metastasis is more common.

For all species, because of the aggressiveness of these nodules, wide excision with intraoperative placement of carboplatin beads or intracavitary carboplatin mixed with the patient's serum may be the treatment of choice. Solar-induced canine cutaneous hemangiosarcomas generally do not have an aggressive biologic behavior, although numerous lesions may continue to appear over a period of several years. Superficial lesions are easily destroyed with topical cryotherapy, which may control the disease for years; however, if lesions become large (>1 cm) or cystic, they are best controlled with excision. If multiple cystic lesions appear, the animal may benefit from a combination of local control and antiangiogenic therapy. Avoidance of further sun irradiation injury may reduce the development of new lesions; however, previously exposed skin may continue to develop lesions as a result of "field cancerization." Adjuvant chemotherapy consisting of vincristine, doxorubicin, and cyclophosphamide (the VAC protocol) has been reported to shrink angiosarcomas;

Solar-induced cutaneous hemangiosarcoma, older Bulldog. Lesions appear as multiple, red, flat or blood-filled cysts in sun-exposed nonpigmented skin. Courtesy of Dr. Alice Villalobos.

carboplatin is also helpful. However, the effects of chemotherapy for systemic control or radiation therapy for local control and longterm survival remain to be defined. Electrochemotherapy delivering bleomycin and platinum-containing drugs into tumors has shown cytotoxic efficacy leading to endothelial cell death in 1 to 3 treatment sessions under heavy sedation. These agents may also be administered intraoperatively. The role of NSAIDs such as piroxicam, meloxicam, etc, is still not completely understood and may vary from drug to drug. Antiangiogenic or angiostatic compounds such as canine recombinant canstatin that attack the blood supply of tumors may control and prevent metastases; however, results of clinical trials remain elusive.

Cutaneous Smooth Muscle Tumors

Because they either are not recognized or do not develop with any regularity in domestic animals, cutaneous smooth muscle tumors (leiomyomas or leiomyosarcomas) are diagnosed rarely. Those reported generally have been malignant and found in dogs and cats. Usually, they are firm cutaneous masses. Leiomyomas are small and tend to be limited to the dermis, whereas leiomyosarcomas are larger and most arise from (or extend into) the subcutaneous fat. The behavior of malignant smooth muscle tumors remains poorly defined. Complete excision is the treatment of choice for both leiomyomas and leiomyosarcomas. They have been responsive to vincristine chemotherapy given IV weekly for 6 wk then tapered; they may also respond to oral masitinib therapy and other tyrosine-kinase inhibitors.

UNDIFFERENTIATED AND ANAPLASTIC SARCOMAS

These malignant mesenchymal tumors are difficult to characterize microscopically. Undifferentiated sarcomas lack distinctive features (eg, architectural patterns, cytoplasmic and nuclear features, cell products). Anaplastic sarcomas have most of the following features: variations in size and shape of nuclei, nuclear hyperchromasia, striking irregularity of chromatin pattern, abnormal mitotic figures, and large numbers of mitotic figures. As such, anaplastic sarcomas are generally undifferentiated, but undifferentiated sarcomas do not have to be anaplastic. In both cases, excision should be deep and wide, with 3-cm margins along with a

combination of the intraoperative and followup oncologic therapy techniques described above, because the first surgery with immediate followup is most important in determining outcome. The prognosis is generally poorer for anaplastic sarcomas than for undifferentiated sarcomas.

LYMPHOCYTIC, HISTIOCYTIC, AND RELATED CUTANEOUS TUMORS

Lymphoid Tumors of the Skin

Canine extramedullary plasmacytomas (atypical histiocytomas, cutaneous neuroendocrine tumors [see p 952], reticulum cell sarcomas, cutaneous nodular amyloidosis) are relatively common cutaneous tumors. Although their derivation was long debated, neoplastic cells characteristically express cytoplasmic immunoglobulin and may produce primary amyloid, leaving little doubt as to their lymphoplasmacytic origin. These tumors of dogs and, rarely, cats are most frequently identified on the head (including ears, lips, and oral cavity) and extremities of mature to aged animals. Cocker Spaniels, Airedales, Scottish Terriers, and Standard Poodles are most at risk. The tumors are generally small (<5 cm) and sometimes pedunculated. Most of these tumors are locally confined, and complete but conservative surgical excision is the treatment of choice. Infrequently, extracutaneous plasmacytomas may be locally invasive or multiple (or both), especially when they occur in the oral cavity. Recurrence has also been correlated with the presence of amyloid (see p 592). Treatment for these tumors targets local control using localized techniques described above. For recurrent, invasive tumors, more aggressive attempts at excision may be required. When tumors are multiple or when surgical excision is not feasible, radiation therapy appears to be the best secondary treatment. For tumors resistant to radiation and for those animals unable to receive radiation therapy, systemic treatment with chemotherapeutic agents, including melphalan, chlorambucil, cyclophosphamide, and glucocorticoids, have been recommended and have yielded longterm survival.

Cutaneous lymphosarcoma may occur as a disease in which the skin is the initial and primary site of involvement, or it may be secondary to systemic, internal disease. (See also CANINE MALIGNANT LYMPHOMA, p 40; BOVINE LEUKOSIS, p 743; and FELINE LEUKEMIA VIRUS AND RELATED DISEASES, p 790.)

Cutaneous lymphosarcoma is uncommon but has been identified in all domestic species. In general, two distinct forms are recognized—an epitheliotropic form (in which there is infiltration by malignant lymphocytes into the epidermis and adnexa) and a nodular, nonepitheliotropic form. Both usually express surface and cytoplasmic antigens characteristic of T cells; this, along with the frequent identification of at least small foci of epitheliotropism in many cases of "nonepitheliotropic" forms in dogs and cats, suggest they may be different variants of the same tumor.

Epitheliotropic cutaneous lymphosarcoma (ECL, mycosis fungoides) is the most frequently recognized form of cutaneous lymphosarcoma in dogs and arguably cats. It is a disease of middle-aged and older dogs, and Poodles and Cocker Spaniels may be predisposed. Classically, the lesions progress from patch to plaque to tumor; however, one or any combination of these three primary lesions may be present. For example, a form of ECL known as Pagetoid reticulosis has minimal to no dermal involvement, and cutaneous lesions always appear as erythematous patches. Another common feature of the disease in dogs is the presence of areas of alopecia due to follicular atrophy caused by infiltration of neoplastic cells into the outer sheath and lumen of hair follicles. Although most cases are associated with diffuse cutaneous involvement, forms limited primarily to mucous membranes or the footpads have been identified. Because of the variable clinical appearance of this tumor, diagnosis based on clinical features can be very difficult, and early stages can be confused with allergic, autoimmune, endocrine, infectious, or seborrheic diseases. Most cases are limited to the cutis until late in the course of the disease. ECL with concurrent leukemia is known as Sézary syndrome.

In dogs, ECL is a slow to moderately progressive disease for which a number of therapies have been attempted. To date, all appear more effective in improving the clinical features of the disease than in prolonging an affected dog's life. Methchlorathamine (nitrogen mustard) has been used in the past as a topical therapy, but because large areas of a dog's body may be affected (including the mucous membranes) and because of its sensitizing potential in people, it is infrequently used. The disease is often transiently responsive to steroids. Chemotherapeutic agents, such as combinations of adriamycin, chlorambucil, cyclophosphamide, doxorubicin, and vincristine, are variably effective. Lomus-

tine (an alkylating nitrosourea), retinoids with and without glucocorticoids, and high-dose linoleic acid supplementation (safflower oil at 3 mL/kg, 3 consecutive days/wk) may occasionally achieve partial or complete remission. Studies show that a lymphocyte T-cell immunomodulator, which signals the differentiation of late stage CD₄ lymphocytes and causes apoptosis of malignant T cells, is a reasonable adjunctive therapeutic agent to use and may improve the clinical course in some cases.

ECL is rare in cats and tends to develop in older animals. Lesions often follow a defined progression, appearing initially as a crusty plaque that is variably pruritic. Biopsies of early lesions are often diagnosed as lymphocytic mural folliculitis. In many cases in which this diagnosis is applied, the lesions evolve into unequivocal cutaneous lymphosarcoma. In contrast to ECL in dogs, epitheliotropism is often extremely subtle in cats. Little is known about therapy or whether therapy used in dogs would be effective if used in cats; however, since the availability of a lymphocyte T-cell immunomodulator for use in cats with feline leukemia virus, it can be offered as a viable option.

Nonepitheliotropic cutaneous lymphosarcoma (NECL) is the most recognized form of cutaneous lymphosarcoma in all domestic animals but dogs and cats. In dogs, NECL is most common in middle-aged or older animals. Lesions are nodules or plaques that most commonly develop on the trunk. They generally are multiple, although solitary lesions may be noted, especially in cats. In many cases, NECL is grossly indistinguishable from the tumor stage of ECL. A definitive diagnosis is important because NECL in dogs is generally more aggressive than ECL, and systemic involvement occurs commonly and early in the course of the disease. Various modes of therapy, including excision, chemotherapy, and less frequently radiotherapy, have been used as monotherapy and in combination. Excision is the choice when the disease is limited to a solitary tumor, and complete cures have occasionally been obtained. Excision or cryosurgery in more diffuse forms infrequently elicit longterm remissions. Chemotherapy or chemoinmunologic protocols used for other forms of canine lymphosarcoma should be considered as palliative. The average remission time is ~8 mo.

In cats, NECL is a rare disease of middle-aged or older animals. The role of

feline leukemia virus remains undefined. The lesions are plaques or nodules that may be solitary or multiple, alopecic or haired, and ulcerated or lined by an intact epidermis. Feline NECL is aggressive; even when complete excision of a solitary nodule is attempted, recurrence is common. No definitive therapy is known; however, using a combination of lomustine, steroids, linolenic acid (oil of evening primrose), and injections of a lymphocyte T-cell immunomodulator may be of some value.

In horses, NECL (nodular lymphosarcoma, subcutaneous lymphosarcoma, lymphohistiocytic lymphosarcoma) may be recognized at any age but is most common in young and middle-aged animals. Firm, nonulcerated nodules are most common in the subcutaneous fat of the ventral body surface. Microscopically, two types of nodular lymphosarcoma are recognized in horses. The most common consists of a mixture of histiocytes and small, well-differentiated lymphocytes, occasionally with plasmacytoid features; the second consists of a monomorphic population of large atypical lymphocytes, with only occasional histiocytic cells. Differentiation between these two forms is important because most cases of cutaneous lymphosarcoma in horses with a monomorphic pattern of cells have internal involvement, and the disease progresses rapidly. In contrast, the lymphohistiocytic form seldom is associated with internal involvement, and affected horses may live for years. As the lymphohistiocytic form progresses, the nodules tend to become more frequent on the ventral cervical regions. In many cases, euthanasia may be warranted when pharyngeal involvement induces dyspnea. Because of the expense of cytotoxic drugs, therapy is generally limited to glucocorticoids administered orally or intralesionally; remission, if induced, is usually short term.

In cattle, cutaneous lymphosarcoma is a disease of young animals (generally <4 yr old). It is one of the sporadic bovine leukosis syndromes that is not transmissible. The term sporadic bovine leukosis is usually reserved for calf, cutaneous, and thymic types of lymphoma, which are defined by the young age of occurrence and the distribution of tumors. The cause or causes are not known. Only lymphomas caused by bovine leukemia virus infection should be termed leukosis or enzootic bovine leukosis. There may also be lymphosarcomatous conditions that do not fall into either the sporadic or enzootic bovine leukosis categories, ie, adult multicentric lymphoma with sporadic

occurrence of unknown etiology. Cutaneous lymphosarcoma of young cattle is presumed not to be associated with bovine leukemia virus infection (see p 743) and presently has an unknown etiology. The lesions are typically nodular, involve the dermis or subcutaneous fat, and are often ulcerated. There is no known therapy.

Cutaneous Mast Cell Tumors

(Mastocytomas, Mast cell sarcomas)

These tumors are the most frequently recognized malignant or potentially malignant neoplasms of dogs. In addition, visceral and leukemic forms can occur. A viral etiology has been speculated but remains controversial. Tumors may be seen in dogs of any age (average 8–10 yr). They may develop anywhere on the body surface as well as in internal organs, but the limbs (especially the posterior upper thigh), ventral abdomen, and thorax are the most common sites; ~10% are multicentric. However, studies suggest that multiple tumors do not carry a worse prognosis when they are all adequately excised if grade 1 or low grade. Initial size at the time of surgery is highly predictive of outcome; tumors >3 cm correlate with decreased survival time. Tumors that are incompletely excised, grow rapidly, or arise from mucocutaneous junctions, muzzle, ventrum, prepuce, or subungual areas or in animals with clinical signs at diagnosis are associated with more aggressive biologic behavior.

Many breeds appear to be predisposed, especially Boxers and Pugs (in which tumors are often multiple), Rhodesian Ridgebacks, and Boston Terriers. The tumors vary markedly in size, and clinical appearance alone cannot establish a diagnosis. Most commonly, they appear as raised, nodular masses that may be soft to solid on palpation. Although they often seem encapsulated, mast cell tumors in dogs are seldom discrete. Rather, they consist of a highly cellular center surrounded peripherally by a halo of smaller numbers of mast cells that palpate as normal skin. Dogs can also develop clinical signs associated with the release of vasoactive products from the malignant mast cells. Most common is gastroduodenal ulceration that may be present in up to 25% of cases. Cytologic evaluation of Wright-stained, fine-needle aspirates or impression smears can be used to establish the diagnosis of mast cell tumors in dogs. All skin tumors should be examined by fine-needle aspiration cytology before excision to exclude mast cell tumor. If the surgeon is

aware that the tumor is of mast cell origin, a surgical plan for wide and deep excision will yield the best results. All mast cell tumors should be submitted for biopsy to determine margins and grade, because cytology is not a substitute for histopathology—only the latter has been well correlated with prognosis. However, certain cytologic features can be used to identify high-grade tumors. Two systems of histopathologic grading have been defined, the Bostock system of 1973 and the Patnaik et al system of 1984. To avoid confusion, it is essential to know which system is being used. The commonly used Patnaik grading system has the following designations: grade I = low grade, grade II = intermediate grade, grade III = high grade. Up to 80% of canine mast cell tumors are classified as grade II and are further divided into subgroups of low grade II (mitotic index ≤ 5) and high grade II (mitotic index > 5) along with characteristics that may predict clinical behavior in this large category.

Although there is believed to be a benign variant of canine mast cell tumor, there is no clinical or microscopic means of identifying it. In addition, small mast cell tumors may remain quiescent for long periods before becoming aggressive. A subcutaneous variant of canine mast cell tumor, which does not have a primary infiltrative dermal involvement, occurred in ~10% of biopsied tissues in one study. This variant appeared most frequently in the hindlimb, with 66% having incomplete excision, most commonly at the deep margin. These tumors have intermediate histologic grade, a lower rate of recurrence (only 9%), and extended mean survival times, with only a 6% rate of metastases.

Up to 65% of incompletely excised mast cell tumors do not recur. This suggests that their biologic behavior is not always aggressive and that aggressive treatment may not always be warranted. Specialized stains can be used to distinguish tumor grades more adequately. Proliferation marker expression can help determine the likelihood that an incompletely removed mast cell tumor will recur or metastasize. The combination of Ki-67 > 23 /grid; proliferating cell nuclear antigen, Agnor count > 54 ; mutations in exon 8 and exon 11 of c-Kit gene; and increased PCNA levels are prognostic for local recurrence and a poor prognosis. Correlation of test results with survival times can be useful but is not always a reliable predictor of the outcome. There is agreement on cytologic features for high-grade mast cell tumors: seven or more mitotic figures/10 high-power fields (hpf),

three multinucleated cells/10 hpf, three bizarre nuclei/10 hpf, and karyomegaly in 10% of the cells. These high-grade features confer a prognosis of a 4-mo survival time vs > 2 yr for low-grade mast cell tumors. Because of the difficulty of subcategorizing canine mast cell tumors, all should be treated as at least potential malignancies. The Mast Cell Tumor Panel to determine prognosis and treatment guidance can be requested for grade II tumors at the Diagnostic Center for Population and Animal Health at Michigan State University.

Treatment depends on the clinical stage of the disease and the predicted aggressive biologic behavior. For Stage I tumors (a solitary tumor confined to the dermis without nodal involvement), the preferred treatment is complete excision with a wide margin; at least 3 cm of healthy tissue surrounding all palpable borders should be removed in an attempt to excise both the nodule and its surrounding halo of neoplastic cells. Intraoperative cytology (examination of impression smears at the excised tissue margins) can guide the surgeon, who should continue to remove tissue until the margins are adequate and free of mast cells. If histologic evaluation suggests that the tumor extends beyond the surgical margins, reexcision or tumor bed excision should be attempted. Because mast cells are sensitive to radiation, intraoperative radiation therapy is an option along with followup external beam radiation therapy, which may be curative if the remaining tumor is small or microscopic. Combination or multimodal treatments using radiation therapy (if affordable), with intralesional chemotherapy and/or local hyperthermia or electrochemotherapy along with systemic chemotherapy including tyrosine-kinase inhibitors, may be more effective than radiation alone to control biologically and locally aggressive mast cell tumors.

There is no agreed upon mode of therapy for Stage II-IV mast cell tumors; however, the advent of multitargeted kinase inhibitors represents a new option, which when used in combination with cytotoxic chemotherapy, requires dose reduction to avoid adverse events. Standard care options for Stage II tumors (a solitary tumor with regional lymph node involvement) include excision of the mass and the affected regional node (if feasible), prednisolone, and radiotherapy, used either singly or in combination. Triamcinolone or dexamethasone sodium phosphate, mixed with the patient's serum and injected evenly into the tissues of the tumor bed at the time of

surgery or postoperatively as a followup series, may also help reduce recurrence. Intraoperative radiation therapy and/or followup external beam therapy is still considered the highest standard of care but is often declined because of cost. Injections into the tumor bed after incomplete excision using hypotonic, deionized, or distilled water has been debated. Treatment of Stage III (multiple dermal tumors with or without lymph node involvement) or Stage IV (any tumor with distant metastasis or recurrence with metastasis) tumors is generally considered palliative. One recommended therapy is prednisolone (2 mg/kg, PO, for 5 days, followed by a maintenance dose of 0.5 mg/kg/day) or intralesional injections of triamcinolone (1 mg/cm diameter of tumor, every 2 wk). Treatment with H_1 - and H_2 -receptor antagonists for the peripheral and gastric effects of histamine, respectively, may be indicated for animals with systemic disease or clinical signs referable to histamine release. Chemotherapy with vinca alkaloids (vincristine, vinblastine), L-asparaginase, and cyclophosphamide has also been used with some effectiveness. Prednisone and vinblastine used as adjuvant chemotherapy to incomplete surgical resection conferred an apparent improvement over historical survival data using surgery alone, yielding a 57% 1- and 2-yr disease-free state and a 45% survival at 1 and 2 yr for dogs with grade III tumors. In 19 dogs on a high dose of lomustine given every 21 days, 42% of mast cell tumors showed measurable responses, ranging from stable to partial with one complete response. Neutropenia appears 7 days after treatment, with neutrophil counts of 1,500 cells/ μ L. Vincristine doses must be lowered if used in combination with multikinase inhibitors. Lomustine at metronomic doses given daily along with multikinase inhibitors may be helpful and may avoid the adverse events associated with high-dose lomustine.

Novel small molecule multikinase inhibitors such as masitinib mesylate and toceranib phosphate are available to treat mast cell tumors and have been shown to be very helpful in management of difficult cases. They inhibit the c-Kit tyrosine kinase receptor, an activated or mutated proto-oncogene associated with the development of mast cell tumors. Tissue sampling to determine the biologic aggressiveness of mast cell tumors and to look for the presence of the mutated tyrosine kinase c-Kit receptor has been recommended before starting treatment, although evidence shows that many mast cell tumors

respond regardless of their c-Kit status. A study of 202 client-owned dogs with or without prior treatment, having measurable cutaneous grade II or III mast cell tumors without nodal or visceral metastasis, found that masitinib (12.5 mg/kg/day, PO) was a relatively safe and beneficial treatment option. Another clinical trial found that toceranib (3.25 mg/kg, PO, every 48 hr), a receptor tyrosine kinase inhibitor, results in inhibition of Kit phosphorylation in canine mast cell tumors and was of clinical benefit with continued use. Note that the toceranib dosage stated on the package insert may lead to unacceptable toxicity. Veterinary oncologists are the most informed sources for clinical application using these novel tyrosine kinase inhibitor drugs against mast cell tumors, which may also benefit other malignancies.

In cats, cutaneous mast cell tumors are the second most common skin tumor; however, the disease is seen only occasionally in practice. In addition to cutaneous tumors, primary splenic, systemic, leukemic, and GI forms have been recognized. Two distinct variants of the cutaneous form occur—a mast cell type analogous to, but not identical with, cutaneous mast cell tumors in dogs, and a histiocytic type unique to cats. Feline cutaneous mast cell tumors may be either solitary or multiple. Primary splenic, systemic, recurrent, and multiple tumors (five or more) are associated with a guarded prognosis.

The mast cell type is most common. It is found primarily in cats >4 yr old and may develop anywhere on the body but most commonly on the head and neck. The tumors are single, alopecic nodules, generally 2–3 cm in diameter, that occasionally extend into the subcutaneous fat. Lymphoid nodules are common; eosinophils are rare. Unlike mast cell tumors in dogs, those in cats are generally benign; atypia and clinical behavior are poorly correlated. Surgical excision is the treatment of choice; 30% of tumors recur after surgery and some metastasize. Cryotherapy may be a good option to treat multiple recurrent small lesions to avoid anesthesia. Recurrent tumors may respond to chemotherapy, radiation therapy, and novel small molecule targeted therapy (see above).

The histiocytic type of cutaneous mast cell tumor in cats is recognized primarily in Siamese cats <4 yr old. Lesions may develop anywhere on the body and appear as multiple (miliary), small (generally 0.5–1 cm in diameter), firm, subcutaneous papulonodules. Usually, the older the cat, the fewer

the lesions. This variant may be difficult to distinguish morphologically from a granulomatous inflammatory response. Because some of these tumors are reported to resolve spontaneously, treatment may not be necessary.

In horses, mast cell tumors are uncommon and generally benign, although metastasis has been reported and should be considered. There has been debate as to whether mast cell tumors are actually a neoplastic process or an unusual inflammatory response; however, they are currently considered a neoplastic process caused by a gain of function mutation of the Kit proto-oncogene. Lesions may develop anywhere on the body but are most common on the head and legs. Typically, there is a single, solitary mass in the dermis or subcutaneous fat that rarely expands to involve the underlying musculature. Erythema and wheal formation (Darrier sign) is not a clinical feature of equine mastocytoma. Most affected horses are male, with an average age of 7 yr (range 1–18 yr). The tumor begins as a nodule composed of a generally monomorphic proliferation of mast cells. As the lesion evolves, the mast cells are limited to aggregates in a fibrous stroma that surrounds large foci of liquefactive necrosis containing numerous eosinophils. In the late stages, the necrotic foci undergo dystrophic mineralization, and mast cells may be very difficult to identify. Once mineralization occurs, the lesion is gritty on sectioning. The classification system used to grade mast cell tumors in dogs is unreliable in horses because of the variable histologic appearance of tumors in this species. Alopecia and ulceration are variable features.

A variant of cutaneous mast cell tumor is seen in newborn foals, in which the lesions may become generalized but regress over time, suggesting an equine equivalent of urticaria pigmentosa in people.

Conventional therapy for equine metastatic mast cell cancer is suboptimal. Excision is the treatment of choice; however, lesions have been reported to metastasize occasionally. Affordable protein tyrosine kinase inhibitors or “small molecule” drugs such as masitinib mesylate and toceranib phosphate that selectively target mutated forms of the c-Kit tyrosine kinase receptors may become available in the future.

In pigs and cattle, mast cell tumors are rare. In pigs, most appear as discrete, solitary, cutaneous nodules. Most are benign but disseminated, and leukemic variants do occur. In cattle, most are malignant and characterized by multiple cutaneous nodules often accompanied by

systemic involvement; purely cutaneous forms have been recognized occasionally.

Tumors with Histiocytic Differentiation

Tumors with histiocytic differentiation comprise a group of poorly defined skin diseases all characterized by a proliferation of histiocytes (tissue macrophages) in the absence of any known stimulus.

Cutaneous histiocytomas are common in dogs and rare in goats and cattle; it is debatable whether they are found in cats. Strong immunohistochemical evidence suggests that in dogs they are derived from Langerhans (intraepidermal antigen processing) cells. These tumors are typically seen in dogs <3.5 yr old but can be seen at any age. English Bulldogs, Scottish Terriers, Greyhounds, Boxers, and Boston Terriers are most at risk. The head (including the pinnae) and limbs are the most common sites of involvement. These classic “button tumors” appear as solitary, smooth, pink, raised nodules that are generally covered by alopecic skin, or they may be ulcerated. They are freely movable. Although a common neoplasm, histiocytomas are not always easy to diagnose histologically and can be confused with granulomatous inflammation, mast cell tumors, plasmacytomas, and cutaneous lymphosarcomas. Canine histiocytomas should be considered benign, and most resolve spontaneously within 2–3 mo without treatment. Surgical excision is optional once the diagnosis is established (which can often be made via cytology).

In goats and cattle, histiocytomas are extremely rare and behave the same as those in dogs. Histiocytomas have also been reported in young cats; however, they most likely represent the histiocytic form of mast cell tumor in cats.

Cutaneous histiocytosis is associated with development of numerous plaques and nodules involving the dermis or subcutaneous fat. It is rare in dogs and can develop at any age but is most common in young adults. Chinese Shar Pei, Collies, Border Collies, Shetland Sheepdogs, Briards, Bernese Mountain Dogs, Golden Retrievers, and German Shepherds may be predisposed. Shar-Pei have excessive skin folding and severe cutaneous mucinosis due to an accumulation of dermal hyaluronan, a protein associated with angiogenesis and tumor cell motility. The nodules and plaques tend to wax and wane, and the extremities and trunk are involved most commonly. Lesions also occur on the face and nasal

planum, and swelling of the nares may cause difficulty breathing. Lesions are nonpruritic, and larger lesions may ulcerate. Cutaneous histiocytosis seldom involves internal organs, but its diffuse nature and the unsightly appearance often force the owner to consider euthanasia. Various forms of therapy have been tried, including systemic glucocorticoids and a combination of glucocorticoids and chemotherapy and more recently in combination with masitinib and other tyrosine kinase inhibitors. Leflunomide without steroids has been used as well as azathioprine and cyclosporine. Response is variable; the lesions in some dogs respond rapidly and permanently, whereas in others, lesions are either transiently improved or unchanged.

The histiocytoses of Bernese

Mountain Dogs are systemic, familial disorders of unknown etiology with two manifestations: a more indolent and generally cutaneous form known as systemic histiocytosis and a more aggressive form in which skin lesions are rare, known as malignant histiocytosis. Malignant histiocytosis has been infrequently identified in other canine breeds. In systemic histiocytosis, males (mean age at onset 4 yr) are affected more often than females. There are multiple cutaneous nodules, papules, and plaques involving the skin (especially of the scrotum), nasal mucosa, and eyelids. The lesions are poorly circumscribed and variably alopecic and may be ulcerated; they develop in waves and slowly regress, only to recur several months later. The clinical disease tends to become more severe with each new wave of eruptions. Although the skin is the primary target organ, lesions may also develop in other organs, including lymph nodes,

spleen, and bone marrow. The disease may be episodic in its clinical presentation, but it is progressive and eventually fatal.

Malignant histiocytosis is seen in male Bernese Mountain Dogs (mean age at onset 7 yr) and, less frequently, in other canine breeds. The lungs, lymph nodes, and liver are the most common organs affected, and the disease tends to spare the skin. Grossly, the lesions appear as large, solitary, firm masses that may cause pleural effusion or efface large portions of affected internal organs. The disorder is rapidly progressive and does not wax and wane as does systemic histiocytosis. Few dogs survive >6 mo.

Various chemotherapeutic regimens mentioned above have been used to treat both forms; hopefully, masitinib and other tyrosine kinase inhibitors used in combination with vincristine or other combinations of antineoplastic drugs will be of benefit. Bovine thymosin fraction 5 may help induce remissions, especially in the systemic form. However, both forms of the disease are ultimately fatal.

Transmissible Venereal Tumors

See also CANINE TRANSMISSIBLE VENEREAL TUMOR, p 1408. These can also develop initially on haired skin due to inoculation via cutaneous injuries.

TUMORS OF MELANOCYTIC ORIGIN

These tumors are most common in dogs, gray horses, and miniature pigs; uncommon in goats and cattle; and rare in cats and sheep. The terminology used to describe melanocytic lesions in veterinary medicine is different from that used in human dermatology. In animals, the terms melanocytoma and malignant melanoma are used to describe benign and malignant melanocytic proliferations, respectively. In people, a benign melanocytic proliferation (whether congenital or acquired) is called a nevus, and the term melanoma by definition refers to a malignancy (ie, in people, there are no benign melanomas). In addition, although solar injury is a common cause of melanocytic tumors in people, actinic damage is seldom associated with development of analogous tumors in domestic animals.

Dogs: Melanocytomas of the skin are diagnosed much more frequently than

Malignant histiocytosis and pleural effusion in thorax of a dog. Courtesy of Dr. Alice Villalobos.

malignant melanomas. They most commonly develop on the head and forelimbs in middle-aged or older dogs. There may be a predilection for males. Miniature and Standard Schnauzers, Doberman Pinschers, Golden Retrievers, Irish Setters, and Vizslas are the breeds in which these tumors are most commonly recognized. They can appear as macules or patches; as papules or plaques; or as elevated, occasionally pedunculated masses. Most have a pigmented surface. Although generally solitary, lesions may be multiple, especially in the breeds at risk. These tumors are benign, and complete excision is curative.

Malignant melanomas most commonly develop in dogs somewhat older than those that develop melanocytomas. Miniature and Standard Schnauzers and Scottish Terriers are most at risk. The mucocutaneous junctions of the lips, in the oral cavity (*see* p 366), and in the nail beds are the most common sites of development. Malignant melanomas of haired skin are rare, and most arise on the ventral abdomen and the scrotum. Males are affected more commonly than females. Most malignant melanomas appear as raised, generally ulcerated nodules that are variably pigmented depending on the melanin content; some malignant melanomas are amelanotic. When present on the mucocutaneous regions of the lip, the tumors may be pedunculated with a papillated surface; when present in the nail bed, they appear as swellings of the digit, often with loss of the nail and destruction of underlying bone, mimicking osteomyelitis. Whenever a toe is festering in an older dog, radiographs and a deep punch biopsy that includes bone are indicated for diagnosis. Canine malignant melanomas are locally aggressive and have a high potential for metastasis; however, there is considerable variability in reported survival times. Reported median survival times for dogs with oral malignant melanomas treated with definitive surgery alone are 511 days for WHO stage I disease, 324 days for stage II, and 336 days for stage III disease. A comprehensive study found that up to 32% of oral melanocytic tumors in dogs exhibited less aggressive biologic behavior, which emphasizes the need to accurately classify them in clinical trials.

Treatment generally consists of complete excision; however, the infiltrative nature of the tumor may make achieving adequate margins difficult. When present on the digits, amputation is indicated; when present on the mandible, a hemimandibulectomy may allow for

complete excision with adequate margins and an acceptable postsurgical cosmetic appearance and survival. Lesions at rostral locations on the maxilla or mandible allowed the best survival times of 10.9 mo in one study. Melanomas are generally considered insensitive to radiation therapy, and there is no established chemotherapeutic protocol shown to be highly effective. Survival times range from 1–36 mo, indicating that individual variations in host defense mechanisms and aggressiveness of the tumor may play a role in establishing a prognosis. The nuclear protein Ki67 has been established as a highly sensitive and specific immunohistochemical marker for predicting the outcome of oral malignant melanoma, with indices >19.5 corresponding to lower survival times. A mitotic index of >4/10 high-power field and a nuclear atypia score of >30% also indicate poor survival times. In one study of 117 dogs with digit masses, 24 had melanoma and a median survival time of 12 mo, with 42% alive at 1 yr and 13% alive at 2 yr.

A series of novel xenogeneic gene therapy vaccinations using plasmid DNA encoding human tyrosinase can induce an immune response in dogs, resulting in antibody and cytotoxic T-cell responses that may shrink their melanomas. A canine melanoma vaccine was shown to have potential therapeutic value for dogs as an adjuvant therapy for completely removed oral melanoma and for some advanced malignant melanoma cases in clinical trials in the New York area. It was conditionally licensed in the USA in 2007; however, no benefit was found in a study that followed 23 vaccinated dogs and 17 nonvaccinated dogs in Michigan. A clinical trial using masitinib in combination with the canine melanoma vaccine in dogs with melanomas expressing mutated c-Kit and another study that adds doxorubicin for nonmutated c-Kit are being evaluated for efficacy. Chondroitin sulfate proteoglycan-4 is an immunohistochemical biomarker and a potential immunotherapeutic target for canine malignant melanoma, as in people.

Cats: Cutaneous melanocytic neoplasms are uncommon and most often identified on the head (especially the pinnae), neck, and distal extremities in middle-aged or older cats. An association with the oral cavity and subungual regions is less well defined than in dogs, and a higher percentage are malignant. Excision is the treatment of choice.

Horses: Most melanocytic neoplasms are in gray horses, in which the coat turns gray (or white) with age. They are especially common in Lipizzaners, Arabians, and Percherons, and 80% of gray or white horses of these breeds may be affected. They are generally recognized in older horses but usually begin their development when animals are 3–4 yr old. The perineum and the base of the tail are the most common sites of development, but these tumors may develop in any location, including the parotid area. The tumors are often multiple and may appear as coalescent, frequently pedunculated nodules that often extend in a linear arrangement up the tail base. They increase in size and number over time. Although most are benign, invasive variants, some with metastatic potential, can develop. Most are black on cross-section. Many gray horses have evidence of lymph node involvement; however, there is debate as to whether this represents metastasis or whether the intranodal melanocytes and melanophages represent a stimulation of extracutaneous melanocytes that are normally present in the lymph node. Treatment consists of surgical or cryosurgical removal; however, affected horses are predisposed to develop additional tumors over time. Little is known about the use of radiation or chemotherapy for the treatment of equine melanocytoma or malignant melanoma. Cimetidine was reported to be of value in controlling recurrence, but followup studies did not find benefit. Electrochemotherapy or intralesional chemotherapy with cisplatin or carboplatin after surgical debulking may be of benefit in the treatment of large or inoperable masses. Recurrent tumors do not develop resistance to cisplatin, and they can be treated a second time, sometimes with good results.

Melanocytic neoplasms of nongray horses are rare tumors usually found on the trunk and extremities of young (often <2 yr old) horses. They may represent expansion of a congenital lesion. Masses characteristically appear as solitary nodules. Most are benign; however, congenital malignant melanomas may infrequently develop. Such tumors are invasive, with little metastatic potential. Surgical excision or cryosurgery is the treatment of choice. If the tumors are benign and surgically extirpated, the prognosis is excellent. For invasive tumors, the prognosis is guarded.

Pigs: Melanocytic neoplasms of pigs are seen as congenital lesions and sporadically in adults of the Sinclair (Hormel) miniature

pigs and Duroc and Duroc crosses. Selective breeding in these strains has increased the prevalence of tumors. These tumors develop both pre- and postnatally, anywhere on the body. Generally multiple, they can appear as pigmented macules or patches with smooth borders; as raised, often ulcerated pigmented lesions; or as deeper, slightly raised, blue masses. Deeply invasive melanomas are often associated with metastatic disease. The lymph nodes and lungs are the most common sites of metastasis. Not all of these tumors become invasive, and many undergo spontaneous regression associated with an intense lymphocytic infiltrate. Melanocytic lesions in pigs are not treated; because of the heritable nature of the disease, prevention by selective breeding is recommended if lesions are frequently recognized in a herd.

Cattle: Melanocytic neoplasms in cattle develop infrequently anywhere on the body. They can be found at any age but are most commonly recognized in young animals; congenital forms have been recognized. Angus cattle appear to be predisposed. Most commonly, the tumors are large nodular masses, densely pigmented on cut surface, and benign. Excision is curative for most; however, rare malignant variants have been recognized with distant metastasis.

Sheep: Melanocytic neoplasms in sheep are most common in middle-aged or older animals but have been recognized in neonates. They are most common in Suffolks and Angoras, in which they appear as multiple, densely pigmented dermal or subcutaneous masses. They should be considered malignant; metastasis is common.

Goats: Melanocytic tumors in goats are rare. They are most common in middle-aged or older animals and possibly in Angoras. There may be a site predilection for the coronary band and udder. Lesions are seen as solitary or multiple masses with variable pigmentation on cut surface. Most tend to grow rapidly, and metastasis is common.

METASTATIC TUMORS

The spread of a primary neoplasm to the skin is unusual in domestic animals. It is occasionally identified in dogs; less commonly in cats; and rarely in horses, cows, sheep, goats, and pigs. Although all malignant neoplasms are capable of secondary cutaneous involvement, metastatic potential is greatest in mammary

gland adenocarcinomas, squamous cell carcinomas, transitional cell carcinomas, transmissible venereal tumors, pulmonary adenocarcinomas, and angiosarcomas. Although appearance is variable, the lesions most commonly are multiple, ulcerated papulonodules. Early cutaneous metastasis is characterized by aggregates of neoplastic cells within superficial and deep dermal vessels. As these lesions evolve, they extend into the dermis and are associated with effacement of adnexa. Generally, it is difficult to distinguish the primary neoplasm based on the morphologic

features of a metastatic site. This is because only a small population of cells in the primary tumor have the potential for metastasis, and these cells may have different microscopic features. In cats, pulmonary adenocarcinomas appear to preferentially metastasize to the distal extremities, and when carcinomas are diagnosed on multiple feet, radiographic examination for a primary lung tumor should be performed. Cutaneous metastasis is usually a feature of aggressive tumors and is associated with a guarded to poor prognosis.

ACANTHOSIS NIGRICANS

Acanthosis nigricans is a clinical reaction in dogs characterized by axillary and inguinal hyperpigmentation, lichenification, and alopecia.

Etiology and Clinical Findings: Acanthosis nigricans is a disorder of hyperpigmentation. There is no sex predilection. Primary acanthosis nigricans is a genodermatosis that can occur in many breeds but particularly **Dachshunds**. Clinical signs are usually present by 1 yr of age in this breed. Secondary acanthosis nigricans or postinflammatory hyperpigmentation can occur in any breed of dog and at any age; it is most common in breeds predisposed to conditions that result in inflammation of the axillary or inguinal region due to conformational abnormalities, obesity, endocrinopathies (eg, hypothyroidism; hyperadrenocorticism, sex hormone abnormalities), axillary and inguinal pruritus associated with atopic dermatitis, food allergy, contact dermatitis, primary disorders of keratinization, and skin infections (eg, staphylococcal pyoderma, *Malassezia* dermatitis).

Clinical signs start with increased pigmentation in the axillary and/or inguinal region. In primary acanthosis nigricans, the hyperpigmentation is initially diffuse and noninflammatory. It tends to develop uniformly in the affected areas. In secondary acanthosis nigricans, the distribution is patchy and often starts with a lacey appearance. It may not develop in all areas at the same time. Inflammation is mild but becomes more severe with time. Lesions of postsecondary inflammation are

not necessarily present in both the axillary and inguinal region, nor are they necessarily symmetric. In primary acanthosis nigricans, secondary inflammatory lesions (ie, lichenification) most commonly develop as a result of conformational friction. Postinflammatory hyperpigmentation is triggered by inflammation and/or friction. Lesions can develop into severe areas of hyperpigmentation, with marked lichenification, hair loss, and seborrhea. Often, these areas are odiferous and may be painful. The edges of these lesions are often erythematous; this is a sign of secondary bacterial and/or yeast pyoderma. With time, lesions may spread to the ventral neck, groin, abdomen, perineum, hocks, periocular area, and pinnae. Pruritus is variable and is usually the result of secondary microbial overgrowth (staphylococcal or *Malassezia* dermatitis) or pruritus from the underlying disease.

Diagnosis: The physical findings compatible with a clinical diagnosis of primary acanthosis nigricans are not difficult to recognize. Postinflammatory hyperpigmentation is a clinical sign of an underlying disease and should be aggressively evaluated through a careful history and physical examination to identify the underlying trigger. Skin scrapings should be performed to exclude demodicosis, and impression smears should be performed to confirm suspected bacterial and *Malassezia* infections. Postinflammatory inflammation associated with endocrinopathies is not pruritic, and testing for thyroid and adrenal

disease may be useful in older dogs; endocrine skin diseases are not pruritic unless accompanied by secondary skin infections. Intradermal skin testing and/or a food trial may be necessary. Skin biopsies are usually not necessary to confirm primary disease and are usually not helpful in identification of underlying disease associated with secondary disease, with the possible exception of primary seborrhea. In some cases, skin biopsy can identify secondary bacterial infections not previously recognized. The presence of such infections is common; secondary infections are underdiagnosed in this condition. In most cases, it is useful to treat the secondary bacterial and/or *Malassezia* infections before proceeding with other diagnostic tests.

Treatment: Primary acanthosis nigricans in Dachshunds is not curable. In some dogs, lesions do not progress beyond a cosmetic problem. If inflammation is present, early cases may respond to antimicrobial shampoo therapy and local topical glucocorticoids, eg, triamcinolone acetate spray or betamethasone valerate ointment. As lesions progress, more aggressive systemic therapy may be useful. The following systemic therapies have been used, alone or in combination, with varying degrees of success: vitamin E, 200 IU, PO, bid, for 2–3 mo; systemic glucocorticoids, 1 mg/kg/day, PO, for 7–10 days, then on

alternate days; melatonin, 2 mg/day/dog, SC, for 3–5 days, then weekly or monthly as needed. The concurrent treatment of secondary bacterial or *Malassezia* infections is helpful and is required before systemic glucocorticoids are administered; antimicrobial therapy is compatible with the other therapies. Antiseborrheic shampoos are often beneficial for removing excess oil and odor but must be used frequently (ie, 2–3 times/wk).

In postinflammatory hyperpigmentation, most of the lesions will resolve after identification and correction of the underlying cause. Some residual lacey hyperpigmentation may remain. Treatment of secondary bacterial and yeast overgrowth is critical. If the dog has not been previously treated for a staphylococcal bacterial infection of the skin, therapy with narrow-spectrum drugs based on culture and susceptibility and/or use of topical chlorhexidine spray or baths is recommended. Culture is recommended to minimize development of methicillin-resistant staphylococci. Yeast infections may be successfully treated with concurrent oral itraconazole or ketoconazole (5–10 mg/kg). Affected dogs benefit greatly from appropriate antimicrobial therapy and antiseborrheic shampoos (2–3 times/wk). If the lesions are caused by friction, emollients may be beneficial.

Clinical signs resolve slowly, possibly over months.

EOSINOPHILIC GRANULOMA COMPLEX

The cause of this group of diseases that affects cats, dogs, and horses is primarily an underlying hypersensitivity reaction. This is particularly true in cats and horses. Insect, environmental, and dietary hypersensitivities have been documented in cats, while insect hypersensitivity has been seen in some equine cases and in a smaller number of canine cases. Genetic predisposition and bacterial infections have also been noted as causes in cats. In all species, idiopathic cases exist.

CATS

In cats, three disease entities have been grouped in the complex.

Eosinophilic Ulcer: This well-circumscribed, erythematous, ulcerative lesion, often neither painful nor pruritic, is usually found on the upper lip. Some are associated with a hypersensitivity to flea bites. Although reported to occur, progression to squamous cell carcinoma is extremely rare. Histology shows an ulcerative dermatitis, with a cellular infiltrate of eosinophils, neutrophils, plasma cells, and mononuclear cells predominating. Mild to moderate fibroplasia is common. Peripheral eosinophilia is not as common as in the eosinophilic plaque or the linear granuloma. Occasional cases due to pyoderma or dermatophytes have been reported; thus, a fungal culture of the surrounding hairs is recommended.

Eosinophilic Plaque: This well-circumscribed, erythematous, raised lesion is most commonly found in the medial thigh and abdominal regions; it is extremely pruritic. Regional lymphadenopathy can be seen. Histology shows a diffuse eosinophilic dermatitis with marked epidermal inter- and intracellular edema and vesicles containing eosinophils. Mast cells may also be present in the dermis. Peripheral eosinophilia is common.

Eosinophilic Granuloma: These typically raised, well-circumscribed, yellowish to pink lesions may be found anywhere on the body but are most common on the caudal thighs and in the oral cavity. When these lesions develop on the head, face, bridge of the nose, pinnae, or pads of the feet, mosquito bites may be the inciting cause. The caudal thigh lesions are usually distinctly linear. Histologically, a granulomatous inflammatory response surrounds collagen fibers. Tissue and peripheral eosinophilia are marked when the lesions are in the mouth but vary when lesions are on the skin.

Treatment: Hypersensitivity disorders (allergy to fleas, food, or inhalants) should be investigated by instituting strict flea control, testing for environmental allergens (intradermal or in vitro), and conducting dietary elimination trials. Hyposensitization, continued insect control, and dietary management should be used when appropriate. Antibiotic therapy (amoxicillin-clavulanate, cephalosporins, or fluoroquinolones) should be tried empirically, especially in refractory cases. If no underlying cause can be determined and the condition is refractory, corticosteroids, such as methylprednisolone acetate (4 mg/kg, IM, once every 2 wk for 2–3 injections), oral prednisolone (2–4 mg/kg/day), or oral triamcinolone (0.8 mg/kg/day), can be tried. Oral corticosteroids should be tapered to alternate days (or to every third day in the case of triamcinolone) and dosages reduced when used for long-term management. Long-acting injectable methylprednisolone acetate should not be used more often than every 12 wk because of the potential to induce hyperadrenocorticism and/or diabetes mellitus. Cyclosporine (7 mg/kg/day) has been used successfully in the eosinophilic granuloma and plaque, less so in the lip ulcer. This may require laboratory monitoring (at least twice yearly) for metabolic (eg, renal) changes, although internal organ dysfunction is relatively rare.

Progestational drugs, such as megestrol acetate or medroxyprogesterone acetate, have also been effective; however, they are not recommended because of their potential adverse effects.

DOGS

In dogs, the lesions reported as eosinophilic granulomas histologically resemble the eosinophilic granuloma of cats, with marked collagen degeneration surrounded by a granulomatous and eosinophilic infiltrate. These lesions may be seen as ulcerated or vegetative masses in the oral cavity or, less commonly, as plaques, nodules, or papules on the lips and other areas of the body. Any breed may be affected, but Siberian Huskies and Cavalier King Charles Spaniels may be at greater risk.

Most lesions respond to corticosteroids, and therapy is usually oral prednisone or prednisolone (0.5–2 mg/kg/day initially, tapering the dosage throughout 20–30 days). Lesions recur in some dogs, in which case low-dose, every-other-day corticosteroid therapy is indicated.

Canine eosinophilic furunculosis is a closely related disease. It has been reported in many breeds but typically is seen in long-nosed large breeds or curious small breeds (eg, terriers) with potential access to wasps, bees, ants, spiders, etc. It is thus felt to be due to arthropod bites or stings. Consistent with this, the disease may be very rapid in onset, leading to nasal/muzzle swelling, exudation, and pain. Large, swollen erythematous lesions on the muzzle are the most common lesions, but in some dogs similar lesions may be seen on the head, periorcularly and around the pinna. Impression smears often show eosinophils. Although diagnosis is usually done on a clinical basis, histologic confirmation will show lesions similar to that of the canine eosinophilic granuloma but with more eosinophilic infiltration into the epidermis and follicular wall, a furunculosis, and fewer areas of eosinophilic debris-coated collagen. Treatment is as described for feline eosinophilic granuloma.

HORSES

In horses, the disease also has been termed equine eosinophilic granuloma with collagen degeneration, nodular necrobiosis of collagen, and collagenolytic granuloma. The lesions are nodular, nonulcerative, and nonpruritic. They often are found in the

saddle, central truncal, and lateral cervical areas and may have a gray-white central core. Older lesions may become mineralized. Both insect bites and trauma have been suggested as causes, although the occasional onset during winter in cold climates and in noncontact saddle or tack areas suggests multifactorial causes. Histology reveals multifocal areas of collagen fibers surrounded by granulomatous inflammation containing eosinophils. Thus, histologically, this lesion is similar to eosinophilic granuloma of cats and dogs.

Solitary lesions may be treated with surgical excision or sublesional corticoste-

roid injections. Mineralized lesions often require excision. Triamcinolone acetonide (3–5 mg/lesion) or methylprednisolone acetate (5–10 mg/lesion) is effective. No more than a total of 20 mg triamcinolone acetonide should be administered sublesionally at any one time because of the potential to induce laminitis. Horses with multiple lesions may be treated with oral prednisone or prednisolone at 1.1 mg/kg/day, for 2–3 wk. In horses with recurrent lesions, intradermal allergy testing, particularly with insect antigens, is recommended. Hyposensitization and insect control can be palliative in some cases.

HYGROMA

A hygroma is a false bursa that develops over bony prominences and pressure points, especially in large breeds of dogs. Repeated trauma from lying on hard surfaces produces an inflammatory response, which results in a dense-walled, fluid-filled cavity. A soft, fluctuant, fluid-filled, painless swelling develops over pressure points, especially the olecranon. If longstanding, severe inflammation may develop, and ulceration, infection, abscesses, granulomas, and fistulas may occur. The bursa contains a clear, yellow to red fluid.

If diagnosed early and if still small, hygromas can be managed medically via aseptic needle aspiration, followed by corrective housing. Soft bedding or padding

over pressure points is imperative to prevent further trauma. Surgical drainage, flushing, and placement of Penrose drains are indicated for chronic hygromas. Small lesions can be treated with laser therapy. Areas with severe ulceration may require extensive drainage, extirpation, or skin grafting procedures. Use of intrahygromal corticosteroids is not recommended. Severe lesions can develop into decubital ulcers.

Hygromas can become complicated with comedones and furunculosis. Furthermore, some dogs develop follicular cysts or calcinosis cutis circumscripta at these sites. A skin biopsy of atypical lesions or lesions that do not respond to conservative medical therapy is recommended.

MISCELLANEOUS SYSTEMIC DERMATOSES

A number of systemic diseases produce various lesions in the skin. Usually, the lesions are noninflammatory, and alopecia is common. In some instances, the cutaneous changes are characteristic of the particular disease. Often, however, the dermatosis is not obviously associated with the underlying condition and must be carefully differentiated from primary skin disorders. Some of these secondary dermatoses are

mentioned briefly below and are also described in the chapters on the specific disorders.

Dermatosis may be associated with nutritional deficiency, especially of proteins, fats, minerals, some vitamins, and trace elements. However, this is uncommon in dogs and cats fed modern, balanced diets. Siberian Huskies, and occasionally other breeds, may develop a disease similar to

parakeratosis in pigs and require additional zinc in their diet (elemental zinc at 2–3 mg/kg/day). Zinc-responsive dermatoses also have been reported in cattle, sheep, goats, and llamas and may be associated with either a higher individual requirement or a dietary deficiency. The latter may be precipitated by oversupplementation of calcium. A zinc-responsive dermatosis has also been reported in a dingo and a red wolf.

Dermatitis is sometimes seen in association with disorders of internal organs, such as the liver, kidneys, or pancreas. Hepatic parenchymal dysfunction has been associated with superficial necrolytic dermatitis (hepatocutaneous syndrome, diabetic dermatosis) in old dogs and rarely in cats. This has been associated with hypoaminoacidemia. The cutaneous lesions include erythema, crusting, oozing, and alopecia of the face, genitals, and distal extremities, as well as hyperkeratosis and ulceration of the footpads. The skin disease may precede the onset of signs of the internal disease. Histopathologic findings are diagnostic and include superficial perivascular to lichenoid dermatitis, with marked diffuse parakeratotic hyperkeratosis and striking inter- and intracellular edema limited to the upper half of the epidermis. Hyperglucagonemia has also been documented in dogs with this syndrome; however, dogs tend to have hepatic parenchymal dysfunction more commonly than glucagonomas. In dogs, therapy relies on IV or oral amino acid treatment or surgical removal of the glucagonoma. Skin fragility syndrome (excessive skin friability) in cats has been seen in association with pancreatic or hepatic neoplasia, hepatic lipidosis, or adrenal dysfunction. Pancreatic neoplasia has also been associated with crusting of the footpads and alopecia in cats. A generalized nodular dermatofibrosis syndrome in German Shepherds, and occasionally other breeds, associated with renal cystadenomas, cystadenocarcinomas, or renal epithelial cysts, has been reported. Histopathologic examination of the skin nodules reveals dense collagen fibrosis.

Poisoning by thallium sulfate (rat poisons, *see* p 3165), ergot (*see* p 3012), mercury (*see* p 3080), and iodides may cause various skin changes. Hyperkeratosis in cattle can be caused by chlorinated naphthalene toxicity.

In dogs, dermatosis can develop as a result of endocrine dysfunction (*see THE ENDOCRINE SYSTEM*, p 538 et seq). In males with Sertoli cell tumors, bilateral alopecia and occasional pruritus with a papular eruption may be

seen. Intact female dogs with hormonal imbalances are usually pruritic and have a papular eruption, mammary tissue enlargement, and frequent estrous cycles. The skin lesions of both disorders may begin in the inguinal or flank region and progress cranially. Dermatitis due to neutering is not common in dogs and cats; when it does occur, it is generally nonpruritic, with mild alopecia in the perineal or inguinal areas.

Dermatoses have been seen in hypothyroidism (*see* p 553). The skin lesions are characterized by diminished hair growth and bilaterally symmetric alopecia. The skin is dry, scaly, thickened, and sometimes cool to the touch. Pyoderma and seborrhea may occur. The margins of the pinna may develop excess scale. In rare cases, cutaneous myxedema develops.

Faulty production of hypophyseal hormones may rarely cause dermatoses. Hypopituitarism is characterized by alopecia, especially in the axillary regions and on the lateral thorax and abdomen. Hyperadrenocorticism also is manifest by skin changes such as hyperpigmentation, alopecia, seborrhea, calcinosis cutis, and secondary pyoderma. In cats, the skin becomes extremely friable. In diabetes mellitus, pruritus and secondary infection sometimes occur, especially in cats with generalized *Malassezia* sp infection.

The canine nasal mite (*Pneumonyssoides caninum*, *see* p 1480) is a parasite found in the nasal cavity and sinuses of the dog. *P caninum* infection in dogs causes nonspecific clinical signs of the upper respiratory tract, such as sneezing, reverse sneezing, rhinitis, impaired scenting ability, and pawing at the muzzle.

Rarely, underlying neurologic disorders, especially in dogs, may manifest as cutaneous lesions. These include sensory neuropathies in English Pointers and Longhaired Dachshunds, cauda equina syndrome, pseudorabies, neoplasia of peripheral nerves, and syringomyelia and/or Chiari-like malformation of Cavalier King Charles Spaniels. Clinical signs generally include pruritus and/or scratching (sometimes "air scratching" in some cases of syringomyelia/Chiari-like malformation) but also manifest as pain in the cauda equina syndrome and self-mutilation in the sensory neuropathies.

Treatment of all the above conditions depends on a specific etiologic diagnosis. Once this is established and managed, the skin lesions usually need only symptomatic care (eg, control of scratching) until they resolve with resolution of the primary disease.

NASAL DERMATOSES OF DOGS

(Collie nose, Nasal solar dermatitis)

Nasal dermatoses of dogs may be caused by many diseases. Lesions may affect the haired bridge of the muzzle, the planum nasale, or both. In pyoderma, dermatophytosis, and demodicosis, the haired portions of the muzzle are affected. In systemic lupus erythematosus or pemphigus, the whole muzzle is often crusted (with occasional exudation of serum) or ulcerated. In systemic and discoid lupus, and occasionally in pemphigus and cutaneous lymphoma, the planum nasale is depigmented, erythematous, and eventually may ulcerate. The normal "cobblestone" appearance of the nasal planum is effaced.

Nasal dermatosis due to solar radiation probably is not as common as previously thought and may often be a misdiagnosis for the lupus variants. In true nasal solar dermatitis, the nonpigmented areas of the planum nasale are affected first, and occasionally the bridge of the nose may become inflamed and sometimes ulcerated. The lesions are worse in the summer, although lupus and pemphigus may also show this seasonal variation.

Any of the diseases listed above may affect the periocular areas. (*See also* SYSTEMIC LUPUS ERYTHEMATOSUS, p 829, and

AUTOIMMUNE SKIN DISORDERS, p 827.) A sudden onset of nasal swelling, erythema, and exudation is often eosinophilic furunculosis; this is thought to be caused by an arthropod sting or bite. The protozoal disease leishmaniasis may cause depigmentation of the nasal planum.

Treatment depends on the cause. Diagnostic tests should include skin scrapings, bacterial and fungal cultures, and biopsies for both histopathology and immunologic testing, although such testing is not used as often as in the past because of the increase in veterinary dermatopathologists who may be able to make the diagnosis based on histopathology alone. If systemic lupus erythematosus is considered, blood for an antinuclear antibody test should be obtained.

If the diagnosis is nasal solar dermatitis, a topical corticosteroid lotion (betamethasone valerate, 0.1%) may help relieve inflammation. Exposure to sunlight must be severely curtailed. Topical sunscreens may be effective but need to be applied at least twice daily. Treatment for eosinophilic furunculosis is systemic corticosteroids, prednisone or prednisolone at 1 mg/kg, bid, for 1 wk, after which the dosage should be gradually decreased over the course of 1 mo.

PARAKERATOSIS

Parakeratosis is a nutritional deficiency disease of 6- to 16-wk-old pigs characterized by lesions of the superficial layers of the epidermis. It is a metabolic disturbance resulting from a deficiency of zinc (*see also* p 2337) or inadequate absorption of zinc due to an excess of calcium, phytates, or other chelating agents in the diet. Predisposing factors include rapid growth, deficiency of essential fatty acids, or malabsorption due to GI diseases.

Parakeratosis is unlikely in commercial swine unless errors have been made in diet formulation, but it may be seen in backyard pigs. The widespread use of high zinc levels in feed to prevent enteric disease in

weaned pigs has further reduced the likelihood of the disease.

Signs are limited to the skin, although mild lethargy, anorexia, and growth depression may be seen in severe cases; there is little if any pruritus. The outstanding lesions are symmetrically distributed areas of excessive and abnormal keratinization of the epidermis with the formation of horny scale and fissures. Brown spots or papules are first seen on the ventrolateral areas of the abdomen and inner thigh, pastern, fetlock, hock, and tail regions. These lesions coalesce to involve larger areas until the entire body may be covered. The

scale is horny, dry, and usually easily removed. Occasionally, secondary infection of the cracks and fissures causes them to fill with dark, sticky exudate and debris, which may resemble exudative epidermitis (see p 860); however, this usually occurs in younger piglets. Chronic sarcoptic mange and deficiencies of B vitamins or iodine must also be considered in the differential diagnosis. Clinical signs, skin biopsy, and low serum levels of zinc and alkaline phosphatase help confirm the diagnosis.

Highly satisfactory results can be obtained by adjusting the intake of calcium or zinc, or both. Nursery pig diets should contain 0.8%-0.85% calcium (with standardized total tract digestible phosphorus of 0.4%-0.45%) and 100 mg/kg of zinc, assuming daily feed intake of 280-500 g. Grower diets should contain 0.6%-0.65% calcium and 60 ppm zinc, whereas finisher diets should contain 0.45%-0.5% calcium and 50 ppm zinc. Sow and boar diets should contain 0.9% calcium and 150 ppm zinc. Correction of the deficiency results in rapid recovery.

PHOTOSENSITIZATION

Photosensitization occurs when skin (especially areas exposed to light and lacking significant protective hair, wool, or pigmentation) becomes more susceptible to ultraviolet light because of the presence of photodynamic agents. Photosensitization differs from sunburn and photodermatitis, because both of these conditions result in pathologic skin changes without the presence of a photodynamic agent.

In photosensitization, unstable, high-energy molecules are formed when photons

react with a photodynamic agent. These high-energy molecules initiate reactions with substrate molecules of the skin, causing the release of free radicals that in turn result in increased permeability of outer cell and lysosomal membranes. Damage to outer cell membranes allows for leakage of cellular potassium and cytoplasmic extrusion. Lysosomal membrane damage releases lytic enzymes into the cell. This can lead to skin ulceration, necrosis, and edema. The time interval between exposure to the photodynamic agent and the onset of clinical signs depends on the type of agent, its dose, and the exposure to sunlight.

Photosensitization is typically classified according to the source of the photodynamic agent. These categories include primary (type I) photosensitivity, aberrant endogenous pigment synthesis (type II) photosensitivity, and hepatogenous (secondary, type III) photosensitivity. A fourth category termed idiopathic (type IV) photosensitivity has been described.

A wide range of chemicals, including some that are fungal and bacterial in origin, may act as photosensitizing agents. However, most compounds that are important causes of photosensitivity in veterinary medicine are plant-derived. Photosensitization occurs worldwide and can affect any species but is most commonly seen in cattle, sheep, goats, and horses.

Photosensitization, causing cracking and peeling of the skin, in an adult horse. Courtesy of Dr. Stephen White.

Primary Photosensitization: Primary photosensitization occurs when the photodynamic agent is either ingested, injected, or absorbed through the skin. The agent enters the systemic circulation in its

native form, where it results in skin cell membrane damage after the animal is exposed to ultraviolet light. Examples of primary photosensitizing agents include hypericin (from *Hypericum perforatum* [St. John's wort]) and fagopyrin (from *Fagopyrum esculentum* [buckwheat]). Plants in the families Umbelliferae and Rutaceae contain photoactive furocoumarins (psoralens), which cause photosensitization in livestock and poultry. *Ammi majus* (bishop's weed) and *Cymopterus watsonii* (spring parsley) have produced photosensitization in cattle and sheep, respectively. Ingestion of *A. majus* and *A. visnaga* seeds has produced severe photosensitization in poultry. Species of *Trifolium*, *Medicago* (clovers and alfalfa), *Erodium*, *Polygonum*, and *Brassica* have been incriminated as primary photosensitizing agents. Many other plants have been suspected, but the toxins responsible have not been identified (eg, *Cynodon dactylon* [Bermudagrass]). Additionally, coal tar derivatives such as polycyclic aromatic hydrocarbons, tetracyclines, and some sulfonamides have been reported to cause primary photosensitization. Phenothiazine anthelmintics have been reported to cause primary photosensitivity in cattle, sheep, goats, and swine.

Aberrant Pigment Metabolism: Type II photosensitivity due to aberrant pigment metabolism is known to occur in both cattle and cats. In this syndrome, the photosensitizing porphyrin agents are endogenous pigments that arise from inherited or acquired defective functions of enzymes involved in heme synthesis. Bovine congenital erythropoietic porphyria (see p 986) and bovine erythropoietic protoporphyria (see p 852) are the most commonly reported diseases in this category.

Secondary (Hepatogenous) Photosensitization: Secondary or type III photosensitization is by far the most frequent type of photosensitivity observed in livestock. The photosensitizing agent, phylloerythrin (a porphyrin), accumulates in plasma because of impaired hepatobiliary excretion. Phylloerythrin is derived from the breakdown of chlorophyll by microorganisms present in the GI tract. Phylloerythrin, but not chlorophyll, is normally absorbed into the circulation and is effectively excreted by the liver into the bile. Failure to excrete phylloerythrin due to hepatic dysfunction or bile duct lesions increases the amount in the circulation.

Thus, when it reaches the skin, it can absorb and release light energy, initiating a phototoxic reaction.

Phylloerythrin has been incriminated as the phototoxic agent in the following conditions: common bile duct occlusion; facial eczema (see p 3015); lupinosis (see p 3018); congenital photosensitivity of Southdown and Corriedale sheep (see p 978); and poisoning by numerous plants, including *Tribulus terrestris* (puncture vine), *Lippia rehmanni*, *Lantana camara*, several *Panicum* spp (kleingrass, broomcorn millet, witch grass), *Cynodon dactylon*, *Myoporum laetum* (ngaio), and *Narthecium ossifragum* (bog asphodel).

Photosensitization also has been reported in animals that have liver damage associated with various poisonings: pyrrolizidine alkaloid (eg, *Senecio* spp, *Cynoglossum* spp, *Heliotropium* spp, *Echium* spp [see p 978]), cyanobacteria (*Microcystis* spp, *Oscillatoria* spp), *Nolina* spp (bunch grass), *Agave lechuguilla* (lechuguilla), *Holocalyx glaziovii*, *Kochia scoparia*, *Tetradymia* spp (horse brush or rabbit brush), *Brachiaria brizantha*, *Brassica napus*, *Trifolium pratense* and *T. hybridum* (red and alsike clover), *Medicago sativa*, *Ranunculus* spp, phosphorus, and carbon tetrachloride. Phylloerythrin is likely the phototoxic agent in many of these poisonings.

Type IV Photosensitivity: Photosensitivity in which the pathogenesis is unknown or the photodynamic agent is not identified is classified as type IV. One such example involved a case of primary photosensitivity in cattle presumed to be caused by *Thlaspi arvense* (field pennycress), even though field pennycress has not been reported to cause photosensitization. Outbreaks of photosensitization have been reported in cattle exposed to water-damaged alfalfa hay, moldy straw, and foxtail-orchardgrass hay. These cases were suspected to be hepatogenous in origin. *Ranunculus bulbosus* (buttercup) has also been presumed to be a cause of hepatogenous photosensitization. Other plants associated with photosensitization include winter wheat (cattle), *Medicago* spp (alfalfa), *Brassica* spp (mustards), and *Kochia scoparia* (fireweed). Many of these plants are believed to be type I photosensitizers. Forages such as oats, wheat, and red clover have been suspected in cases of photosensitization and may be associated with specific environmental conditions such as heavy rainfall.

Clinical Findings and Lesions: Dermatologic signs associated with photosensitivity are similar regardless of the cause. Photosensitive animals are photophobic immediately when exposed to sunlight and appear agitated and uncomfortable. They may scratch or rub lightly pigmented, exposed areas of skin (eg, ears, eyelids, muzzle). Lesions initially appear in white-haired, nonpigmented, or hairless areas such as the nose and udder. However, severe phyloerythrinemia and bright sunlight can induce typical skin lesions, even in black-coated animals. Erythema develops rapidly and is soon followed by edema. If exposure to light stops at this stage, the lesions soon resolve. When exposure is prolonged, lesions may progress to include vesicle and bulla formation, serum exudation, ulceration, scab formation, and skin necrosis. The final stage involves skin sloughing. In cattle, and especially in deer, exposure of the tongue while licking may result in glossitis, characterized by ulceration and deep necrosis. Irrespective of coat color, cattle may develop epiphora, corneal edema, and blindness.

Depending on the initial cause of the accumulation of the photosensitizing agent, other clinical signs may be seen. For example, if the photosensitivity is hepatogenous, icterus may be present. In bovine congenital erythropoietic porphyria, discoloration of dentin, bone (and other tissues), and urine often accompanies the skin lesions. Photodermatitis is the sole manifestation seen in bovine erythropoietic protoporphyria.

Diagnosis: Diagnosis of photosensitization is based on clinical signs, evidence or history of exposure to photosensitizing agents or hepatotoxins, and characteristic lesions. Photophobia in combination with erythema and edema of hairless, nonpigmented areas of skin is strongly suggestive of the disease. The period from exposure to photodynamic or hepatotoxic agents to the onset of clinical signs can vary from several hours up to 10 days. Clinical signs; increased serum biochemical measurements, including sorbitol dehydrogenase, gamma glutamyltransferase, alkaline phosphatase, and direct bilirubin; and gross or histologic signs of liver disease help support a diagnosis of hepatogenous photosensitization. A presumptive diagnosis of porphyria is based on signalment (sex, breed, age) combined with clinical signs, and a definitive diagnosis can be made by measuring porphyrin levels in blood, feces, and urine.

Treatment: The prognosis for animals with hepatogenous photosensitization and porphyria is poor; however, the prognosis for animals with primary photosensitization is generally good. Treatment involves mostly palliative measures. While photosensitivity continues, animals should be shaded fully or, preferably, housed and allowed to graze only during darkness. The severe stress of photosensitization and extensive skin necrosis can be highly debilitating and increase mortality. Corticosteroids, given parenterally in the early stages, may be helpful. Secondary skin infections and suppurations should be treated with basic wound management techniques, and fly strike prevented. The skin lesions heal remarkably well, even after extensive necrosis.

CONGENITAL PHOTOSENSITIZATION IN SHEEP

Southdown and Corriedale sheep may inherit a hepatobiliary incompetence that results in photosensitization.

In mutant Southdown sheep, the inherited defect involves hepatic uptake of unconjugated bilirubin and organic anions. Plasma levels of unconjugated bilirubin are consistently increased and, because bilirubin is partially excreted, icterus is not a clinical feature. Phyloerythrin is less effectively excreted, and affected lambs become photosensitized when they first begin grazing green plant material. Unless chlorophyll is excluded from the diet, or exposure to sunlight is prevented, lesions and stress of photosensitization result in death within weeks. Mutant sheep so protected develop progressive renal lesions in which radial, fibrous bands form in the medulla, along with increasing numbers of cystic tubules. The changes ultimately result in renal insufficiency and death. The liver is small, with pericanalicular deposits of lipofuscin. This semilethal trait appears to be inherited as a simple recessive trait. Elimination of carriers is the only feasible control.

In mutant Corriedale sheep, the hepatocellular incompetence involves excretion of conjugated bilirubin and other conjugated metabolites. There is no obvious icterus, but phyloerythrin excretion is sufficiently impaired to produce photosensitization. Hepatic pigmentation is obvious grossly. Brown-black, melanin-like pigment is confined to centrilobular parenchymal cells. This condition is transmitted as an autosomal recessive trait. Control is by detection and removal of carriers.

PITYRIASIS ROSEA IN PIGS

(Porcine juvenile pustular psoriasiform dermatitis)

Pityriasis rosea is a sporadic disease of unknown etiology of pigs, usually 8–14 wk old, but occasionally as young as 2 wk and very rarely in pigs as old as 10 mo. One or more pigs in a litter may be affected. The disease is mild, but transient anorexia and diarrhea have been reported. The initial skin lesions are characterized by small erythematous papules, which rapidly expand to form a ring (collarete) with distinct raised and reddened borders. The lesions enlarge at their periphery, and adjacent lesions may coalesce. The center of the lesion is flat and covered with a bran-like scale overlaying normal skin. The lesions are found predominantly on the ventral abdomen and inner thighs but occasionally may be seen over the back, neck, and legs. Characteristically, there is no pruritus, and recovery is spontaneous in 6–8 wk. Treatment is generally considered unnecessary. Diagnosis can usually be made from the characteristic lesions, but laboratory tests, culture, and biopsy may be used to differentiate it from dermatomycosis, exudative epidermitis, dermatosis vegetans, and swinepox.

The disease is considered to be partially hereditary, pigs of the Landrace breed being most commonly affected, but the mode of inheritance is uncertain. The disease does

Pityriasis rosea lesions, hindlimb, pig. Note the small, ring-like early stage lesions and the older, expanding larger rings healing centrally as they expand. Courtesy of Dr. Randal D. A. Cameron.

not resemble pityriasis rosea in people clinically or pathologically.

Lesions appear to be more extensive in pigs reared in high stocking densities with high ambient temperatures and high humidity. Under these conditions, secondary bacterial infection (eg, *Staphylococcus hyicus*) is common. Treatment is of little value and does not affect the course of the disease; however, treatment aimed at controlling secondary infections may be warranted.

SADDLE SORES

(Collar galls)

The area of riding horses that is under saddle, or the shoulder area of those driven in harness, is frequently the site of injuries to the skin and deeper soft and bony tissues. Clinical signs vary according to the depth of injury and the complications caused by secondary infection. Emaciated horses are at increased risk. Sores affecting only the skin are characterized by inflammatory changes that range from erythematous to papular, vesicular, pustular, and finally necrotic. Frequently, the condition starts as an acute inflammation of the hair follicles and progresses to a purulent folliculitis.

Affected areas show hair loss and are swollen, warm, and painful. The serous or purulent exudate dries and forms crusts. Advanced lesions are termed "galls." When the skin and underlying tissues are more severely damaged, abscesses may develop. These are characterized as warm, fluctuating, painful swellings from which purulent and serosanguineous fluid can be aspirated. Severe damage to the skin and subcutis or deeper tissues results in dry or moist necrosis. Chronic saddle sores are characterized by a deep folliculitis/furunculosis (boils) with fibrosis or a

localized indurative and proliferative dermatitis. Lesions are usually caused by poorly fitting tack.

Identification and elimination of the offending portion of tack is more important than any other treatment. Excoriations and inflammation of the skin of the saddle and harness regions are treated as any other dermatosis. Absolute rest of the affected parts is necessary. During the early or acute stages, astringent packs (Burow solution) are indicated. Chronic lesions and those superficially infected may be treated by warm applications and topical or systemic

antibiotics. Hematomas should be aspirated or incised. Necrotic tissue should be removed surgically. In severe folliculitis and furunculosis, antibiotics, ideally chosen on the basis of culture and sensitivity, are always indicated. Scars and/or leukotrichia (white hairs) are common sequelae of healed areas. Recurrence of hematomas, seromas, and/or sloughing skin upon initial saddlings of a young Quarter horse or Paint horse should elicit suspicion of the genetic disease hereditary equine dermal asthenia. A simple DNA test, performed on the hair bulbs of the tail, will confirm this diagnosis.

SEBORRHEA

Primary idiopathic seborrhea is a skin disease seen in dogs and rarely in cats. It is characterized by a defect in keratinization or cornification that results in increased scale formation, occasionally excessive greasiness of the skin and hair coat, and often secondary inflammation and infection. Secondary seborrhea, in which a primary underlying disease causes similar clinical signs, is more common than primary seborrhea. Seborrhea in horses is usually secondary to either pemphigus foliaceus or equine sarcoidosis (chronic granulomatous disease).

Etiology, Clinical Findings, and Diagnosis:

Primary seborrhea is an inherited skin disorder characterized by faulty keratinization or cornification of the epidermis, hair follicle epithelium, or claws. It is seen more frequently in American Cocker Spaniels, English Springer Spaniels, Basset Hounds, West Highland White Terriers, Dachshunds, Labrador and Golden Retrievers, and German Shepherds. There is usually a familial history of seborrhea, suggesting genetic factors. The disease begins at a young age (usually <18–24 mo) and typically progresses throughout the animal's life. A diagnosis of generalized primary idiopathic seborrhea should be reserved for cases in which all possible underlying causes have been excluded.

Most seborrheic animals have secondary seborrhea, in which a primary underlying disease predisposes to excessive scaling, crusting, or oiliness, often accompanied by superficial pyoderma, *Malassezia* (yeast) infection, and alopecia. The most common

underlying causes are endocrinopathies and allergies. The goal is to identify and treat any underlying cause of the seborrhea. Palliative therapies that do not compromise the diagnostic evaluation should be instituted concurrently to provide as much immediate relief as possible.

Underlying diseases may present with seborrhea as the primary clinical problem. The signalment (age, breed, sex) and history may provide clues in diagnosing the underlying cause. Environmental allergies (atopic dermatitis) are more likely to be the underlying cause if age at onset is <5 yr, whereas an endocrinopathy or neoplasia (especially cutaneous lymphoma) is more likely if the seborrhea begins in middle-aged or older animals.

The degree of pruritus should also be noted. If pruritus is minimal, endocrinopathies, other internal diseases, or certain diseases limited to the skin (eg, demodicosis or sebaceous adenitis) should be excluded. If pruritus is significant, allergies and pruritic ectoparasitic diseases (eg, scabies, fleas) should be considered. The presence of pruritus does not exclude nonpruritic disease as the underlying cause, because the presence of a pyoderma, *Malassezia* infection, or inflammation from the excess scale can cause significant pruritus. However, a lack of pruritus helps to exclude allergies, scabies, and other pruritic diseases as the underlying cause.

Other important considerations include the presence of polyuria, polydipsia, or polyphagia; heat-seeking behavior; abnormal estrous cycles; occurrence of pyoderma; the influence of seasonality; diet;

response to previous medications (including corticosteroids, antibiotics, antifungals, antihistamines, or topical treatments); zoonosis or contagion; and the environment. The duration and severity of disease as well as level of owner frustration are important factors in determining the aggressiveness of the diagnostic plan.

A thorough physical examination, including internal organ systems and a comprehensive dermatologic examination, is the first step in identifying the underlying cause. The dermatologic examination should document the type and distribution of the lesions; the presence of alopecia; and the degree of odor, scale, oiliness, and texture of the skin and hair coat. The presence of follicular papules, pustules, crusts, and epidermal collarettes usually indicates the existence of a superficial pyoderma. Hyperpigmentation indicates a chronic skin irritation (such as pruritus, infection, or inflammation), and lichenification indicates chronic pruritus. Yeast (*Malassezia* spp) infection should always be considered when evaluating a seborrheic animal.

Secondary infection plays a significant role in most cases of seborrhea. The sebum and keratinization abnormalities that are common in seborrhea frequently provide ideal conditions for bacterial and yeast infections. The self-trauma that occurs in pruritic animals increases the likelihood of a secondary infection. Often, coagulase-positive *Staphylococcus* spp or *Malassezia* spp are present. The infections add to the pruritus and are usually responsible for a significant amount of the inflammation, papules, crusts, alopecia, and scales.

One of the first diagnostic steps is to obtain superficial cytology of the affected areas to identify the quantity and type of bacteria or yeast present. If numerous cocci and neutrophils are present, pyoderma is likely. In addition to systemic therapy, topical shampoos will aid in the treatment of secondary infections. In a seborrheic dog with pruritus, the infection may cause all or most of the pruritus. Instead of considering allergies as the underlying disease in these dogs, nonpruritic diseases (eg, endocrinopathies) may be uncovered by addressing the infections.

After the infections have been addressed, other diagnostic tests that should be considered include multiple deep skin scrapings, dermatophyte culture, impression smears, trichograms, and flea combing. If these are negative or normal, a skin biopsy, CBC, serum biochemical profile, and complete urinalysis will complete the

minimum database. Examples of diagnostic clues include increased serum alkaline phosphatase (which may suggest hyperadrenocorticism or previous steroid therapy), cholesterol (which may suggest hypothyroidism), blood glucose (which suggests diabetes mellitus), and BUN or creatinine (which may suggest renal disease).

Treatment: Palliative therapy is needed to keep the animal comfortable while the underlying cause is identified and secondary skin diseases are corrected. For treatment of pyoderma, an antibiotic with known sensitivity against *Staphylococcus pseudintermedius* should be appropriate. Examples of such antibiotics are amoxicillin-clavulanate 13.75 mg/kg bid, cephalexin 20–30 mg/kg bid-tid, cefpodoxime 5–10 mg/kg/day, lincomycin 20 mg/kg bid, ciprofloxacin 30 mg/kg/day, enrofloxacin 5–10 mg/kg/day, marbofloxacin 3–6 mg/kg/day, azithromycin 10 mg/kg/day, 4 days/wk, doxycycline 5 mg/kg bid, trimethoprim-sulfa 30 mg/kg bid, clindamycin 11 mg/kg bid, and chloramphenicol 50 mg/kg tid in dogs and 12.5–20 mg/kg bid in cats. Because most staphylococcal infections in seborrhea cases are superficial pyodermas, they should be treated for a minimum of 4 wk.

With the increase in methicillin-resistant *S pseudintermedius*, *S aureus*, and *S schleiferi*, it is now strongly recommended to perform a bacterial culture of any animal with pyoderma that does not begin to respond to an antibiotic after 3–4 wk. Epidermal collarettes may be cultured using a dry sterile culturette rolled across the collarettes. Although methicillin-resistant *S pseudintermedius* infections are more difficult to treat, they are not more virulent or visually striking than those due to methicillin-susceptible *S pseudintermedius*. Previous (ie, within the past year) hospitalization, surgery, or previous antibiotic treatment are all possible risk factors for development of methicillin-resistant *S pseudintermedius* infections.

Malassezia may be treated systemically with an azole such as ketoconazole or fluconazole (5 mg/kg/day, for 4 wk). In addition to addressing any secondary infections, antipruritic therapy and shampoo therapy are usually needed to help control the seborrhea and speed the return of the skin to a normal state. Shampoo therapy can decrease the number of bacteria and yeast on the skin surface, the amount of scale and sebum present, and the level of pruritus; it also helps normalize the epidermal turnover rate.

In the past, seborrhea has been classified as seborrhea sicca (dry seborrhea), seborrhea oleosa (oily seborrhea), or seborrheic dermatitis (inflammatory seborrhea). Most seborrheic animals have varying degrees of all three of these classifications of seborrhea.

Most products contained in shampoos can be classified based on their effects as keratolytic, keratoplastic, emollient, antipruritic, or antimicrobial. **Keratolytic products** include sulfur, salicylic acid, tar, selenium sulfide, propylene glycol, fatty acids, and benzoyl peroxide. They remove stratum corneum cells by causing cellular damage that results in ballooning and sloughing of the surface keratinocytes. This reduces the scale and makes the skin feel softer. Shampoos containing keratolytic products frequently exacerbate scaling during the first 14 days of treatment because the sloughed scales get caught in the hair coat. The scales will be removed by continued bathing, but owners should be warned that the scaling often worsens initially. **Keratoplastic products** help normalize keratinization and reduce scale formation by slowing down epidermal basal cell mitosis. Tar, sulfur, salicylic acid, and selenium sulfide are examples of keratoplastic agents. **Emollients** (eg, lactic acid, sodium lactate, lanolin, and numerous oils, such as corn, coconut, peanut, and cottonseed) are indicated for any scaling dermatosis, because they reduce transepidermal water loss. They are most effective after the skin has been rehydrated and are excellent adjunct products after shampooing. **Antibacterial agents** include benzoyl peroxide, chlorhexidine, ethyl lactate, tris-EDTA, and triclosan. **Antifungal ingredients** include chlorhexidine, sulfur, ketoconazole, and miconazole. Boric and acetic acids are also used as topical antimicrobials.

It is important to know how individual shampoo ingredients act, as well as any additive or synergistic effects they have, because most shampoos are a combination of products. The selection of appropriate antiseborrheic shampoo therapy is based on hair coat and skin scaling and oiliness, of which there are four general presentations: 1) mild scaling and no oiliness, 2) moderate to marked scaling and mild oiliness (the most common), 3) moderate to marked scaling and moderate oiliness, 4) mild scaling and marked oiliness. These categories are intended to guide the type of shampoo therapy necessary; however, all factors for each individual animal should be considered.

Animals with mild scaling and no oiliness need mild shampoos that are gentle, cleansing, hypoallergenic, or moisturizing. These shampoos are indicated for animals that have mild seborrheic changes, are irritated by medicated shampoos, or bathed too often. These products often contain emollient oils, lanolin, lactic acid, urea, glycerin, or fatty acids. Emollient sprays or rinses are often used in conjunction with these shampoos.

Animals with moderate to marked scaling and mild to marked oiliness should be bathed with shampoos that contain sulfur and salicylic acid. Both agents are keratolytic, keratoplastic, antibacterial, and antipruritic. In addition, sulfur is antiparasitic and antifungal. Some of these shampoos also contain ingredients that are antibacterial, antifungal, and moisturizing, which can help control secondary pyoderma, *Malassezia* spp, and excessive scaling. Shampoos that contain ethyl lactate lower the cutaneous pH (which has a bacteriostatic or bactericidal action by inhibiting bacterial lipases), normalize keratinization, solubilize fats, and decrease sebaceous secretions. These actions also result in potent antibacterial activity.

In the past, dogs with moderate to severe scaling and moderate oiliness were often treated with tar-containing shampoos. However, because tar shampoos usually have an unpleasant odor and can be irritating, along with poor owner compliance, they usually are no longer recommended.

In animals with severe oiliness and minimal scaling, profound odor, erythema, inflammation, and a secondary generalized pyoderma or *Malassezia* dermatitis are often present. Shampoos that contain benzoyl peroxide provide strong degreasing actions along with potent antibacterial and follicular flushing activities. Because benzoyl peroxide shampoos are such strong degreasing agents, they can be irritating and drying. Other antibacterial shampoos are better suited in animals that have superficial pyoderma without significant oiliness. These shampoos usually contain 2%–4% chlorhexidine (often in association with tris-EDTA) or ethyl lactate. The follicular flushing action of benzoyl peroxide makes it helpful for animals with numerous comedones or with demodicosis. Benzoyl peroxide gels (5%) are good choices when antibacterial, degreasing, or follicular flushing actions are desired for focal areas, such as in localized demodicosis, canine acne, or Schnauzer comedone syndrome. However, these gels also may be irritating.

METABOLIC DISORDERS INTRODUCTION

Metabolic diseases may be inherited or acquired, the latter being more common and significant. Metabolic diseases are clinically important because they affect energy production or damage tissues critical for survival.

METABOLIC STORAGE DISORDERS AND INBORN ERRORS OF METABOLISM

Storage diseases and inborn errors of metabolism are classified as either genetic or acquired. These diseases are characterized by the accumulation or storage of specific lysosomal enzyme substrates or byproducts within cells because of partial or complete deficiency of those enzymes. Although lysosomal storage diseases are often widespread throughout the body, the majority of clinical signs are due to the effects on the CNS.

Genetic storage diseases are named according to the specific metabolic byproduct that accumulates in the lysosomes. Animals are typically normal at birth, then manifest clinical signs within the first weeks to months of life. These diseases are progressive and usually fatal, because specific treatments do not exist. In small animals, the gangliosidoses (GM₁ and GM₂) are seen in Siamese, Korat, and domestic cats, and in Beagle crosses, German Shorthaired Pointers, and Japanese Spaniels. Sphingomyelinosis is seen in German Shepherds and Poodles and in Siamese and domestic shorthaired cats. Glucocerebrosidosis is seen in

Australian Silky Terriers and Dalmatians. Ceroid lipofuscinosis is seen in English Setters, Cocker Spaniels, Dachshunds, Chihuahuas, Salukis, Border Collies, and domestic cats. Mannosidosis is seen in Persian and domestic cats. Glycogenosis is seen in Silky Terriers and in domestic shorthaired and Norwegian forest cats. Globoid cell leukodystrophy (Krabbe disease) is seen in Cairn Terriers, West Highland White Terriers, Beagles, Bluetick Hounds, Poodles, and domestic shorthaired cats. Mucopolysaccharidosis type I is seen in Siamese, Korat, and domestic shorthaired cats; type IV is seen in Siamese cats. In dogs, mucopolysaccharidosis is seen in Miniature Pinschers, Plott Hounds, and mixed breed dogs and is associated with lameness. Diseases associated with decreased RBC survival and anemia include pyruvate kinase deficiency in Basenjis, Beagles, and West Highland White and Cairn Terriers; phosphofructokinase deficiency in English Springer and American Cocker Spaniels; and porphyria in Siamese and domestic shorthaired cats.

In large animals, α -mannosidosis occurs in Angus, Murray Grey, Simmental, Galloway, and Holstein cattle. β -Mannosidosis is seen in Saler cattle and Nubian and Nubian-cross goats. Generalized glycogenosis (GM₁) is seen in Holstein cattle and Suffolk sheep. Generalized glycogenosis (GM₂) is seen in Shorthorn and Brahman cattle, and in pigs. Globoid cell leukodystrophy is seen in polled Dorset sheep. Other identified diseases that are manifest by neurologic signs and appear to be inherited include neuronal lipodystro-

phy in Angus and Beefmaster cattle, shaker calf syndrome of horned Hereford cattle, maple syrup urine disease of Hereford and polled Shorthorn cattle, and hereditary neuraxial edema of polled and horned Hereford and Hereford-Friesian cross cattle. There have been no reports of lysosomal storage diseases in horses; however, inherited diseases manifest by neurologic signs include inherited myoclonus of Peruvian Paso foals and congenital encephalomyelopathy in Quarter horses.

Other inherited diseases that involve basic errors of metabolism in various tissues include goiter of sheep and goats, inherited parakeratosis (edema disease) of cattle, osteogenesis imperfecta of sheep and cattle, and possibly cardiomyopathy of cattle, the hypotrichoses, baldy calves, photosensitization of sheep (*see* p 978), dermatosis vegetans and porcine stress syndrome (*see* p 1027) of pigs, dermatosparaxia and Ehlers-Danlos syndrome of cattle, hemochromatosis of cattle (*see* p 349), and Marfan syndrome in cattle. Many other inherited defects, especially those based on abnormal growth of collagen, cartilage, and bone, also are likely to have basic errors of metabolism of structural tissues. Many disorders of metabolism have been described involving dysfunctions of the immune system.

Acquired storage diseases are caused by ingestion of plants that contain inhibitors of specific lysosomal catabolic enzymes. Chronic ingestion of locoweed plants (*Astragalus* or *Oxytropis* spp) results in an acquired neurologic storage disease. Several toxic components, including locoine, swainsonine *n*-oxide, and indolizidine alkaloids, interfere with α -mannosidase activity. Horses are most susceptible to intoxication; however, cattle, sheep, and goats can also be affected. (*See also* p 3103.)

PRODUCTION-RELATED METABOLIC DISORDERS

Although the development of the following diseases is largely related to production or management factors, the pathogenesis of each disease is primarily related to alterations in metabolism. In most cases, the basis of disease is not a congenital or inherited error in metabolism, but rather an increased demand for a specific nutrient that has become deficient under certain conditions. Diseases such as hypocalcemia, hypomagnesemia, and hypoglycemia are augmented by management practices directed toward improving and increasing

production. They are therefore correctly considered production diseases. However, they are also metabolic diseases because management of the animal is directed at production, which at its peak is beyond the capacity of that animal's metabolic reserves to sustain a particular nutrient at physiologic concentrations. For example, parturient paresis of cows (*see* p 988) occurs when the mass of calcium in the mammary secretion is greater than the cow's diet or its skeletal reserves can supply. Comparable situations occur with magnesium and glucose metabolism, and with phosphorus in relation to postparturient hemoglobinuria (*see* p 1002).

Most production-induced metabolic diseases result from a negative balance of a particular nutrient. In some cases, dietary intake of the nutrient is rapidly reduced because of an ongoing, high metabolic requirement for that nutrient. Examples include pregnancy toxemia in ewes (*see* p 1021), protein-energy malnutrition in beef cattle (*see* p 2248), fat cow syndrome in dairy cattle (*see* p 1018), and hyperlipemia in ponies (*see* p 346). Furthermore, some diseases may be precipitated when producers, primarily because of economic concerns, are compelled to not supplement the diet of animals that already have a substandard nutritional plane.

Exertional rhabdomyolysis of horses (*see* p 1178) is another production-induced metabolic disease. In this case, the production activity (draft or racing) is maintained by and matched to a level of caloric intake. Management decisions not to work or race these horses without a concomitant decrease in caloric intake may result in accumulation of muscle glycogen to dangerous levels. Disease results when work is resumed and the production of lactate exceeds its metabolism.

The difference between production-related metabolic diseases and nutritional deficiencies is often subtle. Typically, nutritional deficiencies are longterm, steady-state conditions that can be corrected through dietary supplementation. Metabolic diseases are generally acute states that dramatically respond to the systemic administration of the deficient nutrient or metabolite, although affected animals may require subsequent dietary supplementation to avoid recurrence. An important aspect of dealing with production-induced metabolic diseases is accurate and rapid diagnosis. Ideally, diagnostic tests can be used to predict the occurrence of disease before its clinical onset.

CONGENITAL ERYTHROPOIETIC PORPHYRIA

(Porphyrinuria, Pink tooth, Osteohemochromatosis)

Congenital erythropoietic porphyria (CEP) is a rare hereditary disease of cattle, pigs, cats, and people that results from a significant yet variable decrease in uroporphyrinogen III synthase (URO-synthase) activity. URO-synthase is the fourth enzyme in the heme biosynthesis pathway, and it normally converts hydroxymethylbilane to uroporphyrinogen III. With decreased URO-synthase activity, hydroxymethylbilane accumulates primarily in erythrons and is nonenzymatically converted to uroporphyrinogen I. Further decarboxylation of uroporphyrinogen I leads to the formation of various porphyrinogen I isomers, with coproporphyrinogen I occurring as the final product. Coproporphyrinogen I cannot be further metabolized to heme and is thus nonphysiologic. Porphyrinogen I isomers are pathogenic when they accumulate in large amounts and are oxidized to their corresponding porphyrins. Accumulation of porphyrinogen isomers in bone marrow erythroid precursors results in cell damage and hemolysis. Porphyrin I isomers are also released into circulation and deposited in skin, bone, and other tissues. Cutaneous photosensitivity occurs, because porphyrins deposited in skin are photocatalytic and cytotoxic. Presumably, exposure of skin to sunlight (and other sources of long-wave ultraviolet light) leads to phototoxic excitation of isomers, formation of oxygen radicals, and subsequent tissue and vessel damage. Urinary porphyrin excretion is greatly increased (100–1,000 times normal) and primarily consists of uroporphyrin I and coproporphyrin I with lesser amounts of other isomers. Although isomer I porphyrins predominate, isomer III porphyrins are also increased.

CEP was first reported in South African Shorthorn cattle; however, most cases have since been reported in the Holstein breed. It is inherited as a simple autosomal recessive and is usually confined to herds in which inbreeding or close line-breeding is practiced. It has been recognized in the USA, Canada, Denmark, Jamaica, England, South Africa, Australia, and Argentina. This broad geographic distribution suggests that the disease likely is found worldwide and probably affects all meat-producing animals, especially cattle, swine, and sheep.

Heterozygous animals seem to be normal, but homozygous recessive animals are affected at birth with reddish brown discoloration of the teeth, bones, and urine that persists for life. The excess coproporphyrin I and uroporphyrin I in the urine colors it an amber or reddish brown. Bones, urine, and teeth (especially the deciduous teeth) fluoresce pink when irradiated with near ultraviolet light. Prolonged exposure to sunlight causes typical lesions of photosensitization with hyperemia, vesicle formation, and superficial necrosis of unpigmented portions of the skin. Severity of the skin lesions depends on the intensity of the solar radiation and the extent of cutaneous pigmentation found in specific families of animals. A normochromic, hemolytic anemia with macrocytes and microcytes and marked basophilic stippling develops. Splenomegaly eventually develops. The texture of bones is not altered except in cases in which bones have increased fragility because of a diminished cortex. Affected animals are generally of medium to good condition unless solar injury has occurred. Some animals become progressively unthrifty unless protected from sunlight. A similar disease, bovine protoporphyria (*see* p 852), causes photosensitivity only in Limousin cattle and people. A recent molecular study of CEP in cattle supports the hypothesis that CEP is caused by a mutation affecting the URO-synthase gene; however, additional functional studies are needed to identify the exact causative mutation.

In people, a series of porphyrias caused by defective functions of enzymes in porphyrin-heme biosynthesis have been described and grouped according to their presenting signs. These vary broadly and may include severe cutaneous lesions on exposed areas of the body, acute photosensitivity reactions, serious liver damage, and acute attacks of neurologic dysfunction. In animals, the recognized diseases are commonly classified as CEP, congenital erythropoietic protoporphyria, or porphyria. It is likely that all of the syndromes described in people also occur in animals and that a broader classification could be used.

Porphyria in swine is rare and incompletely described. Affected pigs have

discoloration of teeth and excessive uroporphyrin in urine. In contrast to CEP in cattle and people, affected swine are not anemic and do not present with signs of photosensitization. The specific genetic defect is unknown; therefore, its relevance to CEP in other animals is also unknown. Nonetheless, the disorder is inherited as an autosomal dominant trait.

Recently, the first feline model of human CEP due to deficient URO-synthase activity was identified by characteristic clinical phenotype and confirmed by biochemical and molecular genetic studies. In this case, sequencing of the cat's URO-synthetase gene revealed two homozygous, missense mutations in exons 3 and 6. This synergistic interaction of two rare amino acid substitutions in the URO-synthase polypeptide resulted in the feline model of human CEP. Previously, cats presenting with brownish discolored teeth that fluoresced pink under UV light and increased URO and coproporphyrinogen concentrations were believed to have CEP. The disease was also observed to be

inherited as an autosomal dominant trait (as in some pig models), whereas in people and cattle, the disease is inherited as an autosomal recessive trait. It is now understood that cats with the CEP-like phenotype and autosomal dominant inheritance actually have feline acute intermittent porphyria and not CEP.

Diagnosis should be based on the excretion of abnormal uroporphyrins, the brown discoloration of the teeth (which fluoresce when irradiated with near-ultraviolet light), the appearance of discolored urine, and hemolytic anemia.

The recessive genetic character is widely distributed in cattle, but the clinical condition is comparatively rare. Clinically normal heterozygotes have lower levels of uroporphyrinogen III cosynthetase than do normal animals, but laboratory identification of the carrier state is impractical because of the low incidence of the disease and is not widely used. Morbidity can be controlled by keeping affected animals indoors and out of direct sunlight.

DISORDERS OF CALCIUM METABOLISM

HYPOCALCEMIC TETANY IN HORSES

(Transport tetany, Lactation tetany, Eclampsia)

Hypocalcemic tetany in horses is an uncommon condition associated with acute depletion of serum ionized calcium and sometimes with alterations in serum concentrations of magnesium and phosphate. It occurs after prolonged physical exertion or transport (transport tetany) and in lactating mares (lactation tetany). Signs are variable and relate to neuromuscular hyperirritability.

Etiology: Mechanisms of hypocalcemia include decreased absorption from the intestines; increased loss of calcium from the kidneys, sweat, or milk; or inhibition of osteolysis due to alterations in parathyroid hormone, calcitonin, or vitamin D. In lactating mares, high milk production and grazing of lush pastures appear to be predisposing factors. Hypocalcemia after

prolonged physical activity (eg, endurance rides) results from sweat loss of calcium, increased calcium binding during hypochloremic alkalosis, and stress-induced high corticosteroid levels. Corticosteroids inhibit vitamin D activity, which leads to decreased intestinal absorption and skeletal mobilization of calcium. Stress and lack of calcium intake have been associated with transport tetany. Occasionally, hypocalcemic tetany may be precipitated by hypocalcemia after blister beetle ingestion (*see* p 3157).

Clinical Findings: The severity of clinical signs corresponds with the serum concentration of ionized calcium. Increased excitability may be the only sign in mild cases. Severely affected horses may show synchronous diaphragmatic flutter (*see* p 1183), anxious appearance, and signs of tetany, including increased muscle tone, stiffness of gait, muscle tremors, prolapse of the third eyelid, inability to chew, trismus, salivation, recumbency, convulsions, and cardiac arrhythmias. In lactating mares,

if not treated, the disease may take a progressive and sometimes fatal course over 24–48 hr.

Differential diagnoses include tetanus, endotoxemia, colic, exertional rhabdomyolysis or other muscle disorder, seizure disorder, laminitis, and botulism.

Diagnosis: A tentative diagnosis is based on clinical signs, history, and response to treatment. Definitive diagnosis requires demonstration of low serum levels of ionized calcium. Most laboratories measure only total (protein-bound and free) serum calcium, which is an acceptable diagnostic test in most cases. However, discrepancies may arise in alkalotic and hypoalbuminemic horses. Alkalosis increases albumin binding of calcium, which results in a decreased concentration of ionized calcium. Thus, alkalotic horses may have normal total serum calcium while exhibiting signs of hypocalcemia. Likewise, hypoalbuminemic or acidotic horses may have decreased total serum calcium without developing signs of hypocalcemia. Total serum calcium can be adjusted for albumin concentration by the following formula:

$$\text{adjusted Ca}^{2+} = \text{measured Ca}^{2+} - \text{serum albumin concentration} + 3.5$$

Treatment: IV administration of calcium solutions, such as 20% calcium borogluconate or solutions recommended for treatment of periparturient paresis in cattle, usually results in full recovery. These solutions should be administered slowly (over 20 min) at 250–500 mL/500 kg, diluted at least 1:4 in saline or dextrose, and the cardiovascular response should be closely monitored. An increased intensity of heart sounds is expected. If arrhythmias or bradycardia develop, the IV treatment should be discontinued immediately. Once the heart rate has returned to normal, the infusion may be resumed at a slower rate. If the horse does not improve within 1–2 hr of the initial infusion, a second dose may be given, although laboratory verification of hypocalcemia is indicated. Some horses require repeated treatments over several days to recover from hypocalcemic tetany. Mildly affected horses may recover without specific treatment. If the tetany is associated with physical exertion, incorporating magnesium into the solution may be advisable.

Prevention: A balanced feed ration should be provided to supply adequate amounts and ratios of calcium and phospho-

rus throughout gestation. In times of increased calcium demand such as lactation, fasting should be avoided and high-quality forage such as alfalfa or calcium-containing mineral mixes should be provided. Stress and fasting during transport should be minimized. In endurance horses, water and electrolyte deficits associated with prolonged exercise and sweating may be prevented by provision of a sufficient water supply and electrolyte supplementation.

PARTURIENT PARESIS IN COWS

(Milk fever, Hypocalcemia)

Parturient paresis is an acute to peracute, afebrile, flaccid paralysis of mature dairy cows that occurs most commonly at or soon after parturition. It is manifest by changes in mentation, generalized paresis, and circulatory collapse.

Etiology: Dairy cows will secrete 20–30 g of calcium in the production of colostrum and milk in the early stages of lactation. This secretion of calcium causes serum calcium levels to decline from a normal of 8.5–10 mg/dL to <7.5 mg/dL. The sudden decrease in serum calcium levels causes hyperexcitability of the nervous system and reduced strength of muscle contractions, resulting in both tetany and paresis. Parturient paresis may be seen in cows of any age but is most common in high-producing dairy cows entering their third or later lactations. Incidence is higher in Channel Island breeds.

Clinical Findings and Diagnosis: Parturient paresis usually occurs within 72 hr of parturition. It can contribute to dystocia, uterine prolapse, retained fetal membranes, metritis, abomasal displacement, and mastitis.

Parturient paresis has three discernible stages. During stage 1, animals are ambulatory but show signs of hypersensitivity and excitability. Cows may be mildly ataxic, have fine tremors over the flanks and triceps, and display ear twitching and head bobbing. Cows may appear restless, shuffling their rear feet and bellowing. If calcium therapy is not instituted, cows will likely progress to the second, more severe stage.

Cows in stage 2 are unable to stand but can maintain sternal recumbency. Cows are obtunded, anorectic, and have a dry muzzle, subnormal body temperature, and cold extremities. Auscultation reveals tachycardia

and decreased intensity of heart sounds. Peripheral pulses are weak. Smooth muscle paralysis leads to GI stasis, which can manifest as bloat, failure to defecate, and loss of anal sphincter tone. An inability to urinate may manifest as a distended bladder on rectal examination. Cows often tuck their heads into their flanks, or if the head is extended, an S-shaped curve to the neck may be noted.

In stage 3, cows lose consciousness progressively to the point of coma. They are unable to maintain sternal recumbency, have complete muscle flaccidity, are unresponsive to stimuli, and can suffer severe bloat. As cardiac output worsens, heart rate can approach 120 bpm, and peripheral pulses may be undetectable. If untreated, cows in stage 3 may survive only a few hours.

Differential diagnoses include toxic mastitis, toxic metritis, other systemic toxic conditions, traumatic injury (eg, stifle injury, coxofemoral luxation, fractured pelvis, spinal compression), calving paralysis syndrome (damage to the L6 lumbar roots of sciatic and obturator nerves), or compartment syndrome. Some of these diseases, in addition to aspiration pneumonia, may also occur concurrently with parturient paresis or as complications. (See also p 1188.)

Treatment: Treatment is directed toward restoring normal serum calcium levels as soon as possible to avoid muscle and nerve damage and recumbency. Recommended treatment is IV injection of a calcium gluconate salt, although SC and IP routes are also used. A general rule for dosing is 1 g calcium/45 kg (100 lb) body wt. Most solutions are available in single-dose, 500-mL bottles that contain 8–11 g of calcium. In large, heavily lactating cows, a second bottle given SC may be helpful, because it is thought to provide a prolonged release of calcium into the circulation. SC calcium alone may not be adequately absorbed because of poor peripheral perfusion and should not be the sole route of therapy. No matter what route is used, strict asepsis should be used to lessen the chance of infection at the injection site. Solutions containing formaldehyde or >25 g dextrose/500 mL are irritating if given SC. Many solutions contain phosphorus and magnesium in addition to calcium. Although administration of phosphorus and magnesium is not usually necessary in uncomplicated parturient paresis, detrimental effects of their use have not been reported. Magnesium may protect against myocardial irritation caused by the

administration of calcium. Magnesium is also necessary for appropriate parathyroid hormone (PTH) secretion and activity in response to hypocalcemia. Most products available to veterinarians contain phosphite salts as the source of phosphorus. However, phosphorus found in blood and tissues of cattle is primarily in the form of the phosphate anion. Because no pathway exists for the conversion of phosphite to the usable phosphate form, it is unlikely these solutions are of any benefit in addressing hypophosphatemia.

Calcium is cardiotoxic; therefore, calcium-containing solutions should be administered slowly (10–20 min) while cardiac auscultation is performed. If severe dysrhythmias or bradycardia develop, administration should be stopped until the heart rhythm has returned to normal.

Endotoxic animals are especially prone to dysrhythmias caused by IV calcium therapy.

Administration of oral calcium avoids the risks of cardiotoxic adverse effects and may be useful in mild cases of parturient paresis; however, it is not recommended as the sole approach for clinical milk fever cases.

Products containing calcium chloride are effective but can be caustic to oral and pharyngeal tissues, especially if used repeatedly. Calcium propionate in propylene glycol gel or powdered calcium propionate (0.5 kg dissolved in 8–16 L water administered as a drench) is effective, less injurious to tissues, avoids the potential for metabolic acidosis caused by calcium chloride, and supplies the gluconeogenic precursor propionate. Oral administration of 50 g of soluble calcium results in ~4 g of calcium being absorbed into the circulation.

Regardless of the source of oral calcium, it is important to note that cows with hypocalcemia often have poor swallowing and gag reflexes. Care must be exercised during administration of calcium-containing solutions to avoid aspiration pneumonia. Gels containing calcium chloride should not be administered to cows unable to swallow.

Hypocalcemic cows typically respond to IV calcium therapy immediately. Tremors are seen as neuromuscular function returns. Improved cardiac output results in stronger heart sounds and decreased heart rate. Return of smooth muscle function results in eructation, defecation, and urination once the cow rises. Approximately 75% of cows stand within 2 hr of treatment. Animals not responding by 4–8 hr should be reevaluated and retreated if necessary. Of cows that respond initially, 25%–30% relapse within 24–48 hr and require additional therapy. Incomplete milking has been advised to

reduce the incidence of relapse. Historically, udder inflation has been used to reduce the secretion of milk and loss of calcium; however, the risk of introducing bacteria into the mammary gland is high.

Prevention: Historically, prevention of parturient paresis has been approached by feeding low-calcium diets during the dry period. The negative calcium balance results in a minor decline in blood calcium concentrations. This stimulates PTH secretion, which in turn stimulates bone resorption and renal production of 1,25 dihydroxyvitamin D. Increased 1,25 dihydroxyvitamin D increases bone calcium release and increases the efficiency of intestinal calcium absorption. Although mobilization of calcium is enhanced, it is now known that feeding low-calcium diets is not as effective as initially believed. Furthermore, on most dairy farms today, it is difficult to formulate diets low enough in calcium (<20 g absorbed calcium/cow/day), although the use of dietary straw and calcium-binding agents such as zeolite or vegetable oil may make this approach more useful.

Alternative methods to prevent hypocalcemia include delayed or incomplete milking after calving, which maintains pressure within the udder and decreases milk production; however, this practice may aggravate latent mammary infections and increase incidence of mastitis. Prophylactic treatment of susceptible cows at calving may help reduce parturient paresis. Cows are administered either SC calcium on the day of calving or oral calcium gels at calving and 12 hr later.

Most recently, the prevention of parturient paresis has been revolutionized by use of the dietary cation-anion difference (DCAD), a method that decreases the blood pH of cows during the late prepartum and early postpartum period. This method is more effective and more practical than lowering prepartum calcium in the diet. The DCAD approach is based on the finding that most dairy cows are in a state of metabolic alkalosis due to the high potassium content of their diets. This state of metabolic alkalosis with increased blood pH predisposes cows to hypocalcemia by altering the conformation of the PTH receptor, resulting in tissues less sensitive to PTH. Lack of PTH responsiveness prevents effective use of bone calcium, prevents activation of osteoclastic bone resorption, reduces renal reabsorption of calcium from the glomerulus, and inhibits renal conversion to its active form.

An important strategy to decrease blood pH in periparturient cattle is to reduce the potassium content of the diet. It is essential to include corn silage as a major portion of the dry cow's diet, because it tends to have the lowest content potassium of available forages. Alfalfa is another forage source that may prove beneficial in maintaining proper blood pH. In the past, including alfalfa in a dry cow ration was not considered ideal because of the high calcium content. However, it has since been determined that calcium has little effect on the alkalinity of cow's blood. Withholding potassium fertilizers on fields used to grow dry cow forages is another way to decrease potassium levels in hay fed to dry cows. Alternatively, readily absorbable anions can be added to the diet to increase the total negative charges in the blood, allowing more H^+ to exist, decreasing the pH of the blood. Anionic salts to consider include calcium chloride, magnesium chloride, magnesium sulfate, calcium sulfate, ammonium sulfate, and ammonium chloride. Research evaluating the acidifying activity of different anionic salts has resulted in the following equation that describes the ion balance in rations:

$$DCAD = (Na^+ + K^+) - (Cl^- + S^{2-})$$

The target value for close-up dry cow rations is -15 to $+15$ mEq/100 g dry matter. Sodium and potassium should be provided as close to the required levels as possible (0.1% dietary dry matter sodium, and 1% dietary dry matter potassium). Chloride should be added to the ration to offset the effects of low levels of potassium on blood alkalinity. In general, providing $\sim 0.5\%$ less dietary chloride than the concentration of potassium being fed will result in appropriate acidification. Urine pH provides an inexpensive and relatively accurate estimate of blood pH in dairy cattle. Mean urine pH ranges from ~ 6 – 6.5 are optimal to manage DCAD and prevent milk fever. Urine should be measured >24 hr after addition of an anionic diet in pre-fresh cows.

An important drawback to feeding anionic salts is poor palatability, which can be overcome by using a mixture of anionic salts within a moist, palatable ration such as corn silage, brewer's grain, distiller's grain, or molasses. Although sulfate salts are more palatable than chloride salts, they are less effective in acidifying the blood. Dietary sulfur should be $>0.22\%$ dry matter to support rumen microbial amino acid synthesis but $<0.4\%$ dry matter to avoid neurologic signs associated with sulfur toxicity. If dry matter intake drops >1 kg/day

in a group of pre-fresh dry cows fed an acidifying diet, the dose of anions should be decreased to the point that dry matter intake is restored.

Administration of vitamin D₃ and its metabolites effectively prevents parturient paresis. Large doses of vitamin D (20–30 million U/day), given in the feed for 5–7 days before parturition, reduces the incidence. However, if administration is stopped >4 days before calving, the cow is more susceptible. Dosing for periods longer than those recommended should be avoided because of potential toxicity. A single injection (IV or SC) of 10 million IU of crystalline vitamin D given 8 days before calving is an effective preventive. The dose is repeated if the cow does not calve on the due date. Newer compounds used (where available and approved) in lieu of vitamin D and less likely to cause hypervitaminosis include 25-hydroxycholecalciferol, 1,25-dihydroxycholecalciferol, and 1 α -hydroxycholecalciferol. After calving, a diet high in calcium is required. Administering large doses of calcium in gel form (PO) is commonly practiced. Doses of 150 g of calcium gel are given 1 day before, the day of, and 1 day after calving.

Use of synthetic bovine PTH may prove to be superior to administration of vitamin D metabolites. Vitamin D metabolites enhance GI calcium absorption, whereas PTH enhances GI calcium absorption and stimulates bone resorption. PTH is administered either IV 60 hr before parturition, or IM 6 days before parturition. Drawbacks to the use of PTH include increased labor requirements for administration, as well as the availability of such compounds.

PARTURIENT PARESIS IN SHEEP AND GOATS

(Milk fever, Hypocalcemia)

Parturient paresis in pregnant and lactating ewes and does is a disturbance of metabolism characterized by acute-onset hypocalcemia and rapid development of hyperexcitability and ataxia, progressing to depression, recumbency, coma, and death. Unlike parturient paresis in dairy cattle, which primarily occurs within a few days of calving, the condition in ewes and does usually occurs before and less commonly after parturition. This condition may be underdiagnosed in some situations.

Etiology: Parturient paresis is caused by a decrease in calcium intake under conditions

of increased calcium requirements, usually during late gestation. This results in a low serum calcium concentration, particularly in animals pregnant with multiple fetuses. Some cases are complicated by concurrent pregnancy toxemia. Ewes that are both hypocalcemic and hyperketonemic may not be able to produce endogenous glucose as readily as ewes that are only hyperketonemic, leading to the risk of more severe disease developing when both conditions are present. Parturient paresis can occur at any time from 6 wk before to 10 wk after parturition; however, the greatest demand for calcium because of mineralization of the fetal skeleton occurs 1–3 wk prepartum, particularly when multiple fetuses are present in utero. Whenever an abrupt decrease in calcium intake occurs, the body requires 24–72 hr to activate the metabolic machinery necessary to mobilize stored calcium. Mobilization of stored calcium can be inadequate to meet the animal's needs in older ewes and does, in animals with chronic calcium deficiency, and when diets are calcium deficient. Examples of forages with low calcium levels include cereal hays or pasture, poor-quality grassy hays and pasture, and corn silage. Most grains also contain little calcium but additionally have high levels of phosphorus, causing an inverse calcium:phosphorus ratio, increasing dietary risk. Vitamin D deficiency, which occurs in housed ruminants during winter months, also depresses calcium absorption from the GI tract.

Clinical Findings and Diagnosis: Characteristically, parturient paresis occurs in outbreaks, with most cases occurring in the last few weeks of gestation, although it is not uncommon for individual animals to be affected. Usually, <5% of animals are affected, but severe outbreaks may involve up to 30% of the flock. The onset is sudden and often follows—within 24 hr—an abrupt change of feed, a sudden change in weather, or short periods of fasting imposed by circumstances such as shearing or transportation (see also p 1030). In early hypocalcemia in sheep, the most commonly noted signs are stiff gait, ataxia, salivation, constipation, and depressed rumen motility, progressing to hyposensitivity, bloat, recumbency, loss of anal reflex and, if untreated, death. Tachycardia may be present; heart sounds are quieter than normal. Often when recumbent, ewes are in a sternal frog-lying position, with the hindlegs extended behind. Goats have a similar presentation, although muscle tremors are more commonly seen than in sheep.

A working diagnosis is based on the history and clinical signs. In outbreaks occurring before parturition, pregnancy toxemia (*see* ► 1021) is the main differential diagnosis. These diseases also occur concurrently. A tentative diagnosis of acute hypocalcemia is supported by a dramatic and usually lasting response to slow IV administration of calcium. Diagnosis can be confirmed by testing serum calcium levels before treatment. Urine ketone or serum β -hydroxybutyrate levels should always be evaluated at the same time. Hypocalcemia is often classified as total serum calcium levels <2 mmol/L or, if expressed as ionized calcium, <1.1 mmol/L. Normal values are reported as 2.8–3.2 mmol/L for sheep and 2.2–3.05 mmol/L for goats. (To convert from mmol/L to mg/dL, divide the value by 0.25.) Animals with low serum albumin, such as occurs with Johne's disease and clinical GI parasitism, may have low total serum calcium and normal ionized calcium.

Treatment and Prevention: Treatment should be initiated immediately, usually administered as calcium borogluconate IV (50–150 mL of a 23% solution). Calcium-containing products that also contain phosphorus and magnesium, as well as dextrose, likely have additional therapeutic value. Oral or SC administration of a calcium solution helps to prevent relapse. During treatment, the heart should be monitored, and therapy slowed or stopped if arrhythmias occur. For ease of IV administration, it may be preferred to increase the volume of the product by adding 50–150 mL of a 23% calcium borogluconate or gluconate solution to 1 L of a 5% dextrose solution and administering this volume over 10 min. Dietary modifications to increase the calcium:phosphorus ratio ($>1.5:1$) and ensure total calcium in the diet meets NRC requirements (*see* TABLE 1),

as well as vitamin D levels, may help to prevent further cases in pregnant animals. Sudden dietary changes or other stressors should be avoided during late gestation, and risk factors for pregnancy toxemia investigated.

PUERPERAL HYPOCALCEMIA IN SMALL ANIMALS

(Postpartum hypocalcemia, Periparturient hypocalcemia, Puerperal tetany, Eclampsia)

Puerperal hypocalcemia is an acute, life-threatening condition usually seen at peak lactation, 2–3 wk after whelping. Small breed bitches with large litters are most often affected. Hypocalcemia may also occur during parturition and may precipitate dystocia.

Etiology and Pathogenesis: Hypocalcemia most likely results from loss of calcium into the milk and from inadequate dietary calcium intake. This imbalance in calcium metabolism occurs because calcium mobilization from bone into the serum pool is insufficient to maintain the efflux of calcium leaving through the mammary glands. Heavy lactational demands from large puppies or a large litter are often noted. The incidence is increased in small breeds of dogs, although puerperal hypocalcemia can occur in any breed, with any size litter, and at any time during lactation. Rarely, it occurs during late gestation in bitches. Although uncommon in queens, it may occur during early lactation. In dogs, supplementation with oral calcium during pregnancy may predispose to eclampsia during peak lactation, because excessive calcium intake during pregnancy causes downregulation of the calcium regulatory system and subsequent clinical hypocalcemia when calcium demand is high.

TABLE 1

CALCIUM REQUIREMENTS OF A MEAT EWE AND DAIRY DOE DURING GESTATION AND LACTATION

70-kg adult with twins	Calcium Requirements (g/day)			
	Early gestation	Late gestation	Early lactation	Mid lactation
Ewe (meat)	6.5	8.8	7.9	6.5
Doe (parlour milked)	6.6	6.6	20.7	21.4

Adapted, with permission, from *Nutrient Requirements of Small Ruminants*, Animal Nutrition Series, 2007. National Academy of Sciences, National Academy Press, Washington DC.

Inadequate production of parathyroid hormone (PTH) during the hypocalcemic crisis is not responsible for eclampsia in dogs. In dairy cows with a similar condition (see p 988), production of PTH is adequate, but the pool of osteoclasts for PTH to stimulate is not. The small osteoclast pool results from feeding a high level of dietary calcium during the nonlactating period, which suppresses parathyroid gland secretion of PTH and stimulates parafollicular C-cell secretion of calcitonin. Hypocalcemia at parturition interferes with the release of acetylcholine at the neuromuscular junction, which is normally mediated by extracellular calcium entering presynaptic nerve terminals through voltage-gated calcium channels and triggering the fusion of acetylcholine-filled synaptic vesicles with the presynaptic nerve terminus. The paresis seen in cattle, rather than the tetany seen in dogs, is probably the result of a combination of factors. Cows often have concurrent mild hypomagnesemia. Magnesium is a calcium-channel antagonist and plays a key role in modulating any activity governed by intracellular calcium fluxes. Cows also have increased volatile fatty acids (which are inhibitory at neuromuscular synapses), and cows have a higher threshold potential at neuromuscular junctions than do dogs.

In dogs with hypocalcemia, unlike cows, excitation-secretion coupling is maintained at the neuromuscular junction. The low concentration of calcium in the extracellular fluid has an excitatory effect on nerve and muscle cells, because it lowers the threshold potential (voltage level at which sodium channels become activated) so it is closer to the resting membrane potential. With hypocalcemia, sodium channels become activated (opened) by very little increase in membrane potential from their normal, negative level. Therefore, the nerve fiber becomes highly excitable, sometimes discharging repetitively without provocation rather than remaining in the resting state. The probable way that calcium ions affect the sodium channels are that calcium ions bind to the exterior surfaces of sodium channels. The positive charge of these calcium ions alters the electrical state of the sodium channel protein, thus altering the voltage level required to open the sodium channel. Because of the loss of stabilizing membrane-bound calcium ions, nerve membranes become more permeable to sodium ions and require a stimulus of lesser magnitude to depolarize. Tetany occurs as a result of spontaneous repetitive firing of motor nerve fibers. Hypoglycemia can occur concurrently.

Clinical Findings: Panting and restlessness are early clinical signs. Mild tremors, twitching, muscle spasms, and gait changes (stiffness and ataxia) result from increased neuromuscular excitability. Behavioral changes such as aggression, whining, salivation, pacing, hypersensitivity to stimuli, and disorientation are frequent. Severe tremors, tetany, generalized seizure activity, and finally coma and death may be seen. Hyperthermia may occur in severe cases. Prolonged seizure activity may cause cerebral edema. Tachycardia, hyperthermia, polyuria, polydipsia, and vomiting are sometimes seen. Historically, the bitch has been otherwise healthy and the neonates have been thriving.

Although hypocalcemia usually occurs postpartum, clinical signs can appear prepartum or at parturition. Mild hypocalcemia (serum calcium concentration >7 mg/dL but below the normal reference range) may contribute to ineffective myometrial contractions and slow the progression of labor without causing any other clinical signs.

Heavy panting may produce a respiratory alkalosis. Ionized calcium is the physiologically available fraction; it is affected by protein concentration, acid-base status (alkalosis favors protein binding of serum calcium and will decrease blood levels of the biologically important ionized calcium, thus exacerbating hypocalcemia), and other electrolyte imbalances. Thus, the severity of clinical signs may not correlate with total calcium concentration.

Diagnosis: Diagnosis is often made from the signalment, history, clinical signs, and response to treatment. A pretreatment total serum calcium concentration <7 mg/dL (<6 mg/dL in cats) confirms the diagnosis. (IV therapy with calcium is often started, however, before serum calcium concentration is determined.) A serum chemistry profile is useful to exclude concurrent hypoglycemia and other electrolyte imbalances. Prolongation of the QT interval and ventricular premature contractions may be seen on the ECG.

Differential diagnoses include other causes of seizures such as hypoglycemia, toxicoses, and primary neurologic disorders such as idiopathic epilepsy or meningoencephalitis. Other causes of irritability and hyperthermia such as metritis and mastitis should also be excluded. If the parathyroid glands are functioning normally, serum PTH will be increased in the face of hypocalcemia. Low or undetectable serum PTH in a hypocalcemic animal is strongly suggestive

of primary hypoparathyroidism (*see* p 1057). A commercially available human intact-PTH assay has been validated in both cats and dogs; PTH-curve curves are also similar in cats and dogs.

Treatment and Prevention: Slow IV administration of 10% calcium gluconate is given to effect (0.5–1.5 mL/kg over 10–30 min; 5–20 mL is the usual dose). This usually results in rapid clinical improvement within 15 min. Muscle relaxation should be immediate.

During administration of calcium, heart rate should be carefully monitored by auscultation or by ECG for bradycardia or arrhythmias. Signs of toxicity from too rapid administration of calcium include bradycardia, shortening of the QT interval, and premature ventricular complexes. If an arrhythmia develops, calcium administration should be discontinued until the heart rate and rhythm are normal; then administration is resumed at half the original infusion rate.

It is important to calculate the dosage of calcium based on elemental (available) calcium, because different products vary in the amount of calcium available. The dosage of elemental calcium for hypocalcemia is 5–15 mg/kg/hr. Calcium gluconate, 10%, contains 9.3 mg of elemental calcium/mL. Calcium chloride, 27%, contains 27.2 mg of elemental calcium/mL. Thus, for 10% calcium gluconate the dosage is 0.5–1.5 mL/kg/hr, IV, and for 27% calcium chloride the dosage is 0.22–0.66 mL/kg/hr, IV. Calcium gluconate, as a 10% solution, is recommended because, unlike calcium chloride, calcium gluconate extravasation is not caustic.

Once the animal is stable, the dose of calcium gluconate needed for initial control of tetany may be diluted in an equal volume of normal (0.9%) saline and given SC, tid, to control clinical signs. (Calcium chloride cannot be given SC.) Alternatively, 5–15 mg of elemental calcium/kg/hr can be continued IV. This protocol effectively supports serum calcium concentrations while waiting for oral vitamin D and calcium therapy to have effect. Ideally, serum calcium concentration should be maintained >8 mg/dL. Serum calcium concentrations <8 mg/dL indicate the need to increase the dosage of parenteral calcium, whereas concentrations >9 mg/dL suggest that it be reduced. The aim of longterm therapy is to maintain the serum calcium concentration at mildly low to low-normal concentrations (8–9.5 mg/dL).

The bitch may remain nonresponsive after correction of hypocalcemia if cerebral edema has developed. Cerebral edema, hyperthermia, and hypoglycemia should be treated if present. Fever usually resolves rapidly with control of tetany, and specific treatment for fever may result in hypothermia.

It is best not to let the puppies or kittens nurse for 12–24 hr. During this period, they should be fed a milk substitute or other appropriate diet; if mature enough, they should be weaned. If tetany recurs in the same lactation, the litter should be removed from the bitch and either hand raised (<4 wk old) or weaned (>4 wk old).

After the acute crisis, elemental calcium at 25–50 mg/kg/day in three or four divided doses is given PO for the remainder of the lactation. Again, the dose of calcium is based on the amount of elemental calcium in the product (ie, calcium carbonate tablets contain 295 mg elemental calcium/1 g tablet). In dogs, the dosage is usually 1–4 g/day, in divided doses. In cats, the dosage of calcium is ~0.5–1 g/day, in divided doses. Longterm maintenance therapy with oral vitamin D and oral calcium supplementation usually requires a minimum of 24–96 hr before an effect is achieved. Hypocalcemic animals should, therefore, receive parenteral calcium support during the initial posttetany period. Calcium carbonate is a good choice because of its high percentage of elemental calcium, general availability in drugstores in the form of antacids, low cost, and lack of gastric irritation. The dosage of calcium can be gradually tapered to avoid unnecessary therapy; there is usually sufficient calcium in commercial pet food to meet the needs of dogs and cats. However, to avoid acute problems of hypocalcemic tetany, oral calcium supplementation should continue throughout lactation.

Vitamin D supplementation is used to increase calcium absorption from the intestines. The concentration of serum calcium should be monitored weekly. The dosage of 1,25-dihydroxyvitamin D (calcitriol) is 0.03–0.06 mcg/kg/day. Calcitriol has a rapid onset of action (1–4 days) and short half-life (<1 day). Iatrogenic hypercalcemia is a common complication of this therapy. If hypercalcemia results from overdosage, it can be rapidly corrected by discontinuing calcitriol. The toxic effects resolve in 1–14 days. This is a much briefer period than that seen with dihydrotachysterol (1–3 wk) or ergocalciferol (vitamin D₂; 1–18 wk) therapy.

Corticosteroids lower serum calcium and, therefore, are contraindicated. They may interfere with intestinal calcium transport and increase urinary loss of calcium.

Owners should be warned that puerperal hypocalcemia is likely to recur with future pregnancies. Preventive steps to consider in the bitch include feeding a high-quality, nutritionally balanced, and appropriate diet during pregnancy and lactation, providing food and water ad lib during lactation, and supplemental feeding of the puppies with milk replacer early in lactation and with solid food after 3–4 wk of age. Oral calcium supplementation during gestation is not indicated and may cause rather than prevent postpartum hypocalcemia. Calcium administration during peak milk production may be helpful in bitches with a history of puerperal hypocalcemia.

HYPOCALCEMIA AS AN ELECTROLYTE DISTURBANCE IN SMALL ANIMALS

Hypocalcemia is also an important electrolyte disturbance in critically ill

dogs and cats. The incidence of hypocalcemia is 16% in critically ill dogs and 24% in dogs with sepsis. Hypocalcemia is best detected by measuring ionized calcium (<2.5 mEq/L), which is the biologically active form, rather than total or corrected calcium. Hypocalcemia, hypovitaminosis D, and metabolic acidosis occur in dogs with induced endotoxemia. LPS may mediate a decrease in vitamin D-binding protein, with subsequent loss of vitamin D in the urine. Also, dogs with blunt and penetrating traumatic injuries, particularly abdominal trauma, are significantly more likely to have ionized hypocalcemia (16% incidence). These dogs spend longer time in the hospital and ICU, require more intensive therapies, and are less likely to survive (57% survival rate) than dogs with normocalcemia (89% survival rate). Hypocalcemia from critical illness or traumatic injury can cause clinical signs similar to those of puerperal hypocalcemia (hyperexcitability, including tremors, twitching, spasms, or seizures, or more subtle signs related to cardiovascular collapse).

DISORDERS OF MAGNESIUM METABOLISM

Magnesium (Mg) homeostasis is not under direct hormonal control but is mainly determined by absorption from the GI tract; excretion by the kidneys; and the varying requirements of the body for pregnancy, lactation, and growth. Magnesium is the second most common intracellular cation after potassium, with 50%–60% of total body Mg distributed in bone, 40%–50% in soft tissues, and $<1\%$ in the extracellular fluid. Therefore, plasma Mg does not provide an indication of intracellular or bone Mg stores. Intracellular Mg is required for activation of enzymes involving phosphate compounds such as ATPases, kinases, and phosphatases; and for synthesis of RNA, DNA, and protein. Magnesium is a cofactor for >300 enzymatic reactions involving ATP, including glycolysis and oxidative phosphorylation. It is also important in the function of the Na^+/K^+ -ATPase pump, membrane stabilization, nerve conduction, ion transportation, and calcium channel activity. Magnesium also regulates the

movement of calcium into smooth muscle cells, giving it a pivotal role in cardiac contractile strength and peripheral vascular tone. Low ionized Mg concentrations accelerate the transmission of nerve impulses. Clinical manifestations of severe hypomagnesemia include muscle weakness, muscle fasciculations, ventricular arrhythmias, seizures, ataxia, and coma.

Similar to calcium, serum total magnesium (tMg) can be divided into three forms. The physiologically active (free) fraction is ionized magnesium (iMg^{2+}), whereas the protein-bound and chelated fractions are unavailable for biochemical processes. Serum iMg^{2+} cannot be accurately calculated from serum tMg and albumin concentrations; therefore, serum iMg^{2+} concentration must be determined by direct measurement. Because iMg^{2+} concentrations represent the functional pool of serum Mg, determination of iMg^{2+} may provide a better physiologic assessment of Mg status than does tMg. A commercially available

ion-selective electrode for Mg allows routine measurement of iMg^{2+} concentrations.

Magnesium is cleared by glomerular filtration and, in the absence of renal disease, renal homeostatic mechanisms will attempt to maintain Mg balance. When the diet contains excessive Mg, renal tubular resorption decreases, maintaining serum concentrations of Mg within narrow physiologic limits. Renal excretion of Mg may be used to evaluate Mg balance.

IV administration of large doses of Mg is safely used to concurrently diagnose and treat hypomagnesemia. The IV Mg retention test, which involves the determination of urinary Mg retention, has become the gold standard to determine Mg status in human medicine and has been validated in horses, dogs, and cattle. Animals deficient in Mg will retain a large proportion of the administered Mg, whereas animals with sufficient Mg will excrete most of it.

Fractional clearance relates the amount of substance excreted to the amount filtered by the glomerulus without the need for volumetric urine collection. Fractional clearance can be calculated by using concurrently collected spot samples of urine and serum and by measuring the concentrations of creatinine and the electrolyte of interest. This allows assessment of urinary electrolyte excretion without the need for timed urine collections and takes into account variability in urine concentration due to hydration status.

Ruminants are more prone to hypomagnesemia than monogastric animals. The variation in Mg metabolism among species is mainly because of anatomic and physiologic differences in digestive tracts. Ruminants absorb Mg less efficiently than nonruminants (35% vs 70% of intake). The rumen is the main site of absorption, and there are active transport mechanisms. Absorption from the large intestine occurs with high Mg intakes. In nonruminants, the small intestine is the main site of absorption. Species differences in Mg metabolism are attributable to variation in both absorption efficiency of Mg from the gut and reabsorption of Mg by the kidney tubules.

HYPERMAGNESEMIA

Hypermagnesemia (plasma Mg concentration >2 mg/dL [1.1 mmol/L]) is a rare condition reported only in monogastric animals. Horses show signs of sweating and muscle weakness within 4 hr of receiving excessive oral doses of magnesium sulfate

administered as a cathartic for treatment of large-intestinal impactions. This is followed by recumbency, tachycardia (120 bpm), and tachypnea (60 breaths/min). Signs subside after treatment with slow IV infusion of calcium gluconate (23% solution). Hypermagnesemia has been reported in cats with renal failure that were receiving IV fluid therapy. As plasma Mg concentrations exceed 2.5 mmol/L, there may be ECG changes with prolongation of the PR interval; at 5 mmol/L, deep tendon reflexes disappear, followed by hypotension and respiratory depression. Cardiac arrest may occur with blood Mg levels >6.0 – 7.5 mmol/L.

HYPOMAGNESEMIC TETANY IN CATTLE AND SHEEP

(Grass tetany, Grass staggers)

Hypomagnesemic tetany is a complex metabolic disturbance characterized by hypomagnesemia (plasma tMg <1.5 mg/dL [<0.65 mmol/L]) and a reduced concentration of tMg in the CSF (<1.0 mg/dL [0.4 mmol/L]), which lead to hyperexcitability, muscular spasms, convulsions, respiratory distress, collapse, and death. Adult lactating animals are most susceptible because of the loss of Mg in milk. Hypomagnesemic tetany occurs mainly when animals are grazed on lush grass pastures or green cereal crops but can occur in lactating beef cows fed silage indoors. It is rare in nonlactating cattle but has occurred when undernourished cattle were introduced to green cereal crops.

Etiology: The disorder occurs after a decrease in plasma Mg concentration when absorption of dietary Mg is unable to meet the requirements for maintenance (3 mg/kg body wt) and lactation (120 mg/kg milk). This can arise after a reduction in food intake during inclement weather, transport, or when cows graze short-grass dominant pastures containing $<0.2\%$ Mg on a dry-matter basis. Low herbage availability ($<1,000$ kg dry matter/hectare) results in liveweight losses during lactation, and plasma Mg decreases because insufficient Mg is obtained from body tissues mobilized during loss of liveweight to support lactation.

Mg absorption from the rumen may be reduced when potassium and nitrogen intakes are high and sodium and phosphorus intakes are low. Soils naturally high in potassium and those fertilized with potash and nitrogen are high-risk areas for

hypomagnesemic tetany. The more complex mineral interactions are likely to be involved in herds in which hypomagnesemic tetany occurs in first- and second-calving cows as well as in older cows.

Cows often do not develop signs of hypomagnesemic tetany until blood calcium concentrations are <0.8 mg/dL (0.35 mmol/L), which commonly occurs in cattle grazing green cereal crops. The hypocalcemia arises from either a reduction in calcium intake or absorption, or both. Lush grass pastures and green cereal crops may predispose cattle to metabolic alkalosis (urine pH >8.5) with a reduced available pool of ionized calcium and magnesium, thereby increasing the risk of hypocalcemia and hypomagnesemia. Urine Mg concentrations are a useful guide to Mg status and are undetectable in cows with hypomagnesemia.

Clinical Findings: In the most acute form, affected cows, which may appear to be grazing normally, suddenly throw up their heads, bellow, gallop in a blind frenzy, fall, and exhibit severe paddling convulsions. These convulsive episodes may be repeated at short intervals, and death usually occurs within a few hours. In many instances, animals at pasture are found dead without observed illness, but an indication that the animal had convulsions before death may be seen from marks on the ground. In less severe cases, the cow is obviously ill at ease, walks stiffly, is hypersensitive to touch and sound, urinates frequently, and may progress to the acute convulsive stage after a period as long as 2–3 days. This period may be shortened if the cow is transported or driven to a fresh pasture. When animals have hypocalcemia and hypomagnesemia, the signs shown depend on which predominates. With hypomagnesemia, tachycardia and loud heart sounds are characteristic signs.

Clinical signs of hypomagnesemic tetany in sheep occur when hypomagnesemia (plasma tMg <0.5 mg/dL [0.2 mmol/L]) occurs concomitantly with hypocalcemia (plasma tCa <8 mg/dL [2.0 mmol/L]). The disease in lactating ewes occurs under essentially the same conditions and has the same clinical signs as in cattle.

Diagnosis: Diagnosis is usually confirmed by response to treatment, followed by confirmation of hypomagnesemia in samples taken before treatment. Tetany usually occurs when plasma tMg is <1.2 mg/dL (0.5 mmol/L) in cattle and <0.5 mg/dL (0.2 mmol/L) in sheep. Urine Mg is usually

undetectable in cows with hypomagnesemic tetany. Mg concentrations <1.8 mg/dL (0.75 mmol/L) in the vitreous humour of the eye removed from animals within 24 hr after death are indicative of hypomagnesemic tetany.

Treatment: Animals showing clinical signs require treatment immediately with combined solutions of calcium and Mg, preferably given slowly IV while monitoring the heart (*see* p 988). The response to treatment is slower in animals with hypomagnesemic tetany than in animals with hypocalcemia alone, because of the time it takes to restore Mg in the CSF. The animal should not be stimulated during treatment, because this could trigger fatal convulsions. Additional Mg sulfate (200 mL of a 50% solution/cow) can be given SC. After treatment, cows should be left to respond without stimulation and then moved off the tetany-prone pasture, if possible. Animals must be provided with hay treated with 2 oz (60 g) of Mg oxide daily; if this is not done, the condition can recur within 36 hr after initial therapy.

Prevention: Mg must be given daily to animals at risk, because the body has no readily available stores. Daily oral supplements of Mg oxide (2 oz [60 g] to cattle and $\frac{1}{3}$ oz [10 g] to sheep) should be given in the danger period. Most Mg salts are unpalatable and must be combined with other palatable ingredients such as molasses, concentrates, or hay. Feeding hay alone may be all that is required to prevent hypomagnesemic tetany in herds in which only old cows (>6 yr) are affected. If slow-release intraruminal Mg devices are administered, the animals also should be provided with hay. Fertilizers containing Mg effectively increase herbage Mg only on certain soil types. Herbage may be dusted with powdered Mg oxide (500 g/cow) or sprayed with a 2% solution of Mg sulfate at intervals of 1–2 wk. If rainfall exceeds 40–50 mm within 2–3 days of dusting, the herbage will require another dusting.

● Out-wintered stock should be protected from wind and cold and provided with supplementary food. Sheep and cattle should have access to hay, particularly when grazing either green cereal crops or pastures fertilized with potassium or nitrogen (or both).

Hypomagnesemic Tetany in Calves

Magnesium absorption efficiency in calves fed milk falls from 87% at 2–3 wk to 32% at

7–8 wk of age. Hypomagnesemic tetany occurs in 2- to 4-mo-old calves being fed milk only, or in younger calves with chronic scours while being fed milk replacer.

Clinical signs are similar to those of hypomagnesemic tetany in adult cattle (see above) and include hyperexcitability, muscular spasms, convulsions, and death.

Hypomagnesemic tetany in calves must be differentiated from acute lead poisoning (see p 3078), tetanus (see p 611), strychnine poisoning (see p 3170), polioencephalomalacia (see p 1281), and enterotoxemia caused by the toxin of *Clostridium perfringens* (see p 609). Analysis of bone aids diagnosis—normal bone has a Ca:Mg ratio of 70:1; in hypomagnesemic calves, the ratio may be $\geq 90:1$.

Affected calves require prompt treatment with a 10% solution of Mg sulfate (100 mL, SC) followed by Mg oxide at 10 g/day, PO. Provision of good-quality legume hay and a starter ration from 2 wk of age prevents the disorder.

MAGNESIUM AS AN EQUINE DIETARY SUPPLEMENT

Dietary Mg deficiency in horses is very rare, unless extreme conditions combine to result in decreased consumption and increased demand, eg, long-distance transportation of unfed lactating mares or prolonged administration of enteral or parenteral fluid or nutrition solutions deficient in Mg. Despite this, Mg supplements have been advocated by laymen as a calming agent or as an adjunctive therapy for equine metabolic syndrome, and even to prevent laminitis. There is no evidence that these uses are beneficial or effective, and such practices should be discouraged. One randomized placebo controlled study showed no difference in either insulin sensitivity or morphometric variables in horses supplemented with Mg (8.8 g/d) and chromium. Although sedation can be seen in horses administered >500 g of MgSO_4 as a cathartic via stomach tube, low level Mg supplements are unlikely to influence behavior, and larger amounts would be unpalatable in the feed or even dangerous if administered as repeated dosages via nasogastric tube (see p 996). Recommended doses of 3–10 g are unlikely to have a clinical benefit. However, low-level supplementation is considered relatively safe even if not efficacious, because excess Mg will be readily excreted by the kidneys in animals with normal renal function.

The maintenance Mg requirement for horses has been estimated at 13 mg/kg body wt/day and can be provided by a diet containing 0.16% Mg (1,600 ppm of feed) or by adding Mg oxide at 31 mg/kg/day, MgCO_3 at 64 mg/kg/day, or MgSO_4 at 93 mg/kg/day. This may be important when formulating oral replacement fluids for inappetent horses. For a 500-kg horse, this would equate to Mg oxide at ~16 g/day, MgCO_3 at 32 g/d, or MgSO_4 at 47 g/day. Growing, lactating, and exercising animals may require double these amounts. Horses that are obtaining adequate feed by grazing, with hay or grain, are unlikely to be Mg deficient. Horses are able to absorb 30%–60% of the Mg provided in their feed, which is higher than the absorption rate in ruminants.

If a pasture is considered Mg deficient (winter pastures with little herbage that have been fertilized with potash and/or nitrogen), then renal excretion of Mg may be used to evaluate Mg balance. With low dietary Mg intake, urinary Mg excretion falls to negligible levels. Renal Mg excretion is measured in urine collected throughout 24 hr (mg/kg/day). The fractional clearance of Mg can be determined by expressing the renal Mg clearance relative to the creatinine clearance and requires only a single sample each of urine and serum. Fractional clearance of Mg in healthy horses fed grass hay ranges from 15% to 35%, and values $<6\%$ indicate inadequate dietary Mg intake. A Mg retention test to assess total body status has been evaluated in horses receiving Mg-deficient diets, but this test offered no benefit over performing fractional clearances and requires 48 hr of volumetric urine collection.

SUBCLINICAL HYPOMAGNESEMIA IN CRITICALLY ILL ANIMALS

Subclinical hypomagnesemia is common in critically ill horses and small animals and can increase the severity of the systemic inflammatory response syndrome; worsen the systemic response to endotoxin; and lead to ileus, cardiac arrhythmias, refractory hypokalemia, and hypocalcemia.

Low serum Mg concentrations have been reported to occur in 65% of critically ill people, 39%–46% of dogs and cats in the intensive care unit (ICU), 49% of hospitalized horses, 54% of equine surgical colic patients, and 78% of horses with enterocolitis. In human and canine ICU populations, hypomagnesemic patients had higher rates of concurrent hypokalemia and hypona-

tremia and a longer length of hospitalization. In another study, 54% of equine surgical colic patients had low iMg levels, and these horses had a significantly greater prevalence of postoperative ileus.

Although diets for horses and small animals are rarely deficient in Mg, subclinical acute hypomagnesemia is very common in critically ill animals. Serum Mg concentration may be low as a result of altered Mg homeostasis, cellular or third-space redistribution, GI loss of Mg, or diuresis secondary to aggressive fluid therapy with IV fluids unsupplemented with Mg.

Hypocalcemia is also frequently seen in the equine ICU. Although the mechanism of action is unknown, serum Mg may influence serum calcium concentrations; human hypocalcemic patients with concurrent hypomagnesemia are often refractory to calcium therapy unless the low serum Mg levels are identified and corrected. Despite

the precise regulation of serum Mg concentration by the kidney, Mg does not have a complex homeostatic endocrine regulating mechanism. This is in contrast to calcium, which is tightly regulated by parathyroid hormone (PTH), calcitonin, and calcitriol. However, PTH, vitamin D, calcitonin, arginine vasopressin, glucagons, and calcium concentrations do influence Mg absorption and excretion to some degree.

Mild hypocalcemia and hypomagnesemia stimulate PTH release, but severe Mg depletion and acute hypermagnesemia decrease PTH release. Consequently, parallel determination of calcium and PTH concentrations is important in the investigation of Mg homeostasis.

If longterm fluid therapy is required to support an inappetent animal in the ICU, Mg should be supplemented. A constant rate infusion of Mg sulfate at 50–150 mg/kg/day, IV (0.1–0.3 mL/kg/day of the 50% solution), provides daily requirements.

DISORDERS OF PHOSPHORUS METABOLISM

Phosphorus (P) is a macromineral with a plethora of important biologic functions. In addition to being essential for the structural stability of bones and teeth, cell membranes (phospholipids), and nucleic acid molecules, phosphorus plays an important role in metabolic activity such as carbohydrate and energy metabolism that inherently depends on the capacity to phosphorylate intermediate metabolites and to store energy released during oxidation in high-energy phosphate bonds such as ATP or phosphocreatine. Phosphorus is an integral component of 2,3-DPG, a compound that regulates oxygen release from hemoglobin and therefore is critical for oxygen delivery to tissues. Inorganic phosphorus (phosphate, PO_4 , or Pi) is also an important buffer in the body.

In the body, phosphorus is present as a stable inorganic phosphate (Pi), an organic phosphate ester, or a phospholipid. By far the largest fraction of the body phosphorus (~85% of total body phosphorus) is incorporated into bone in an insoluble inorganic phosphate form (dihydroxyapatite). The remainder is largely located in the intracellular space (ICS, ~14%), while <1% of the total body phosphorus is found in the

extracellular space (ECS), which includes blood serum or plasma. In the ECS, phosphorus is present either as Pi, forming the metabolically relevant fraction, or as phospholipids. The extracellular Pi fraction is largely (~85%) ionized (either H_2PQ_4^- or HPO_4^{2-}), while ~10% is protein bound and 5% is complexed with other minerals such as calcium or magnesium.

The concentration of Pi in the ECS and thus in serum is dictated by the equilibrium between Pi uptake from the digestive tract; Pi excretion in urine (monogastric species), saliva (ruminants), and milk; the uptake or release of Pi from bone; and compartmental Pi shifts between the ECS and ICS. Accordingly, hypophosphatemia that is defined as subnormal serum or plasma Pi concentration can be caused by decreased oral phosphorus uptake, increased phosphorus loss, increased cellular phosphorus uptake, or a combination of these factors. Because only increased phosphorus loss and decreased phosphorus uptake are associated with phosphorus depletion of the body but compartmental shifts of phosphorus between the ICS and ECS can strongly affect the extracellular Pi concentration, the serum Pi concentration

is an unreliable parameter to assess the phosphorus status of an animal. Despite the difficult interpretation of the serum Pi concentration, it is still the most commonly used measurement of phosphorus status in veterinary medicine.

HYPOPHOSPHATEMIA

Etiology and Pathogenesis: Chronic phosphorus deficiency is commonly caused by inadequate feed intake or inadequate phosphorus content in the ration over an extended time. This can be seen in grazing animals in arid regions with low phosphorus content in soil. Phosphorus depletion can also result from chronic renal tubular disease due to impaired renal reabsorption of phosphorus (eg, Fanconi syndrome) or primary hyperparathyroidism causing increased renal phosphorus excretion. Hypophosphatemia is a common finding in horses with chronic renal failure.

Acute phosphorus losses associated with hypophosphatemia are a well-recognized problem in high-yielding dairy cows at the onset of lactation. The sudden onset of phosphorus losses through the mammary gland at the onset of lactation and the decreased feed intake around parturition are believed to be the major contributors to periparturient hypophosphatemia of dairy cows. Nonetheless, periparturient hypophosphatemia has also been documented in mastectomized cows, indicating that other mechanisms, such as compartmental shifts, impaired intestinal absorption, or increased losses through the digestive or urinary tracts, must contribute to this phenomenon.

Hypophosphatemia without phosphorus depletion may occur after oral or parenteral carbohydrate administration and after parenteral insulin administration as a result of increased cellular phosphorus uptake in combination with glucose. Alkalemia and respiratory alkalosis enhance cellular phosphorus uptake and therefore also have a hypophosphatemic effect.

Clinical Findings and Lesions: Signs of chronic phosphorus depletion are most commonly seen in cattle fed a phosphorus-deficient diet over several months. Young animals grow slowly, develop rickets, and tend to have a rough hair coat, whereas adult animals in early stages may become lethargic, anorectic, and lose weight. Decreased milk production and fertility have erroneously been attributed to

phosphorus depletion. These signs appear to be the result of decreased energy and protein intake in animals that are anorectic due to phosphorus depletion. In later stages, animals may develop pica, osteomalacia, abnormal gait, and lameness, and eventually become recumbent.

Acute hypophosphatemia has been associated with anorexia, muscle weakness, muscle and bone pain, rhabdomyolysis, increased fragility of RBCs, and ensuing intravascular hemolysis. Other potential effects of hypophosphatemia are neurologic signs presumably related to the altered energy metabolism, impaired cardiac and respiratory function (decreased contractility of striated and heart muscle), and dysfunction of WBCs and platelets that are believed to be caused by ATP depletion.

In cattle, hypophosphatemia occurring at the onset of lactation is widely believed to be associated with periparturient recumbency and the downer cow syndrome (see p 1188). However, this association is based on empirical observation and is not supported by unequivocal evidence. Postparturient hemoglobinuria is another but rare condition seen in high-yielding dairy cows in the first days of lactation. It is characterized by acute intravascular hemolysis and hemoglobinuria, frequently with fatal outcome.

It is currently not well understood whether the above-mentioned clinical signs and conditions are caused by low levels of phosphorus in the blood or by overall depletion of phosphorus in the body.

Necropsy findings in cases of chronic phosphorus depletion are those specific to rickets or osteomalacia. Carcasses appear emaciated with a dull hair coat. Fractures of ribs, vertebrae, or the pelvis, as well as widened growth plates and costochondral junctions, angular deformities, and shortened long bones are common.

Diagnosis: Phosphorus depletion is not readily diagnosed in living animals. Because chronically phosphorus-depleted animals can maintain the serum Pi concentration within normal limits by mobilizing Pi from bone, and because the serum Pi concentration can be decreased even in the absence of phosphorus depletion, the Pi concentration in serum is an unreliable proxy to diagnose chronic phosphorus depletion. Although acute phosphorus depletion can reflect accurately in the serum Pi concentration, the considerable diurnal variation, effects of physical activity, and feed intake complicate the interpretation of results from a single blood sample. Dextrose administered

parenterally shortly before blood sampling can decrease the serum Pi concentration by >30%; 4–6 hr should elapse between the end of dextrose infusion and blood sampling to allow the serum Pi concentration to return to baseline. Other factors that can affect the serum Pi concentration include physical exercise shortly before blood sampling or the site of blood collection. Vigorous physical activity can result in markedly decreased serum or plasma Pi concentrations for >1 hr.

Determination of the bone density or bone phosphorus content in a rib biopsy has been proposed as a reliable parameter to diagnose chronic phosphorus depletion in cattle. Nonetheless, the bone phosphorus content is slow to respond to changes in dietary phosphorus supply, which means the nutritional history has a strong impact on the mineral content of fresh bone. The phosphorus content in fresh bone is therefore a good indicator of body phosphorus reserves but not of current dietary phosphorus supply. Furthermore, obtaining bone biopsies is impractical under field conditions, and determination of bone phosphorus content is generally restricted to postmortem examination or research activities. Alternatively, the extent of bone resorption activity can be determined by measuring the urinary hydroxyproline concentration, an amino acid liberated from collagen as bone is demineralized. Radiographic examination of bone will reveal reduced radiopacity of the bones in chronically phosphorus-depleted animals.

Feed samples can be submitted to determine the phosphorus content in the ration, allowing an estimate of phosphorus intake if the daily feed intake is known. In grazing animals, the phosphorus concentration in either soil or in a fecal sample can be determined and used as an indirect and crude parameter to assess adequacy of the dietary phosphorus content.

Treatment and Prevention: Chronic phosphorus depletion and hypophosphatemia is most effectively treated by providing sufficient amounts of feed with adequate phosphorus content; however, the most appropriate treatment approach for acute phosphorus depletion and hypophosphatemia is controversial. IV administration of phosphorus-containing solutions is often recommended as the most appropriate approach. In small animals, this is achieved by slow IV infusion of sodium phosphate salt solutions, or in case of concomitant hypokalemia of potassium phosphate

solutions. In cattle, rapid administration of sodium phosphate salt solutions is commonly practiced. Mono- or dibasic phosphate salts (either Na_2HPO_4 or NaH_2PO_4) infused IV rapidly increase the serum Pi concentration. Tribasic phosphate (Na_3PO_4) is a caustic detergent that cannot be used under any circumstances for PO or IV phosphorus supplementation. An issue with the IV infusion of phosphorus salt solutions is that unbound Pi in plasma reaching the kidney is filtered by the renal glomeruli and must then be reabsorbed in the renal tubules. Because tubular reabsorption is a saturable process, infusing Pi at a rate that increases plasma Pi concentration above the renal threshold disproportionately increases renal Pi excretion and therefore only transiently increases the plasma Pi concentration. This explains the short-lived effect (<2 hr) of sodium phosphate solutions when administered as an IV bolus as recommended for cattle. Rapid administration of sodium phosphate salts causes transient but severe hyperphosphatemia and therefore bears the risk of causing hypocalcemia due to precipitation of calcium phosphate salts. This risk of calcium phosphate precipitation also precludes the parenteral administration of phosphate salts in combination with parenteral calcium or magnesium infusions. Infusing phosphorus salts slowly over several hours results in a more sustained effect and reduces the risk of hypocalcemia. Currently, no sodium phosphate salt-containing solutions are approved by the FDA for IV administration in cattle; therefore, any effective IV phosphate administration is off-label.

In cattle, solutions containing not phosphate but phosphite (PO_3), hypophosphite, or organic phosphorus compounds such as butaphosphan or toldimpos are often used to supplement phosphorus IV, frequently in combination with calcium, magnesium, and other minerals. However, these phosphorus compounds are not suitable to correct hypophosphatemia, because mammals are unable to convert phosphite or the above-mentioned organic compounds into phosphate (PO_4) and so do not contribute to the biologically active plasma Pi pool. Even when organic phosphorus compounds are usable metabolically, pharmaceutical products containing organic phosphorus compounds administered at label dose do not provide nearly enough phosphorus to correct severe phosphorus depletion, which would be the primary indication for IV treatment.

Mild to moderate phosphorus depletion can be treated effectively by oral Pi supplementation either by adding dairy products to the diet (monogastric species) or by providing solutions of sodium phosphate salts for oral consumption. Oral Pi administration rapidly increases plasma Pi concentration and is safe and effective, but it may not be appropriate in vomiting and possibly in diarrheic animals. In cattle, oral sodium phosphate salts increase the plasma Pi concentration within 3–4 hr and exert a sustained effect lasting >12 hr. Other phosphate salts that have been proposed for rapid correction of hypophosphatemia in cattle include monopotassium phosphate and monocalcium phosphate. Dicalcium phosphate is commonly used for longterm supplementation of phosphorus-deficient diets but because of its poor solubility characteristics is unsuitable for rapid correction of hypophosphatemia.

Phosphorus depletion in healthy grazing animals is prevented by assuring sufficient feed intake with adequate phosphorus content. In animals grazing on phosphorus-deficient soils, depletion may be prevented by fertilizing the soils with phosphorus or by supplementing feeds or the water supply with phosphate salts. In the dairy industry, overfeeding phosphorus is more common because of the widely held but incorrect assumption that feeding phosphorus in excess of the daily requirements improves fertility and milk production. Research consistently confirms that phosphorus concentration of 0.42% in dry matter is adequate for high-yielding dairy cows.

Currently, no effective approach to prevent hypophosphatemia and phosphorus depletion at the onset of lactation is known. Feeding higher amounts of dietary phosphorus during the last weeks of gestation is contraindicated, because it decreases the intestinal absorption rate of phosphorus and increases the risk of periparturient hypocalcemia. The dietary Ca:P ratio that appears to be essential in horses and other species to prevent secondary hypo- or hyperparathyroidism is not important in ruminants. Cattle tolerate Ca:P ratios between 1:1 and 8:1, provided the ration meets minimal requirements for both minerals. This peculiarity in ruminants can be explained by the high salivary phosphorus concentration (5- to 10-fold the concentration in serum) and the large amounts of saliva produced that alter the Ca:P ratio of the rumen content considerably.

HYPERPHOSPHATEMIA

Physiologically increased serum and plasma Pi concentrations are seen in young and growing animals due to enhanced intestinal phosphorus uptake and decreased renal phosphorus excretion, presumably to facilitate bone mineralization. Pathologically increased extracellular phosphorus concentrations can be the result of hemoconcentration, decreased renal excretion, decreased intracellular uptake, or cellular release of phosphorus after cell lysis. Decreased urinary phosphorus excretion in association with chronic renal failure is the most common cause of hyperphosphatemia in many monogastric species except horses. In ruminants, hyperphosphatemia is commonly seen in dehydrated animals and is most likely due to hemoconcentration and a concomitant reduction in saliva production. Massive tissue injury with rhabdomyolysis results in damaged cell membrane integrity, which leads to release of phosphorus together with other predominantly intracellular compounds such as potassium into the extracellular space. Hypoparathyroidism may result in hyperphosphatemia due to increased renal phosphorus reabsorption in the absence of PTH. Incidental cases of severe acute hyperphosphatemia were reported after repeated treatment with enemas containing hypertonic sodium phosphate solutions in people and small ruminants.

Hemolysis occurring during or after blood sample collection results in release of intracellular phosphorus from RBCs and therefore gives erroneously high serum Pi concentrations. Therefore, hemolytic blood samples should not be used to determine the serum or plasma Pi concentration.

Hyperphosphatemia as it occurs during hemoconcentration or decreased glomerular filtration is unlikely to be of any clinical relevance. In more severe cases, concomitant hypocalcemia may result from precipitation of excessive phosphorus with calcium and cause muscle fasciculations and tetanic muscle contractions. In sustained cases, precipitation of calcium-phosphate salts results in extraskeletal tissue mineralization with a potentially fatal outcome.

POSTPARTURIENT HEMOGLOBINURIA

Postparturient hemoglobinuria is a sporadic condition seen worldwide that most commonly affects individual high-yielding

dairy cows at the onset of lactation. It is characterized by development of peracute intravascular hemolysis and anemia with potentially fatal outcome. Beef and nonlactating cattle are rarely affected. The exact cause is unknown, but phosphorus depletion or hypophosphatemia has been incriminated as a major predisposing factor. Severe intracellular phosphorus depletion of RBCs is known to increase osmotic fragility of the RBCs, possibly predisposing to intravascular hemolysis. Although marked hypophosphatemia is commonly diagnosed in affected animals, most cases of severe hypophosphatemia are not associated with intravascular hemolysis, suggesting that hypophosphatemia is not the sole causative factor responsible for postparturient hemoglobinuria. A similar condition reported in New Zealand was associated with copper deficiency, potentially making RBCs more susceptible to oxidative stress. Other potential causes are hemolytic or oxidative plant toxins (often from *Brassica* spp, sugar beets, or green forage).

Clinical cases are rare, but when they occur the case fatality rate is high (10%-30%). With clinical disease, rapid intravascular hemolysis leads to severe anemia, tachycardia, weakness, hemoglobinuria with dark brown or red urine, and pallor over several days. Milk production drops rapidly. Affected cows also may have fever, diarrhea, and tachypnea. Cows that survive the hemolytic crisis may take several months to recover completely. Convalescent cows and cows with subclinical disease develop icterus and evidence of increased erythropoiesis.

Diagnosis is usually made by recognition of clinical signs, particularly dark urine and anemia during the characteristic stage of

lactation. Hemoglobinuria may best be diagnosed by noting failure of the urine to clear with centrifugation (excluding hematuria) and presence of concurrent severe anemia. Intravascular hemolysis caused by *Babesia* (see p 21) or *Theileria* (see p 33) may be excluded by blood smear analysis, and standard laboratory methods can be used to exclude leptospirosis (see p 646) or bacillary hemoglobinuria (see p 601). Diagnostic testing and feed or pasture analysis can be performed to identify toxic plants and deficiency of phosphorus, copper, and other antioxidants.

Transfusion of large quantities of whole blood is the best treatment for severely affected cows. Crystalloid fluids may be beneficial if blood is not available and may protect the kidneys against toxic and anoxic damage, but monitoring the PCV and the total protein concentration is required to prevent third spacing due to the decreased intravascular oncotic pressure. Parenteral treatment with monosodium dihydrogen phosphate (60 g in 300 mL of sterile water) IV followed by oral treatment with 200–300 g of sodium phosphate salts every 12 hr is suitable to rapidly correct hypophosphatemia. Copper glycinate (120 mg available copper) has been recommended in cases in which copper deficiency is suspected as the underlying cause. The efficacy of these treatments to prevent further hemolysis is not documented. No sodium phosphate or copper glycinate solution approved for parenteral administration by the FDA is currently available for use in ruminants. The use of these compounds in dairy cows is therefore extra-label. Correction of mineral deficiencies and elimination of plant toxins from the diet may help prevent recurrence.

DISORDERS OF POTASSIUM METABOLISM

Potassium homeostasis is mainly determined by the balance between absorption of potassium from the GI tract and subsequent excretion by the kidneys (all animals) and saliva (in adult ruminants). Transport of potassium is passive in the small intestine and active in the colon under the influence of aldosterone. The most important hormone affecting renal and salivary

potassium excretion is aldosterone, which is released from the zona glomerulosa of the adrenal gland in response to hyperkalemia and other factors. One of aldosterone's primary actions is to enhance the secretion of potassium ions in the distal renal tubules and collecting ducts. At least 95% of whole body potassium is intracellular, with skeletal muscle containing 60%–75% of the

intracellular potassium. Marked changes in serum or plasma potassium concentrations alter the resting membrane potential of cells, because the potassium gradient generated by Na^+/K^+ -ATPase is the main cause for the negative electric potential across cell membranes. Therefore, hypokalemia or hyperkalemia alters the resting membrane potential, resulting in clinically significant changes in cellular and organ function. Hypokalemia usually indicates whole body depletion of potassium, whereas in hyperkalemia, whole body potassium status cannot be inferred because many animals with hyperkalemia have concurrent acidemia and whole body potassium depletion.

Hypokalemia can occur in any animal receiving large volumes of IV fluid or having a marked and sustained reduction in feed intake. The clinical signs in most animals with mild to moderate hypokalemia are mild and nonspecific. Severe hypokalemia is associated with ventroflexion of the head or recumbency due to generalized muscle weakness and cardiac arrhythmias, including both atrial and ventricular premature complexes that may lead to more complex cardiac arrhythmias. Prolonged and profound hypokalemia can result in a myopathy that is difficult to treat. Cats can be affected by a hypokalemic polymyopathy (*see p 1201*), and Burmese cats have an autosomal recessive disorder that leads to hypokalemic myopathy (*see p 1232*).

Hyperkalemia usually results from inadequate urinary excretion of ingested potassium and is common in monogastric animals with urinary tract obstruction and bladder rupture. Hyperkalemia in horses and ruminants can also result from exertional rhabdomyolysis, because skeletal muscle contains a large percentage of whole body potassium. Hyperkalemia also occurs in heavily muscled Quarter horses and related breeds as a genetic disorder (hyperkalemic periodic paralysis, *see p 1047*). Hyperkalemia is frequently present in dogs with hypoadrenocorticism (*see p 574*). Severe hyperkalemia is associated with generalized muscle weakness, depression, and cardiac conduction disturbances that may lead to lethal cardiac arrhythmias. Pseudohyperkalemia in serum can occur in animals with thrombocytosis as a result of the excessive release of intracellular potassium stores from platelets during clotting. Pseudohyperkalemia in serum and plasma occurs when extensive hemolysis is present due to the high potassium concentration in RBCs.

HYPOKALEMIA IN ADULT CATTLE

Hypokalemia occurs commonly in inappetent adult cattle, particularly in lactating dairy cows because of the additional loss of potassium in the milk.

Etiology: Hypokalemia is common in adult cattle with prolonged inappetence (>2 days), or in those receiving more than one injection of corticosteroids that have mineralocorticoid activity, eg, isoflupredone acetate. This is because mineralocorticoid activity enhances renal and GI losses of potassium. Hypokalemia is extremely rare in adult ruminants with adequate dry matter intake.

Clinical Findings and Diagnosis: Animals with hypokalemia have generalized muscle weakness, depression, and muscle fasciculations. Severely affected animals are unable to stand or lift their head from the ground.

Serum biochemical analysis is required to confirm a suspected diagnosis of hypokalemia. A serum potassium concentration <2.5 mEq/L reflects severe hypokalemia; most animals will be weak, and some will be recumbent. A serum potassium concentration of 2.5–3.5 mEq/L reflects moderate hypokalemia, and some cattle will be recumbent or appear weak with depressed GI motility. In addition to measurement of serum potassium concentration, measurement of serum concentrations of sodium, chloride, calcium, and phosphorus, and serum activities of CK and AST can be very helpful in guiding treatment. Aciduria may be present in response to a marked decrease in urine potassium concentration.

Treatment: Oral potassium administration is the treatment of choice for hypokalemia. Inappetent lactating dairy cattle should be treated with 60–120 g of feed grade KCl twice at a 12-hr interval, with the KCl placed in gelatin boluses or administered by ororumenal intubation. Adult cattle with severe hypokalemia (<2.5 mEq/L) should initially be treated with 120 g of KCl PO, followed by a second 120-g dose of KCl 12 hr later, for a total 24-hr treatment of 240 g KCl. Higher oral doses are not recommended, because they can lead to diarrhea, excessive salivation, muscular tremors of the legs, and excitability.

Potassium is rarely administered IV; the IV route is used only for initial treatment of recumbent ruminants with severe hypokalemia and rumen atony, because it is much more dangerous and expensive than

oral treatment. The most aggressive IV treatment protocol is an isotonic solution of KCl (1.15%), which should be administered at <3.2 mL/kg/hr, equivalent to a maximal delivery rate of K^+ at 0.5 mEq/kg/hr. Higher rates of potassium administration run the risk of inducing hemodynamically important arrhythmias, including premature ventricular complexes that can lead to ventricular fibrillation and death.

Prevention: Oral administration of potassium is a mandatory component of fluid and electrolyte administration to inappetent cattle. Ensuring adequate dry-matter intake is the best method to prevent hypokalemia in adult cattle.

HYPERKALEMIA

Etiology: Hyperkalemia is common in neonatal ruminants with diarrhea, dehydration, acidemia, and strong ion (metabolic) acidosis. Hyperkalemia often accompanies acidemia, because low blood pH results in intracellular acidosis and leakage of potassium from the intracellular compartment to the extracellular space. Hyperkalemia is common in neonatal foals with uroabdomen secondary to ruptured bladder associated with parturition, and in male cats with uroabdomen secondary to obstructive urolithiasis and bladder rupture. Hyperkalemia is rare in steers, wethers, and bucks with obstructive urolithiasis and bladder or urethral rupture, because excess potassium is secreted in adult ruminant saliva and affected animals have a decrease in potassium intake due to illness. Hyperkalemia can be present in horses and ruminants with exertional rhabdomyolysis due to damage to skeletal muscle cells.

Clinical Findings and Diagnosis: Severe hyperkalemia is usually associated with depression, weakness, lethargy, cardiac arrhythmias, and ECG abnormalities, particularly when the serum potassium concentration is >7 mEq/L. Severe cardiovascular effects are evident when the serum potassium concentration is 8 – 11 mEq/L.

Serum biochemical analysis is required to confirm a suspected diagnosis of hyperkalemia. In addition to measurement of serum potassium concentration, measurement of serum concentrations of sodium, calcium, phosphorus, urea, and creatinine; the serum activities of CK and AST; and blood gas analysis can be helpful in guiding treatment. ECG may reveal bradyarrhythmias, suppression in P wave

amplitude or loss of the P wave, widened QRS complexes, and symmetric T waves (narrowing of T wave duration and "tenting" of the T wave). The ECG effects of hyperkalemia are exacerbated by the presence of hyponatremia, acidemia, and hypocalcemia. The ratio of serum sodium to potassium concentration is important in development of cardiac arrhythmias; hyperkalemia in the presence of hyponatremia (sodium:potassium ratio $<25:1$) is commonly associated with the occurrence of cardiac arrhythmias and ECG abnormalities.

Treatment: Hyperkalemia should initially be treated by IV administration of 0.9% NaCl to increase the rate of urine production in dehydrated animals with a patent urinary system, and in selected cases by IV administration of sodium bicarbonate, glucose, insulin, and sometimes calcium. Urine should be removed from the abdomen of animals with obstructive urolithiasis and ruptured bladder, and urethral patency established. Sodium bicarbonate is administered to correct systemic and intracellular acidosis. The rationale for IV glucose and insulin administration is that insulin-mediated glucose entry into cells is accompanied by movement of potassium from the extracellular space to the intracellular compartment. The rationale for calcium administration is that calcium counteracts many of the deleterious effects of hyperkalemia on arrhythmogenesis, and the IV administration of calcium may therefore improve cardiac output. However, hypertonic saline ($2,400$ mOsm/L) is just as effective as hypertonic sodium bicarbonate in decreasing hyperkalemia and hyperkalemia-associated bradyarrhythmias, probably because of hypernatremia-mediated intracellular movement of potassium, extracellular volume expansion, and increased rate of urine production. The focus of treatment in hyperkalemia should therefore be identification and correction of acidemia, plasma volume expansion to assist in renal excretion of potassium, and increasing the serum sodium concentration. Glucose and insulin do not appear to be routinely needed to correct hyperkalemia.

Prevention: Hyperkalemia can be prevented by early diagnosis and treatment of its most common causes. Hyperkalemic periodic paralysis can be prevented in horses by feeding a low-potassium diet or the oral administration of acetazolamide.

EQUINE METABOLIC SYNDROME

(Insulin dysregulation syndrome, Equine syndrome X,
Peripheral Cushing disease)

Equine metabolic syndrome (EMS) describes a characteristic collection of clinical signs and clinicopathologic changes in equids. It is found in both horses and ponies and has also been recognized in donkeys. Affected animals typically are obese, with increased condition score overall and increased adiposity in the neck and tailhead regions. Laminitis, both chronic and acute, is common. Hyperinsulinemia with normal blood glucose concentrations (insulin resistance) is the primary clinical pathologic finding. Other associated signs include infertility, altered ovarian activity, and increased appetite. Other laboratory findings include hypertriglyceridemia, increased serum concentrations of leptin, and arterial hypertension. Previously, this cluster of clinical signs in horses was referred to as hypothyroidism, peripheral Cushing disease, prelaminitic syndrome, or Syndrome X. EMS replaces these earlier terms. EMS may be the end result of an inability to properly metabolize dietary carbohydrate, and many horses exhibit exaggerated glucose and insulin responses to an oral hexose load before developing true insulin resistance. Any abnormality in carbohydrate metabolism in horses has been termed insulin dysregulation.

EMS first develops in horses 5–16 yr old. Breeds most commonly affected include ponies, Saddlebred, Tennessee Walking, Paso Fino, Morgan, Mustang, and Quarter horses. Thoroughbreds and Standardbreds infrequently develop EMS. There is no recognized sex predilection.

Etiology and Pathogenesis: The underlying reason why some horses develop EMS and others do not is not known. There appears to be a genetic disposition, both within and between breeds. Affected horses may possess a “thrifty” gene that enabled their ancestors to survive in harsh environments. This increased efficiency of energy metabolism became maladaptive in modern environments with plentiful, nutrient-dense feedstuffs.

The common denominators behind many of the signs associated with EMS appear to be increased adiposity, insulin resistance, and hyperinsulinemia. When obesity develops, adipose tissues elaborate leptin and other adipokines as well as tumor

necrosis factor and other inflammatory mediators. Increased fat stores in the liver may also predispose to insulin resistance due to down-regulation of insulin receptors.

Experimentally, high blood insulin levels lead to laminitis in horses and ponies. Insulin has vasoregulatory actions. Insulin resistance can decrease nitric oxide production and promote vasoconstriction. Altered glucose and insulin levels may also lead to altered epidermal cell function and glucose uptake by epidermal lamellar cells. These effects predispose horses with EMS to develop laminitis.

Horses with EMS respond to high carbohydrate meals with an exaggerated increase in insulin, a higher than expected blood glucose level, and a very slow return of blood glucose concentrations to baseline values. This indicates a resistance to the peripheral effects of insulin (EMS) and/or an inability to metabolize oral carbohydrate normally (insulin dysregulation).

EMS may be a predisposing factor for pituitary pars intermedia dysfunction (PPID; also called equine Cushing disease). Both endocrine disorders can occur concurrently in middle-aged and older horses. Horses with EMS should therefore be monitored to detect the onset of PPID. (See also p 547.)

Clinical Findings: There is no clinical picture that is pathognomonic for insulin resistance. Horses may exhibit all the phenotypic characteristics of EMS with normal responses to evocative testing. In most instances, the animals in question are obese because of excess calorie intake rather than any underlying metabolic alteration.

Affected horses typically are obese with a body condition score >6 out of 9. Even if the overall condition score is not extremely high, there is increased fat deposition in the neck, leading to a “cresty” appearance. Fat deposition over the ribs and over the top line to the tail head is also common. Geldings may have increased fat deposition in the prepuce, whereas mares may have increased fat deposition around the mammary gland. Laminitis is a common finding. Horses brought in for evaluation with no previous history of laminitis often show evidence of prior episodes such as abnormal hoof growth rings and radiographic evidence of third phalanx

rotation or pedal osteitis. Laminitis may occur secondary to ingestion of feeds high in soluble carbohydrates, either in the form of lush pasture or high-carbohydrate hays and supplements. This can result in bouts of laminitis developing in the spring, when new pasture growth appears, and in the fall, when night temperatures are below freezing.

Horses with EMS may not lose weight without extreme feed restriction; owners commonly report that affected horses remain obese even when fed minimal amounts. Obesity may be exacerbated by laminitis, which may limit exercise. Horses appear to have increased appetites and often will eat continually as long as feed is available. Infertility and abnormal reproductive cycles occur in mares affected with EMS.

Lesions: Increased general adiposity and laminitis are often documented. The pituitary gland is normal in younger horses with EMS, but lesions consistent with PPID may be found in older horses with EMS that are concurrently affected by EMS and PPID.

Diagnosis: Diagnostic testing for EMS should concentrate on documenting insulin resistance while excluding PPID. The presence of obesity and the cresty neck phenotype is not sufficient to make a diagnosis. A careful dietary history and physical examination are essential. Establishing baseline body condition score and neck circumference will enable assessment of the horse's response to treatment. Even if there is no history of laminitis, careful examination of the feet, including lateral images of P3, are indicated.

Because many conditions, including diet, pain, and stress, can affect blood glucose and insulin levels, diagnostic testing should be performed in a controlled manner in a low-stress environment. If the horse has laminitis, diagnostic testing should be delayed until the feet have stabilized and are relatively pain free.

Blood glucose concentrations are in the normal range or only slightly increased with EMS. If persistent hyperglycemia is documented, concurrent PPID should be strongly suspected. Because many factors influence blood glucose and insulin levels, a one-time blood insulin measurement should be used only as a screening test for insulin resistance. Insulin should be determined after the horse has been fasted for 6–8 hr. This can be done by leaving only one flake of hay with the horse after 10 PM the night before and then collecting the blood sample the next morning. If those conditions are met, a blood insulin concentration $>20 \mu\text{U/mL}$ is suggestive of insulin resistance.

To document insulin resistance, the horse's ability to handle glucose should be evaluated. Because a subset of horses are normal in all respects except for their ability to handle an oral carbohydrate load, an oral sugar test (OST) or oral glucose test (OGT) should be performed. The OST is easy to perform in North America, where corn syrup is readily available, whereas the OGT can be performed in other parts of the world. The OST is performed by fasting the horse for 6–8 hr and then giving an oral dose of corn syrup at 0.15 mL/kg . Blood should be collected at 60 or 90 min after administration of the corn syrup for insulin determination. An insulin concentration $>60 \text{ mU/L}$ is abnormal. The OGT is performed by giving a fasted horse 0.5 kg of chaff-based feed to which dextrose powder at 1 g/kg has been added. An insulin concentration $>87 \text{ mU/L}$ in a blood sample collected 2 hr later is abnormal. To determine whether insulin can stimulate normal glucose uptake by peripheral tissues, an insulin tolerance test can be performed. This is accomplished by collecting a baseline blood sample for glucose concentration, giving regular human recombinant insulin at 0.1 IU/kg , IV, and then collecting a second blood sample for glucose concentration 30 min later. A second blood glucose concentration that does not decrease to 50% or less of the baseline value indicates insulin resistance. Other diagnostic testing that has been described includes the IV glucose tolerance test or a combined glucose-insulin response test. The oral glucose tolerance test can be altered by delayed gastric emptying or poor GI absorption and is less desirable. Because of the large number of blood samples required and the fact that change from baseline—not absolute glucose values—is of interest, a hand-held glucometer to determine blood glucose concentration may be used when performing these tests.

Tests for PPID such as measuring endogenous ACTH concentration, the dexamethasone suppression test, domperidone response test, or thyroid releasing hormone response test are normal in horses with EMS. Positive results indicate that the horse is concurrently affected by EMS and PPID, which can occur in older horses. Detection of PPID is important, because it is thought that PPID exacerbates insulin resistance in horses previously affected by EMS.

Treatment and Prevention: Treatment for EMS involves dietary management and, if diet and exercise is not sufficient to treat the condition, medical therapy. Correction of the diet may be all that is needed to

return the horse to normal body weight. Dietary carbohydrate restriction is essential to decrease glycemic and insulinemic response; total calorie intake is restricted to reduce body weight. Pasture access should be eliminated or severely restricted. Use of a grazing muzzle may aid in decreasing pasture ingestion.

The nonstructural carbohydrate (NSC) content of forage should be determined by feed analysis. This can be calculated by adding starch and water-soluble carbohydrate percentages. Ideally, NSC should comprise <10% of the hay dry matter, and it should never exceed 16%. Soaking hay in water for 60 min has been recommended to lower water-soluble carbohydrate concentrations, but the actual amount reduced is extremely variable; hence, this is not a reliable method to produce a low-NSC forage. Supplements should be given to add needed vitamins and minerals but not additional calories. Complete feeds that are formulated to be low in digestible energy and carbohydrate specifically designed for horses with insulin resistance may be used in place of forage and supplements. Numerous dietary supplements have been suggested to increase insulin sensitivity, including cinnamon, chromium, and magnesium. None has been shown to improve insulin sensitivity in horses in experimental situations.

Horses should initially be fed 1.5% of their ideal body weight in forage per day. This amount can be lowered to 1.25% and then to 1% of ideal body weight after 30 days, if necessary. Sudden feed restriction should be avoided, because it may lead to hyperlipemia and further exacerbate insulin resistance. Increasing the amount and level of exercise will increase the rate of weight loss. The amount of exercise necessary to provide maximal benefits has not been established, but five sessions per week that include at least 30 min of trotting and lunging is a realistic goal. In horses with

laminitis, walking as pain allows may be of some benefit.

Weight reduction should be documented by scale weight or weight tapes. In addition, neck thickness and diameter can be monitored over time. If increased exercise and dietary modification is not sufficient to decrease body weight, medical therapy may be of benefit.

The thyroid hormone thyroxine, in the form of levothyroxine sodium, will accelerate weight loss and thereby improve insulin sensitivity when combined with dietary interventions in horses. Horses weighing >350 kg can be given 48 mg/day, PO; smaller horses and ponies should receive 24 mg/day, PO. Treatment periods of 3–6 mo are often needed to achieve desirable weight loss. At that time, the horse should be weaned off the medication over 3–4 wk. If feed intake is not limited concurrently, treatment with levothyroxine is unlikely to resolve clinical signs.

Metformin is poorly absorbed in equids but may decrease postprandial glucose and insulin levels. It may lead to improvement in hyperinsulinemic horses at a dosage of 30 mg/kg, PO, tid or bid. It should be given 30 min before a meal if possible. However, the longterm efficacy and safety of metformin has not been established in horses. If it is used, blood glucose should be carefully monitored. Use of metformin should be discontinued if hypoglycemia is documented.

Prevention of EMS should focus on maintaining normal weight in horses, particularly in high-risk breeds. Because these horses may be more efficient users of ingested calories than others, it is imperative to feed appropriately to maintain an ideal condition score and not to use arbitrary feeding guidelines. Particular care should be exercised when turning horses on pasture during times of high-soluble carbohydrate content, eg, spring and autumn.

FATIGUE AND EXERCISE

Muscular fatigue during exercise is the inability to continue to perform at the same level of intensity, resulting from the inability of the muscles to produce force. Fatigue may occur during both aerobic and anaerobic exercise, and at submaximal effort depending on the ambient tempera-

ture, hydration status, electrolyte concentrations, external motivation, and the animal's desire to work. As effort increases, glycogen depletion, intracellular acidosis, and accumulation of metabolic by-products will contribute to the onset of fatigue. Fatigue during exercise can also be the

result of pathologic conditions, including diseases that affect oxygen uptake, energy metabolism, or neuromuscular function. This chapter will focus on muscular fatigue in normal, healthy animals.

Fatigue is considered a normal consequence of exercise of prolonged duration or high intensity, and is regarded as an intrinsic safety mechanism. Without the onset of fatigue, or if fatigue is delayed for a time, structural damage to the myocytes and supportive tissues may occur. Most knowledge of fatigue has been described in horses using high-speed treadmill exercise, to allow for investigation of the respiratory, cardiovascular, and metabolic responses during exertion. Tests involved include spirometry, arterial blood gases, hematologic analysis, kinematics, electromyography, and muscle biopsies. Fatigue in these studies has been defined as the inability or unwillingness of the horse to maintain the same velocity as the treadmill at a determined speed despite minimal encouragement. Horses run to the point of fatigue on a treadmill exhibit characteristic changes in gait, including decreased stride frequency and a longer stride length.

Fatigue has been classified into two types: peripheral and central. Peripheral fatigue is described as fatigue secondary to altered muscle function. The primary cause is failure of ATP to resynthesize with accumulation of ADP and inorganic phosphate ions. Studies of muscle metabolism after exercise to identify peripheral fatigue have relied mainly on muscle biopsies and direct measurement of muscle glycogen, creatine phosphate, ATP, ADP, inosine monophosphate, inorganic phosphate, glycolytic intermediary products, pH, and other metabolites. Other studies have investigated the expression of mRNA in muscle tissue to monitor adaptations in gene expression of proteins that regulate oxygen-dependent metabolism, glucose metabolism, and fatty acid utilization. Indirect serum biomarkers associated with fatigue may include lactate, ammonia, hypoxanthine and xanthine, ammonia, markers of oxidative damage (thiobarbituric acid reactive substances, glutathione, and glutathione peroxidase), inflammatory mediators, and lymphocytes.

Central fatigue is defined as an alteration in the signals arising from the CNS, directly decreasing performance by modifying the frequency of the action potential in the motor neurons. Central fatigue may occur secondary to pain, dyspnea, perceptions of exertion, hypoglycemia, hyperthermia, ammonia accumulation, increases in

serotonin, altered amino acid metabolism, and changes in extracellular ions. Central fatigue is associated with decreased motivation, lethargy, tiredness, and loss of muscle coordination. However, the cause of central fatigue is multifactorial, and the response to these stimuli is highly variable. For example, some horses can continue endurance exercise at speed despite severe hyperthermia, dehydration, and plasma electrolyte disturbances.

FATIGUE DURING HIGH-INTENSITY EXERCISE

For all intensities of exercise, there is a degree of anaerobic metabolism, but for brief, high-intensity exercise, anaerobic metabolism predominates. Catabolism of creatine phosphate and glycogen is the anaerobic source of energy during high-intensity exercise. This type of exercise at an individual animal's highest attainable speed cannot be maintained for >30–40 seconds. Thereafter, fatigue occurs and the animal slows down.

Energetics of Exercise and Fatigue:

The contribution of aerobic or anaerobic energy pathways during exercise depends on the duration and energy demands of the event. In short, intense exercise lasting 20–30 seconds (eg, Quarter horse races [400 m], some Greyhound races), 60% of energy demands is supplied by anaerobic sources. For intense exercise at maximal speeds for a longer duration (eg, Standard-bred or Thoroughbred races [1,600–2,100 m] lasting 1–3 min), it has been estimated that the energy supply is 20%–30% anaerobic. In contrast, events lasting many hours (eg, endurance races for horses, camels, and dogs) have >90% of energy demands met by aerobic sources.

During brief, high-intensity exercise, fatigue is secondary to engagement of muscle fibers that heavily rely on anaerobic metabolism. The higher the intensity, the greater the anaerobic demand. Fatigue is the result of an increase in hydrogen ions, lactate, inorganic phosphate, ammonia, and ADP, and a decrease in ATP, phosphocreatine, and pH in active muscle cells. Clinically, fatigue is initially identified by a decrease in exercise intensity or a drop in the maximal speed.

As anaerobic metabolism increases, lactate production is directly correlated to the percentage of type IIB muscle fibers present and corresponds to the accumulation

of protons in the muscle tissue. Intracellular acidosis caused by lactate accumulation has a negative feedback effect on the glycolytic enzymes required for energy production and mitochondrial respiration, resulting in a decline in ATP concentrations. Lack of ATP prevents calcium recycling through the sarcoplasmic reticulum, resulting in accumulation of calcium in the sarcoplasm and slowing of the relaxation phase of muscle contraction. Acidosis also interferes with excitation-contraction coupling by interfering with calcium binding to troponin C, reducing the ability of the muscles to contract. Unfortunately, there is no correlation between muscle lactate concentration and placement in a race, or plasma lactate concentrations and performance indexes.

A decrease in muscle ATP after maximal exercise has been noted in conjunction with high muscle lactate concentrations. For high-intensity exercise, eg, a Thoroughbred race lasting 2 min, intramuscular stores of ATP can decrease from 14% to 50%. Depletion of ATP varies by muscle fiber type. In type I fibers, depletion is negligible, whereas in type IIB fibers, ATP loss is significant. Low levels of ATP impair optimal functioning for muscle contraction, reuptake of calcium by the sarcoplasmic reticulum, and the sodium potassium exchange. Fatigue is associated with depletion of phosphocreatine stores and accumulation of ADP and inorganic phosphate. A correlation between stride length and muscle ADP accumulation has been seen at the time of fatigue.

Muscular Fatigue: Increased ADP concentration results in accumulation of AMP, inosine monophosphate, allantoin, ammonia, and uric acid in horses. In treadmill studies, the decrease in muscle ATP during intense exercise is correlated with an increase in plasma uric acid concentration 30 min after exercise. Running time during treadmill tests is correlated with uric acid concentrations after exercise. Significant but low correlations have also been found between racing performance of Standardbred pacers and uric acid concentrations after a race.

Ammonia accumulation in plasma is correlated to decreased ATP and increased muscle lactate. It has been postulated that ammonia accumulation in the plasma may contribute to fatigue. However, infusion with ammonium acetate during treadmill exercise until fatigue did not significantly affect time to fatigue, suggesting plasma ammonia levels do not have a role in fatigue during intense exercise.

Similar to ATP depletion, muscle glycogen concentration decreases up to 30% after a single exercise bout and by as much as 50% with repeated bouts of intense exercise. Again, depletion varies between muscle fiber types, with greater depletion seen in type IIB muscle fibers. Glycogen depletion may play a role in fatigue, in that horses that perform repeated bouts of exercise before an anaerobic exercise session may be at increased risk of fatigue because of the slow rate of glycogen repletion in this species.

During high-intensity exercise, the normal equilibrium between release of potassium from recruited muscle and uptake by inactive muscle fibers is lost, resulting in a continual increase of extracellular potassium until the onset of fatigue. Changes in the ratio of intracellular to extracellular potassium across the sarcolemma alter the resting membrane potential and decrease sarcolemma excitability and the ability to generate an action potential. Reduced excitability contributes to reduced calcium release by the sarcoplasmic reticulum (a process that requires ATP) and a consequent reduction in the force of muscle contraction. This loss of force may relate to the idea of an inherent safety mechanism, in that plasma potassium rapidly declines after cessation of exercise by reuptake into the now inactive muscle.

Intracellular acidosis as a result of lactate accumulation has been blamed for the decrease in efficiency or force of muscle contractions. However, *in vitro* research has demonstrated a protective effect of lactic acidosis or hydrogen ions in maintaining sarcolemma function and muscle force production in the face of potassium shifts within the cell and plasma associated with intense exercise.

Thermoregulation and Fatigue:

Fatigue during high-intensity exercise is also influenced by environmental conditions. Intense exercise in hot conditions is associated with earlier onset of fatigue, due to increased blood flow to the skin for thermoregulation at the expense of cardiac output and oxygen delivery to the exercising muscle. Attenuation of normal increases in muscle blood flow during exercise in hot environments has been suggested as a contributor to the onset of fatigue. There is also a central effect of high temperatures, resulting from increased blood temperature at the hypothalamus. Early onset of fatigue in hot conditions is thought to be a protective response to avoid heat stroke.

FATIGUE DURING PROLONGED EXERCISE

Fatigue as a result of prolonged exercise depends on the duration and intensity of the activity, liver glycogen stores, the ambient temperature, and mechanisms of central fatigue. Prolonged exercise mainly depends on aerobic metabolism. Fatigue during prolonged exercise has been associated with depletion of glycogen stores in muscle and liver, and with hypoglycemia. Intramuscular glycogen provides 50% of the energy during the first 30 min of submaximal exercise but drops to <20% after 1 hr. Blood glucose makes a smaller contribution, providing only 10% of total energy utilized. Although circulating fatty acids may provide an energy source during prolonged exercise, fatigue will set in before these fat stores are completely exhausted.

In prolonged exercise, the heat generated during aerobic ATP resynthesis imposes a high thermoregulatory demand on the animal. Only 25% of the total energy produced by the muscles is converted to mechanical energy, leaving 75%–80% of that energy that must be removed as heat. Physiologic responses to heat production include sweating and/or panting to remove excess heat from the body. Complications from these compensatory mechanisms include dehydration, acid base and electrolyte disturbances (which are implicated as causes of fatigue), exhaustion, and even death (which can occur after prolonged exercise).

Exhausted Horse Syndrome: Horses occasionally develop severe clinical signs of fatigue at endurance events, despite current preventive practices, including evaluation of recovery at rest stops. Horses that compete in sports that include 3-day eventing, endurance rides, or combined driving are at risk of presenting with life-threatening exhaustion. In hot conditions, horses may lose body fluids at a rate of 10–15 L/hr through sweat during prolonged exercise. Urgent treatment of fluid and electrolyte deficits and hyperthermia (rectal temperatures >40.5°C [104.9°F]) may be required. Exhausted horses may lose up to 10% of their body weight in water, with some having body fluid deficits of up to 40 L, depending on their size. Water lost as sweat is mainly lost from the extracellular fluid and circulating plasma. Decreased blood volume reduces perfusion to vital organs and hampers thermoregulation. In severe cases, cardiovascular compromise may result in multiorgan failure, including

damage to the kidneys, GI mucosa, and lamina of the hoof.

Sweating is associated with the loss of electrolytes, mainly sodium, potassium and chloride, as well as calcium and magnesium. Alterations in muscle electrolytes can contribute directly to signs of fatigue. The most common acid-base alteration resulting from electrolyte imbalances is metabolic alkalosis. Aerobic energy metabolism of endurance events produces minimal amounts of lactic acid; therefore, alkalosis caused by alterations in strong ions (hypochloremia and hypokalemia) predominates. Depletion of magnesium and calcium may contribute further to neuromuscular dysfunction, causing ileus, cardiac arrhythmias, and synchronous diaphragmatic flutter. Unlike endurance riding, anaerobic metabolism predominates in 3-day eventing and combined driving, resulting in metabolic acidosis during the event. After recovery, which can range from 30 min to 2 hr after the event, lactate is oxidized and the acidosis resolves. Metabolic alkalosis will then predominate.

Horses affected by exhausted horse syndrome demonstrate a range of symptoms, from changes in attitude and gait inconsistencies to colic, laminitis, clinical signs of myopathies (hard muscle bellies, pain on palpation), depression, ataxia, and eventually recumbency. Persistent tachycardia and tachypnea are noted despite rest, and rectal temperature may be ≥42°C (107.6°F). Perfusion abnormalities and signs of dehydration may be seen. Sweating may be inappropriate or absent.

Treatment involves cooling the horse and providing fluid therapy to restore circulating volumes. Hyperthermic horses should be moved to shade and treated with cool or cold water sponge baths, cold hosing, or misting fans. Water should be scraped off the haircoat and reapplied repeatedly, to prevent an insulating layer of water from forming. Application of ice water should be avoided, as well as alcohol baths or direct ice application, to prevent tissue damage. Cool-water enemas, or peritoneal and gastric lavage, may help to reduce body temperature in severe cases.

Isotonic balanced electrolyte solutions may be provided for dehydration by nasogastric intubation if the horse has normal borborygmi. Horses may be given up to 8 L initially, with subsequent administration of 4–8 L every 1–2 hr, as needed. Commercial electrolyte mixtures for horses are suitable, but hypertonic, hypotonic, and alkaline solutions should not be used. In severe cases, IV fluid therapy is preferred.

A shock dose of a balanced electrolyte solution should be provided initially (20–40 mL/kg bolus) with addition of 100 mL 23% calcium gluconate per 5 L, and 5% dextrose. Additional fluids and additives should be based on reevaluation of serum chemistries and hydration status.

Additional treatments may include NSAIDs for muscle pain and colic, administered simultaneously with fluid therapy to prevent renal injury, and phenothiazines for anxiety caused by myopathies. Anticonvulsant medications may be required, and dexamethasone may help reduce cerebral edema. DMSO may be useful to further reduce inflammation, and low-molecular-weight heparin can be administered to treat coagulopathies.

Environmental temperature and humidity have a major impact on the severity of disturbance of the horse's fluid balance during prolonged exercise. It is important to ensure adequate hydration before an event, especially after long trailer rides to the competition, and to provide access to fluids during and after exercise to reduce the likelihood of dehydration. Administration of supplementary fluids, electrolytes, and glucose before and during competition, when allowed by doping regulations, may reduce the incidence of exhausted horse syndrome.

Overtraining Syndrome: Highly intense exercise training over many weeks can result in a form of chronic fatigue referred to as overtraining syndrome. Racehorse trainers have long used the terms “overtraining,” “staleness,” or “sourness” to describe a syndrome of poor performance, failure to recover from exercise, and prolonged fatigue that does not resolve for weeks or months. By definition, signs of overtraining syndrome should persist after >2 wk of rest or reduced physical activity. A less severe form of overtraining syndrome is termed “overreaching,” which is also a syndrome of poor performance and fatigue, but athletic recovery in overreaching typically occurs from a few days to 2 wk after a reduced workload.

Overtraining syndrome was first reported in Swedish Standardbred trotters based on observations of horses with signs of fatigue and poor performance combined with weight loss, inappetence, and signs of stress, including tachycardia, nervousness, muscle tremors, sweating, and diarrhea. The severity of clinical signs of overtraining was associated with the degree of red cell hypervolemia, and horses exhibited adrenal exhaustion that may be similar to parasympathetic overtraining reported in people.

In experimental studies, a milder form of overtraining has been reproduced, without any evidence of red cell hypervolemia, inappetence, or adrenal gland exhaustion. However, this syndrome was associated with a decrease in the plasma cortisol response to intense exercise, suggesting that overtraining is associated with dysfunction of the hypothalamic-pituitary-adrenal axis. Recent research has shown that overtrained horses have altered growth hormone activities, with an increase in the normal pulsatile growth hormone activity overnight, in addition to altered glucose metabolism. Biomarkers of skeletal muscle metabolism are currently being investigated as a means to identify overtraining syndrome but require invasive muscle biopsies for measurement.

Overtraining syndrome should be suspected in horses with evidence of sustained decreased performance in association with one or more physiologic or behavioral signs. While no single physiologic marker is able to identify the syndrome, clinical signs in horses may include decreased body weight, increased heart rate during exercise, decreased plasma cortisol response to exercise, and increased plasma concentrations of muscle enzymes or gamma glutamyl transferase. Behavioral signs are a consistent and early marker of overtraining syndrome, and development of a behavioral score to assist in early detection of overtraining syndrome in horses is warranted.

PREVENTION OF FATIGUE

Physical Training: Physical training is the most effective way to reduce fatigue and increase capacity for exercise. Physiologic responses to training that contribute to increased exercise capacity include increases in the maximal rate of oxygen transport, cardiac stroke volume, muscle capillary density, circulating blood volume, and total hemoglobin content. Hypertrophy of muscle cells occurs, coupled with increases in concentrations of mitochondria, glycogen, and enzymes concerned with cellular energy production.

Sport-specific training can result in specific adaptations. For example, sprint training can result in decreased proportions of slow-twitch muscle fibers, whereas endurance training can result in increased oxidative capacity of fast-twitch muscle fibers. Sprint training also modulates the ionic changes associated with intense exercise, including decreased potassium efflux from working muscles, resulting in a smaller increase in plasma potassium and delayed onset of fatigue. Training also

modulates the exercise-induced decline in both calcium reuptake by the sarcoplasmic reticulum and calcium-ATPase activity associated with fatigue.

Adaptations to training in skeletal muscle depend on the training intensity. Horses trained at intensities $>80\%$ of their maximal oxygen uptake ($\text{VO}_{2\text{max}}$) had an increase in their percentage of fast-twitch muscle fibers and an 8% increase in the buffering capacity of exercised muscle. These responses did not occur in horses trained at 40% of $\text{VO}_{2\text{max}}$.

Heart rate meters can be used to guide the intensity of training to improve the adaptive response to training. Heart rates that result in 80% of $\text{VO}_{2\text{max}}$ are ~90% of maximal heart rate, which typically ranges from 210 to 240 bpm in horses. Heart rate meters can be used to measure an individual horse's heart rates during slow and fast exercise and to calculate the exercise velocities that result in heart rates of 90% of maximal heart rate. Blood lactate after exercise can also be used to measure the appropriate training intensity. At an exercise intensity of 80% $\text{VO}_{2\text{max}}$, plasma lactate concentrations during treadmill exercise are in the range of 4–10 mmol/L.

Warm-up: Warm-up before exercise significantly increases the time to fatigue during intense exercise. Warm-up increases muscle temperature before exercise, increases the rate at which oxygen uptake increases, and reduces lactate accumulation by enhancing aerobic metabolism. The effect is similar whether the warm-up is low intensity (5–10 min at 50% $\text{VO}_{2\text{max}}$), moderate intensity (1 min at 70% $\text{VO}_{2\text{max}}$), high intensity (1 min at 115% $\text{VO}_{2\text{max}}$), or a combination of low and high-intensity. The practical importance of this finding is that a warm-up before competition involving intense exercise is likely to increase the time to fatigue during Quarter horse, Thoroughbred, and Standardbred races.

Manipulation of Acid-Base Balance, Diet, and Hydration: It has been suggested that fatigue during intense exercise may be delayed by manipulation of acid-base status before exercise to increase the plasma-buffering capacity. Although some trainers have administered sodium bicarbonate before races, this practice is now banned by many racing administrations. The treatment does alter blood pH and lactate concentrations during exercise; however, the effect of alkalinizing solutions on equine performance is equivocal. Studies using bicarbonate at a dosage of 0.6 g/kg have not shown an effect on the time at

which fatigue occurs. Although a metabolic alkalosis could be induced, administration of sodium bicarbonate before intense treadmill exercise did not have any significant effect on metabolic response to exercise. In Greyhounds, a dose of sodium bicarbonate at 0.4 g/kg did not have a significant effect on race time in races >400 m long. However, there may be an ergogenic effect when sodium bicarbonate is administered at high dosages. Sodium bicarbonate at a dosage rate of 1 g/kg (by nasogastric tube) increased the time to fatigue in horses running on a treadmill, and it was concluded that treatment at this dose affected performance.

Energy supply and hydration are frequently manipulated in human athletes to limit fatigue during endurance exercise. Dehydration before exercise results in higher core temperatures during exercise in horses. It would be inappropriate for an animal to begin an endurance exercise with suboptimal hydration. Horses are more susceptible to hyperthermia during prolonged exercise than people because of their high body mass to surface area ratio, which inhibits heat loss. Equine thermoregulation also results in extreme changes to total body fluid status, and there is increasing interest in the way of limiting these excessive responses to exercise by preexercise fluid administration.

Hyperhydration by administration of electrolytes or saline solutions orally before exercise will result in expansion of the blood volume during the event. Studies suggest that hyperhydration before prolonged exercise helps conserve plasma volume during exercise but does not lower body temperature or improve arterial hypoxemia. Maintenance of euhydration with water or a carbohydrate-electrolyte solution during exercise improves perfusion parameters and sweating rates and reduces heat storage. Horses should be acclimated to hot environments before competition.

Horses should not be given large meals (equal to half the ration) 1–2 hr before intense exercise, because plasma volume is decreased for at least 1 hr after a large meal. Large meals may also shift fluid to the GI tract, reducing cardiovascular and thermoregulatory function during exercise. Feeding smaller rations every 4 hr does not result in changes in plasma volume. A short-term reduction in fiber intake before high-intensity racing (fed as ~1% of body wt in hay for 3 days before high-intensity exercise) is a strategy to reduce GI water volume and, hence, body weight. For endurance exercise, feeding before exercise, especially high-fiber feeds, is likely

to be beneficial, because the increased water in the GI tract can be an important reservoir for water and electrolytes to replace sweat losses. Feeding high-fiber feeds also increases voluntary water intake.

Glucose supplementation may be important in limiting fatigue in endurance exercise in horses. Endurance time during treadmill running was prolonged by the IV infusion of a glucose solution during exercise. Plasma glucose was higher than controls, and plasma lactate and body temperature were lower at the point of fatigue. These results suggest that supplemental glucose during exercise prolongs performance time in horses. This increase may be due to increased glucose availability, reduced reliance on anaerobic energy production, lower core temperature, and better maintenance of plasma volume. In endurance horses, hydrolyzable starches and sugars fed within 3 hr of a race may increase glucose utilization in the short term but inhibit lipid oxidation, which could be detrimental for energy production.

Glycogen concentration in skeletal muscle before performance is relevant to fatigue during both short-term/intense and prolonged endurance exercise. Depletion of muscle glycogen before exercise causes a decrease in anaerobic power generation and capacity for high-intensity work. Intense or prolonged exercise depletes the muscle glycogen stores, and it may take 48 hr for glycogen to be replenished in the horse. Although modest increases in glycogen stores may be obtained using high-starch diets in the horse, no benefit on performance has been shown. On the contrary, high-carbohydrate diets have increased heart rates and blood lactate concentrations during intense exercise. Use of glucose or other carbohydrate solutions before racing to promote performance in Standardbred and Thoroughbred racehorses has no scientific basis.

Fat supplementation is now a widespread practice in diets for athletic horses and can increase performance during endurance exercise. Increased free fatty acid concentrations in the bloodstream before prolonged exercise results in an increased use of fat as an energy source and in higher blood glucose and muscle glycogen concentrations during exercise. The shift to increased use of fat as a fuel results in lower respiratory demands for exercise, because less carbon dioxide must be expired when more fat is used for energy. Fat adaptation appears to facilitate the metabolic regulation of glycolysis by sparing glucose and glycogen at low intensity work and by promoting glycolysis when power is

needed for high-intensity exercise. Adding fat to the diet also affects the metabolic and thermoregulatory response to exercise. Feeding vegetable oil at a rate of 10%–12% of the total diet on a dry-matter basis has been suggested, but horses must be acclimated to high-fat diets. In horses not acclimated, fat supplementation can slow the rate of muscle glycogen repletion.

Creatine has been used in horses as an ergogenic aid, but there is no evidence of its efficacy. Horses receiving 25 g of creatine monohydrate bid for 6.5 days did not have significantly different run times until fatigue on a treadmill than control horses. Supplementation with creatine also had no significant effect on muscle or blood creatine concentrations at rest or after exercise until fatigue.

An association between plasma vitamin E concentration and performance has been described in sled dogs. Dogs with a higher prerace vitamin E concentration were more likely to finish the race and were less likely to be withdrawn during the race for poor health, fatigue, or other reasons. Vitamin E concentrations for the dog team overall were not associated with speed during the race. Additional studies are needed to investigate whether the reduced signs of fatigue are directly linked to higher vitamin E concentrations in the bloodstream.

Recovery: Recovery of horses after endurance exercise is influenced by the rehydration strategy used. After prolonged treadmill exercise and furosemide-induced dehydration, horses offered a saline solution (0.9% NaCl) as the initial rehydration fluid maintained a plasma sodium concentration higher than that of control horses. The recovery of body weight was more rapid than in horses offered plain water. A similar study noted ambient temperature fluids were more palatable (20°C [68°F]) and increased voluntary intake. Water intake can also be increased by providing a saline solution (0.9% NaCl) both during and after endurance exercise. Sodium chloride solutions may increase plasma chloride and accentuate a metabolic acidosis; as a result, isotonic polyionic electrolyte solutions formulated specifically for horses should be selected. When providing electrolyte solutions, horses may need to be trained to drink these fluids, and plain water should always be available. However, use of electrolyte solutions should be encouraged, especially in horses required to compete on consecutive days, such as in endurance rides and 3-day events.

FEVER OF UNKNOWN ORIGIN

In both veterinary and human patients, fever may indicate infectious, inflammatory, immune-mediated, or neoplastic disease. In most cases, the history and physical examination reveal the cause of the fever, or the fever resolves spontaneously or in response to antibiotic therapy. However, in a small percentage of patients, the cause of fever is not readily apparent, and the problem becomes persistent or recurrent. These patients are said to have fever of unknown origin (FUO).

In human medicine, classic FUO is defined as fever $>101^{\circ}\text{F}$ (38.3°C) on several occasions over a period $>2\text{--}3$ wk with no diagnosis established after 3 outpatient visits or 3 days in the hospital. There is no recognized definition of this syndrome in veterinary medicine, making it difficult to determine its true prevalence. FUO is probably less prevalent now than in the past because of improved diagnostic technology (eg, imaging, molecular diagnostic tests).

Body Temperature Regulation: Body temperature is regulated by the hypothalamus. This area of the brain acts as a thermostat to maintain temperature as close as possible to a normal set-point. The hypothalamus receives input from internal and external thermoreceptors, and it activates physiologic and behavioral activities that influence heat production, heat loss, and heat gain.

Hyperthermia refers to any increase in body temperature above the normal range. Fever is a particular form of hyperthermia in which the heat loss and heat gain mechanisms are adjusted to maintain body temperature at a higher hypothalamic set-point; thus, fever is essentially a regulated hyperthermia. In nonfebrile cases of hyperthermia (eg, heat stroke, exercise-induced hyperthermia, malignant hyperthermia, seizure), body temperature is increased by abnormal and unregulated heat loss, heat gain, or heat production, and the hypothalamic set-point is not altered. Depending on their severity, these conditions can potentially result in body temperatures $\geq 106^{\circ}\text{F}$ (41.1°C). In comparison, most patients with true fever have body

temperatures in the range of $103^{\circ}\text{--}106^{\circ}\text{F}$ ($39.5^{\circ}\text{--}41.1^{\circ}\text{C}$).

An increase in the hypothalamic set-point may be initiated by exogenous pyrogens, which include drugs, toxins, and viral or bacterial products (eg, endotoxin). These pyrogenic stimuli lead to the release of cytokines, termed endogenous pyrogens, from inflammatory cells. Ultimately, locally synthesized prostaglandin E_2 in the hypothalamus is responsible for increasing the set-point, resulting in fever.

Etiology and Pathogenesis: FUO may be defined as fever that does not resolve spontaneously in the period expected for self-limited infection and for which a cause cannot be found despite considerable diagnostic effort. This excludes patients that respond to antibiotic therapy (and do not relapse) and patients in which the cause of fever is determined from initial history, physical examination, or laboratory tests, or in which fever resolves spontaneously.

Infectious, immune-mediated, and neoplastic disease are the most common causes of FUO in dogs. In a study of 101 dogs with fever, 22% had immune-mediated diseases, 22% primary bone marrow abnormalities, 16% infectious diseases, 11.5% miscellaneous conditions, 9.5% neoplasia, and 19% genuine FUO. In cats, the cause is more likely to be infectious, but there are fewer published data on feline cases than on canine cases. In a case series of horses with FUO, 43% had infectious disease, 22% neoplasia, 6.5% immune-mediated disease, 19% miscellaneous causes, and in 9.5% the cause was not determined. In farm animals, the most likely causes of FUO are infectious or inflammatory diseases such as pneumonia, peritonitis, abscesses, endocarditis, metritis, mastitis, polyarthritis, and pyelonephritis.

Diagnosis: The key to diagnosis of FUO is to develop and follow a systematic plan that allows for the detection of both common and uncommon causes of fever. The plan should always include repetition of relevant tests, because findings can change over time. Owners should be informed that diagnosis of FUO may require considerable time and patience

and may demand more advanced or expensive diagnostic tests. Nevertheless, simple and inexpensive tests may also reveal diagnostic clues that eventually point to the cause of the fever. In one retrospective study of fever in dogs, radiography, cytology, and bacterial or fungal cultures of tissues or fluids were found to be the most useful diagnostic tests.

A staged or tiered approach to diagnosis can assist in choosing appropriate tests. The first stage should include history, physical examination, ophthalmic and neurologic examinations, CBC, fibrinogen, serum chemistry profile, urinalysis and urine culture, feline leukemia virus and feline immunodeficiency virus tests (cats), and usually thoracic and abdominal radiographs in small animals. Any medications that could induce fever should be discontinued. In the second stage, some first-stage tests may be repeated (particularly the physical examination), and additional specialized tests are performed. These may be dictated by abnormal findings in the first stage of testing or may be determined by consideration of the most common known causes of FUO. Tests included in this stage include blood cultures, arthrocentesis, abdominal ultrasonography, lymph node aspiration, aspiration of other organs or masses, analysis of body fluids (eg, fluid from body cavities, milk samples, reproductive tract secretions), rectal cytology, fecal culture, echocardiography (in the presence of a murmur), long-bone and joint radiographs, contrast radiographs, serology, and molecular diagnostic tests. In the third stage, earlier tests may be repeated again, as well as additional specialized procedures. These procedures are most likely to be chosen on the basis of previous findings but may also be considered when all previous testing has been unrewarding. Examples include echocardiography (in the absence of a murmur), dental radiographs, bone marrow aspiration, bronchoscopy and bronchoalveolar lavage, CSF analysis, CT, MRI, laparoscopy, thoracoscopy, biopsies, exploratory surgery, or trial therapy.

History and Physical Examination:

Epidemiologic characteristics such as vaccination, parasite control, exposure to vectors, and travel history should always be reviewed. The response to previous medications should be determined, as well as the presence of illness in other animals or people. Owners should be questioned

carefully about specific clinical signs, because these may help localize the source of the fever. The physical examination should be detailed; always include fundic, neurologic, and rectal examinations; and repeated frequently.

CBC and Serum Chemistry Profile: The CBC and chemistry changes in animals with FUO are often nonspecific but may suggest further diagnostic tests. For example, bile acids assay may be indicated in an animal with changes suggestive of hepatic dysfunction. The CBC should always be accompanied by blood smear evaluation to detect parasites or morphologic changes.

Urine Culture: This test is always indicated to evaluate FUO in small animals, regardless of the appearance of the urine sediment.

Radiography and Advanced Imaging: Thoracic and abdominal radiographs are useful screening tools for the early localization of fever. Skeletal radiographs and contrast radiographs may subsequently be considered, depending on initial findings. For example, myelography may be used to investigate back pain. The use of techniques such as CT or MRI is determined by the results of initial diagnostic testing or by consideration of the body system of interest, eg, MRI is particularly useful to evaluate the CNS. Advanced imaging with nuclear scintigraphy or positron emission tomography is used in human patients with FUO but is not yet widely reported in veterinary medicine.

Ultrasonography and Echocardiography: Abdominal ultrasonography may reveal a source of fever in the abdomen, such as neoplasia, peritonitis, pancreatitis, or abscesses. The thoracic cavity, limbs, and retrobulbar areas may also be examined by ultrasound. Echocardiography is indicated at the early stages of evaluation of the FUO patient with a murmur. This may aid in the detection of endocarditis, although this diagnosis should also be based on signalment, characteristics of the heart murmur, and blood culture results.

Bone Marrow Evaluation: Bone marrow cytology and histology should be evaluated in any animal with unexplained CBC abnormalities. Bone marrow disease is a common cause of FUO in small animals; therefore, bone marrow aspiration and biopsy, if possible, should also be included in the second stage of diagnostic testing in these patients. When obtaining bone marrow aspirates from

cats, a sample should be saved for possible molecular diagnostic testing for feline leukemia virus.

Arthrocentesis: Because immune-mediated polyarthritis is a common cause of FUI in dogs, arthrocentesis of multiple joints is included in the second stage of diagnostic testing in this species, even if the joints are normal on palpation. Some dogs with steroid-responsive meningitis-arthritis also have concurrent immune-mediated polyarthritis; therefore, arthrocentesis should be performed in dogs with spinal pain. Infectious polyarthritis is more commonly recognized in large animals, in which arthrocentesis is an important diagnostic test.

CSF Analysis: CSF sampling is recommended for dogs with FUI if less invasive tests do not reveal the cause of the fever. Fluid should be submitted for cytology, protein measurement, and culture.

Blood Culture: Blood cultures are recommended in all animals with unexplained fever. The techniques used should allow the collection of adequately large volumes of blood under aseptic conditions. If the size of the animal allows collecting more than one set of samples for blood culture, using appropriately sized aerobic and anaerobic bottles increases the sensitivity and specificity of the test. Special enrichment culture methods may be considered for certain organisms, eg, *Bartonella* spp.

Infectious Disease Testing: Tests available for the diagnosis of infectious diseases include assays for detection of antibodies or antigen in blood, body fluids, or tissues. Molecular diagnostic tests detect nucleic acid, with PCR being the most common in this category. Selection of these tests should be based on the signalment, clinical signs, and epidemiologic characteristics of the animal. Interpretation of test results requires an understanding of disease prevalence, vaccination history, and sensitivity and specificity of the test. When requesting PCR-based assays, it is important to use laboratories that have quality management programs that address test performance and consistency, and control for sample contamination.

Other Serologic Tests: The value of immune panels or autoantibody screens in small animal patients with FUI is unclear. Neither antinuclear antibody nor rheumatoid factor titers alone should be used to

diagnose systemic lupus erythematosus or rheumatoid arthritis, respectively.

Microbiology, Cytology, and Histology: Fine-needle aspirates are safe and simple to obtain from effusions, masses, nodules, organs, tissues, and body fluids. Fluids should be examined cytologically and also submitted for microbiologic or molecular diagnostic testing. Tissue biopsies are generally obtained in the second or third stages of diagnostic testing, after clinical signs or initial diagnostic tests have localized the fever. When biopsies are obtained, sufficient samples should be submitted for histopathology, appropriate culture (aerobic and anaerobic, fungal, mycoplasmal, mycobacterial, etc), molecular diagnostics, and special stains. If exploratory surgery is performed, biopsies should be obtained from several sites.

Treatment: In some FUI cases a specific diagnosis is not reached, or diagnostic testing is discontinued, leading to consideration of therapy in the absence of a diagnosis. Options include antibiotics, antifungal agents, and anti-inflammatory or immunosuppressive therapy (usually with corticosteroids). Trial therapy may resolve the clinical signs or confirm a presumptive diagnosis, but it is also associated with significant risk. Before pursuing a therapeutic trial, the owner should be informed of the potential risks and should be committed to careful monitoring of the animal for an appropriate length of time. The therapeutic trial should be based on a tentative diagnosis and should define the parameters to be followed and the criteria used to determine treatment success or failure. If an animal is likely to be referred for in-depth investigation of FUI, trial therapy should not be started because it may affect the results of further testing.

In true fever, the increase in body temperature is regulated; therefore, cooling methods such as water baths work against the body's own regulatory mechanisms. It is also likely that fever itself has some beneficial effects, particularly in infectious diseases. However, fever can lead to anorexia, lethargy, and dehydration. Thus, animals with FUI may benefit from IV fluid therapy or antipyretic medications. Examples include NSAIDs such as aspirin, carprofen, ketoprofen, and meloxicam in small animals, and flunixin meglumine or phenylbutazone in large animals.

HEPATIC LIPIDOSIS

FATTY LIVER DISEASE OF CATTLE

Fatty liver results from a state of negative energy balance and is one of the important metabolic diseases of postparturient dairy cows. Although often considered a postpartum disorder, it usually develops before and during parturition. Periparturient depression of feed intake, and endocrine changes associated with parturition and lactogenesis contribute to development of fatty liver. Cows that are overconditioned at calving are at highest risk. Fatty liver can develop whenever there is a decrease in feed intake and may occur secondary to the onset of another disorder. Fatty liver at calving is commonly associated with ketosis (see p 1024).

Etiology: Mobilization of body fat reserves that is triggered by hormonal cues in states of negative energy balance results in the release of nonesterified fatty acids (NEFAs) from adipose tissue. The liver retains ~15%–20% of the NEFAs circulating in blood and thus accumulates increased amounts during periods when blood NEFA concentrations are increased. The most dramatic increase occurs at calving, when plasma concentrations are often >1,000 $\mu\text{Eq/L}$. Concentrations can reach that level if the animal goes off feed. NEFAs taken up by the liver can either be oxidized or esterified. The primary esterification product is triglyceride, which can either be exported as part of a very low density lipoprotein (VLDL) or be stored in liver cells. In ruminants, export occurs at a very slow rate relative to many other species because of impaired VLDL synthesis. Therefore, under conditions of increased hepatic NEFA uptake and esterification, triglycerides accumulate. Oxidation of NEFAs leads either to the production of ATP in the tricarboxylic acid cycle or to the formation of ketones through peroxisomal or β -oxidation. Ketone formation is favored when blood glucose concentrations are low. Conditions that lead to low blood glucose and insulin concentrations also contribute to fatty liver, because insulin suppresses fat mobilization from adipose tissue.

The greatest increase in liver triglyceride typically occurs at calving. The extent of feed intake depression before and after calving or during disease in combination

with the amount of available body fat reserves moderates the degree of triglyceride accumulation. Excessive intracellular triglyceride accumulation in liver cells results in disturbed liver function and cell damage. Fatty liver can develop within 24 hr of an animal going off feed. Although lipid accumulation in the liver is a reversible process, the slow rate of triglyceride export as lipoprotein causes the disorder to persist for an extended period. Depletion of the liver lipid content usually begins when the cow reaches positive energy balance and may take several weeks to fully subside.

Fatty liver is not a consequence of positive energy balance or overfeeding. Energy consumption above requirements for maintenance and productive purposes will not directly result in deposition of triglyceride in hepatic tissue. Triglyceride deposition will occur only if the animal becomes overconditioned and consequently reduces feed intake.

Clinical Findings: There are no pathognomonic clinical signs of fatty liver disease in cattle. The condition is often associated with feed intake depression, decreased milk production, and ketosis. Increased blood NEFA concentration has been associated with impaired immune function and a proinflammatory effect, presumably reflecting in increased incidence of clinical mastitis, metritis, and other periparturient infectious diseases. However, cause and effect has not been established. Metabolic consequences of triglyceride accumulation in the liver include reduced gluconeogenesis, ureagenesis, hormone clearance, and hormone responsiveness. Consequently, hypoglycemia, hyperammonemia, and altered endocrine profiles may accompany fatty liver.

Fatty liver is likely to develop concurrently with another disease, typically disorders that are seen at or shortly after calving. These include metritis, mastitis, abomasal displacement, or hypocalcemia. Field observations suggest that response to treatment of concurrent disorders is poor if cows have extensive triglyceride infiltration of the liver. Cows slow to increase in milk production and feed intake after calving are likely to have fatty liver. However, fatty liver is probably the result rather than the cause

of poor feed intake. Fatty liver is often associated with obese cows and downer cows (see p 1188) but is unlikely to be a direct cause of the downer cow syndrome. Overconditioned cows exhibit more pronounced feed intake depression before and after calving than nonobese cows and, therefore, are susceptible to fatty liver. Although obesity predisposes to fatty liver disease, it is not restricted to obese cows. Similarly, obese cows do not necessarily have fatty liver.

Diagnosis: Diagnostic tools for fatty liver are of limited value. Fatty liver is usually diagnosed after the animal has been off feed or has died because of another disease. A positive diagnosis does not mean that clinical signs of illness are the result of fatty liver, and misinterpretation of a positive diagnosis is common.

Liver biopsy is a minimally invasive procedure that is the only direct and most reliable method to determine severity of fatty liver in dairy cattle. Measurement of total lipid or triglyceride content by gravimetric or chemical methods after extraction from tissue by organic solvents is necessary for quantitative assessment; however, these assays are not routinely conducted in commercial laboratories. Estimation of triglyceride content by flotation characteristics of the tissue in copper sulfate solutions of varying specific gravity is rapid, easy, and available for use under field conditions.

Blood and urine metabolites or blood enzyme activity have been proposed as indirect diagnostic parameters. Blood glucose concentrations are low and blood NEFA and β -hydroxybutyrate concentrations are high when conditions are conducive to the development of fatty liver. Blood cholesterol concentration is usually low when fatty liver occurs, which may reflect an impaired ability of the liver to secrete lipoproteins. AST, ornithine decarboxylase, and sorbitol dehydrogenase are hepatic enzymes that may be positively associated with liver triglyceride and liver damage. The total bilirubin concentration in blood is often positively associated with the NEFA concentration in blood. Blood metabolites or enzymes are unreliable indices of the degree of fatty liver, because normal concentrations vary widely among animals. The same problem exists when attempting to determine liver function by measuring sulfobromophthalein clearance from blood.

With the availability of handheld devices allowing cowside testing, measuring

β -hydroxybutyrate concentration in blood has become a popular way to identify herds that may be at risk of developing fatty liver. Measurement of plasma NEFA concentration is more expensive and requires submission of blood samples to a diagnostic laboratory. In addition to extreme variations in plasma NEFA concentrations among animals, there is extreme variation in a single individual, because concentrations increase dramatically immediately before and after calving. Therefore, a large number of animals must be sampled at a consistent time relative to calving. Care must be taken not to excite animals before sampling blood, because NEFAs increase rapidly in response to stress; samples should be drawn at standardized times using standardized procedures. The plasma NEFA concentrations at which triglyceride accumulates in the liver have not been established but are probably $\sim 600 \mu\text{Eq/L}$ and higher. These concentrations are common within 24–48 hr of parturition. However, prolonged exposure of the liver to concentrations $>600 \mu\text{Eq/L}$ will likely lead to fatty liver. Primiparous cows are less susceptible to fatty liver during periods of increased plasma NEFAs. Therefore, mature animals should be sampled when using plasma NEFAs as a predictor of fatty liver. To screen a herd for the prevalence and severity of hepatic lipidosis, determination of plasma NEFAs not earlier than 1 wk antepartum is recommended. Even though plasma NEFA concentration is a direct parameter for the lipid mobilization and thus the liver lipid * accumulation, after parturition the plasma β -hydroxybutyrate concentration has been found to more accurately reflect the severity of hepatic lipidosis.

Microscopic evaluation can be used to estimate the volume of the tissue occupied by fat. Estimates obtained by this method agree fairly well with chemical determination of triglyceride when expressed as a percentage of tissue dry weight. Mild, moderate, and severe fatty liver are often defined as $<20\%$, 20% – 40% , and $>40\%$ fat (percentage of cell volume), respectively, but these values have little meaning relative to impact on physiologic function or clinical signs of the animal. However, clinical signs potentially associated with fatty liver disease are rarely seen in animals with $<10\%$ fat in wet liver tissue. Use of ultrasonography as an alternative noninvasive procedure is being developed to determine the severity of fatty liver but is not yet routinely available.

Prevention and Treatment: Reducing severity and duration of negative energy balance is crucial to prevent fatty liver. This can be achieved by avoiding overconditioning cattle, rapid diet changes, unpalatable feeds, periparturient diseases, and environmental stress. Cows within a herd should enter the dry period with an average body condition score (BCS) of 3–3.5 (scale: 1 = thin, 5 = obese). Thin cows (BCS ≤ 2.5) can be fed additional energy during the dry period to replenish condition without fear of causing fatty liver. Overconditioned cattle (BCS ≥ 4) should not be feed restricted, because this will promote fat mobilization from adipose tissue and increase blood NEFAs and liver triglyceride.

The critical time for prevention of fatty liver is ~1 wk before through 1 wk after parturition, when cows are most susceptible. Cows that are candidates for preventive measures are those that are overconditioned or starting to go off feed. Propylene glycol, 300–600 mL/day, given as an oral drench during the final week prepartum has effectively reduced plasma NEFAs and the severity of fatty liver at calving. Propylene glycol can be fed, but feeding may not be as effective if the full dose is not consumed in a short period of time. Glycerin may be a less expensive alternative to propylene glycol.

Glucose or glucose precursors are effective, because they may cause an insulin response. Insulin is antilipolytic, ie, it decreases lipid mobilization from adipose tissue. Slow-release insulin compounds are available but are not approved for use in food-producing animals. A single 100 IU IM dose of a 24-hr slow-release insulin immediately after calving may be prophylactic. Higher doses may cause severe hypoglycemia and should not be used without concurrent glucose administration. Glucagon stimulates glycogenolysis, gluconeogenesis, and insulin production. In contrast to that in nonruminants, the lipolytic effect of glucagon in ruminants is negligible. Glucagon (10 mg/day, IV, for 14 days) is effective at reducing liver triglyceride. A more practical protocol for use of glucagon to prevent fatty liver has not been established. Niacin is an antilipolytic agent that may have potential for prevention of fatty liver, but unequivocal evidence supporting niacin supplementation of animals at risk is not available.

Minimizing stress is important for prevention of fatty liver. Sudden changes in environment should be avoided. For example, changes in ration, housing, temperature, herdmates, etc, may cause a reduction in feed intake and trigger

catecholamine-mediated increases in fat mobilization.

Other than longterm IV infusion of glucagon, there is no proven treatment for fatty liver. Repeated IV bolus administration of 500 mL of 50% dextrose solution is commonly used in dairy practice and can be combined with administration of propylene glycol 250 mL, PO, bid. Dextrose administration at a continuous infusion rate of up to 40 g/hr, IV, suitable to increase the plasma glucose concentration to 100–150 mg/dL without surpassing the renal threshold for glucose, can be used in a clinical setting. Although this treatment effectively suppresses lipolysis and ketogenesis, treatment-induced hyperglycemia is likely to negatively affect feed intake. It is therefore advisable to reduce the infusion rate after 2–3 days and to determine whether the animal is able to maintain normoglycemia as the parenteral glucose supply decreases.

Use of glucocorticoids in cows with fatty liver is controversial because of their potential lipolytic effect. Recent literature suggests that short-term treatment with dexamethasone does not induce lipolysis in dairy cows. The gluconeogenic effect of glucocorticoids that is well documented in several monogastric species has thus far not been confirmed in cattle. The well-established hyperglycemic effect of glucocorticoids in cattle has primarily been attributed to an impaired glucose uptake by the mammary gland in treated cows. In addition, glucocorticoids are thought to have a positive effect on feed intake. In theory, effective treatments would be those that enhance lipoprotein triglyceride export from the liver. However, compounds that are known lipotropic agents in nonruminants have not been proved to be effective in ruminants. IV administration of choline, inositol, methionine, and vitamin B₁₂ are often suggested as treatments, but scientific data are insufficient to support their use. Oral administration of these compounds is not effective, because they are degraded in the rumen. In essence, treatment is the same as prevention; attempts should be made to avoid negative energy balance and to minimize fatty acid mobilization from adipose tissue. Once positive energy balance is attained, liver triglyceride can be reduced significantly in 7–10 days.

PREGNANCY TOXEMIA IN COWS

Pregnancy toxemia in cows is similar to the condition in small ruminants and is the result of fetal carbohydrate or energy

demand exceeding maternal supply during the last trimester of pregnancy. It is precipitated by large or multiple fetuses, feed low in energy or protein or high in poorly digestible fiber, and health conditions that increase energy demand or decrease ability to take in nourishment (eg, lameness and oral diseases). Cold, snowy weather may contribute by increasing the animal's energy requirement and by covering available forage. Inflammation is also increasingly being associated with disorders of energy metabolism; inflammatory mediators tend to promote mobilization of lipid stores and antagonize the actions of insulin. The fetoplasental unit uses carbohydrate for energy and removes these compounds from the blood in an insulin-independent fashion. When this demand exceeds maternal supply, adipose tissue is mobilized to supply energy as acetate or ketonebodies, sparing carbohydrate consumption by other maternal tissues. However, only a small amount of new carbohydrate is generated from fat metabolism (from glycerol). This condition is more severe than ketosis (see p 1024) because fetal demand increases during pregnancy, while milk demand can decline in response to negative energy balance.

Although the mechanism is unknown, clinical disease develops in some cows with negative energy or carbohydrate balance. Proposed mediators of clinical disease include glucose deficiency with intermittent hypoglycemia, ketone body accumulation with metabolic acidosis or appetite suppression, and death of the fetus with secondary infection and toxemia. Individual cows of any breed can be affected, but herd problems are most common in beef cattle, which frequently are managed so that late pregnancy coincides with the poorest availability of feed. Both thin and fat cows can be affected, but the first noted abnormality often is loss of body condition over 1–2 wk. Decreased appetite, rumination, fecal production, and nose-licking are general signs of illness. With time, affected cows become markedly depressed, weak, ataxic, and recumbent. Opisthotonos, seizures, or coma may be seen terminally. Ketonuria is present from the early stage of disease and is the most specific finding; even mild ketonuria should not be found in healthy pregnant cows until a few days before calving. Inexpensive ketone meters are now available and augment the older techniques of nitroprusside tablets or strips. Hypoglycemia is also common, but excited or seizing cows may have hyperglycemia. With more advanced disease, there may be

variable increases in serum activities of muscle or liver enzymes, as well as clinicopathologic evidence of infection, metabolic acidosis, internal organ dysfunction or failure, and circulatory collapse. Hepatic lipidosis in conjunction with large or multiple fetuses is a common necropsy finding; evidence of muscle pressure necrosis and toxemia may also be found.

Successful treatment requires early identification of the disease. There are few differential diagnoses, and pregnancy toxemia must be considered a factor in any disease that affects cattle in late gestation. Cattle that have lost weight but are still eating may be managed by feeding concentrate or propylene glycol (0.5–1 g/kg/day for up to 5 days). Anorectic cattle must be treated aggressively, because the decrease in energy intake causes the disease to progress rapidly. Propylene glycol can be force-fed, or dextrose given IV (0.5 g/kg at least once a day). Cattle with dehydration, organ dysfunction, or metabolic acidosis should be treated with large volumes (20–60 L/day, PO or IV) of electrolyte fluids; if IV fluid administration is practical, continuous dextrose infusion (5%) is recommended. Protamine zinc insulin (200 U, SC, every 48 hr) may be given after dextrose administration to suppress ketogenesis. However, insulin is not approved for use in cattle in the USA. Recumbent cattle may benefit from good nursing care (see p 1188) but rarely respond to treatment. To decrease the energy drain of any cow with pregnancy toxemia, induction of parturition or removal of the fetus by cesarean section should be considered.

On the herd level, the disease can be prevented by adequate attention to nutrition and health care of cattle in late gestation. For the individual cow, recognition of the precarious state of energy and carbohydrate balance during late gestation dictates careful monitoring of energy intake, attitude, and fat mobilization, especially during times of illness or other stress.

PREGNANCY TOXEMIA IN EWES AND DOES

(Twin lamb disease, Pregnancy ketosis)

Pregnancy toxemia affects ewes and does during late gestation and is characterized by partial anorexia and depression, often with neurologic signs, progressing to recumbency and death. It is seen more often in animals carrying multiple fetuses. Generally, clinically affected animals have other risk factors, at either the individual or flock/herd level.

Epidemiology and Pathogenesis:

The primary predisposing cause of pregnancy toxemia is inadequate nutrition during late gestation, usually because of insufficient energy density of the ration and decreased rumen capacity as a result of fetal growth. In the last 4 wk of gestation, metabolizable energy requirements rise dramatically. For example, the energy requirement of a 70-kg ewe carrying a single lamb is 2.8 Mcal/day in early gestation compared with 3.45 Mcal/day in late gestation, or an increase of 23%. This change is more dramatic in ewes bearing twins, with an energy requirement of 3.22 Mcal/day in early and 4.37 Mcal/day in late gestation (36% increase), and in ewes bearing triplets, with an energy requirement of 3.49 Mcal/day in early and 4.95 Mcal/day in late gestation (42% increase). Dairy goats have similar changes in needs.

In late gestation, the liver increases gluconeogenesis to facilitate glucose availability to the fetuses. Each fetus requires 30–40 g of glucose/day in late gestation, which represents a significant percentage of the ewe's glucose production and which is preferentially directed to supporting the fetuses rather than the ewe. Mobilization of fat stores is increased in late gestation as a way to assure adequate energy for the increased demands of the developing fetus(es) and impending lactation. However, in a negative energy balance, this increased mobilization may overwhelm the liver's capacity and result in hepatic lipidosis, with subsequent impairment of function. Additionally, twin-bearing ewes appear to have more difficulty producing glucose and clearing ketone bodies, thus increasing their susceptibility to pregnancy toxemia.

Females with a poor body condition score (BCS ≤ 2) or that are overconditioned (BCS ≥ 4) and carrying more than one fetus are most at risk of developing pregnancy toxemia, although the condition can occur even in ideally conditioned ewes on an adequate ration. Susceptible, thin ewes or does develop ketosis because a chronically inadequate ration is offered or because other diseases limit intake (eg, lameness, dental disease) and, with increasingly insufficient energy to meet increasing fetal demands, the ewe or doe mobilizes more body fat, with resultant ketone body production and hepatic lipidosis. Overconditioned animals may have depressed appetites, and adipose mobilization quickly overwhelms the liver's capacity, resulting again in hepatic lipidosis. In addition, there may be a population of animals less

responsive to insulin production when nutritional intake is inadequate. Ewes fitting these criteria may quickly shift from subclinical ketosis to clinical pregnancy toxemia if feed intake is acutely curtailed by such events as adverse weather, transport, handling for shearing or preventive medication, or other concomitant disease (footrot, pneumonia, etc). These variants of pregnancy toxemia have been termed primary pregnancy toxemia (thin ewes and inadequate nutrition), estate ketosis (fat ewes), and secondary pregnancy toxemia (ewes suffering from other disease). Dairy does often experience ketosis after kidding (serum β -hydroxybutyrate [BHB] > 1.7 mmol/L), which may or may not be connected with pregnancy ketosis before kidding. Ketosis after kidding appears to be more common in herds using a complete pelleted ration.

Clinical Findings: Early clinical signs can be detected by an observant producer. Most cases develop 1–3 wk before parturition. Onset earlier than day 140 of gestation is associated with more severe disease and increased risk of mortality. Decreased aggressiveness at feeding, particularly with grain consumption, indicates a problem. Animals will spend more time lying and have more frequent bouts of lying than their healthy herdmates. As the disease advances, ewes or does may also show signs of listlessness, aimless walking, muscle twitching or fine muscle tremors, opisthotonos, and grinding of the teeth. This progresses (generally over 2–4 days) to blindness, ataxia, and finally sternal recumbency, coma, and death. Cerebral hypoglycemia coupled with ketosis, ketoacidosis, and reduced hepatic and renal function lead to the clinical signs and fetal death. Blood glucose levels may return to normal or even become high terminally, possibly indicating death of the fetus(es). Septicemia develops in the ewe or doe after fetal death.

Lesions: Postmortem changes demonstrate varying degrees of fatty liver, enlarged adrenal glands, and often include multiple fetuses in a state of decomposition indicating premortem death. Very thin animals may appear starved (eg, serous atrophy of the kidney and heart fat). However, these signs alone are not pathognomonic for death due to pregnancy toxemia. Postmortem samples of aqueous humor or CSF can be analyzed for BHB. Levels > 2.5 and 0.5 mmol/L, respectively, are consistent with a diagnosis of pregnancy toxemia.

Diagnosis: Laboratory findings in individual animals may include hypoglycemia (often <2 mmol/L), increased urine ketone levels (evaluated by commercial qualitative test strips), increased serum BHB levels (normal <0.8 mmol/L, subclinical ketosis ≥ 0.8 mmol/L, and clinical disease >3 mmol/L), and occasionally hypocalcemia. Hypoglycemia is not a consistent finding, with up to 40% of cases having normal glucose levels and up to 20% having hyperglycemia. If the diagnosis needs further confirmation, CSF glucose levels may be more accurate than blood; they remain low even when serum glucose rebounds in advanced cases after fetal death. BHB is a more reliable indicator of disease severity than are blood glucose levels. Nonesterified fatty acids can also be increased above 0.4 mmol/L, indicating likely hepatic lipodosis, resulting in impaired hepatic function.

Although hypocalcemia is often found in cases of pregnancy toxemia, it should also be considered when formulating hypotheses regarding recumbent late gestational sheep and goats (*see* p 991). This is similarly true with hypomagnesemia, which is a common finding in cases of pregnancy toxemia but should also be considered as a differential diagnosis for periparturient CNS disease. Other CNS diseases to be considered include polioencephalomalacia, pulpy kidney disease (enterotoxemia), rabies, scrapie, maedi visna/ovine progressive pneumonia, lead poisoning, chronic copper toxicity, and listeriosis. These can be differentiated based on clinical and laboratory findings or during necropsy.

Treatment: Ewes or does in the early stages (ie, are ambulatory, have a decreased appetite for grain, and are showing few nervous signs) can often be treated successfully with oral propylene glycol (60 mL, bid, for 3 days, or 100 mL/day). Adding oral calcium (12.5 g calcium lactate), oral potassium (7.5 g KCl), and insulin (0.4 IU/kg/day, SC) has increased survival rates. Oral commercial calf electrolyte solutions containing glucose may also be given by stomach tube at a dose of 3–4 L, qid, or drenched as a concentrated solution. It may also be prudent to induce parturition/abortion if the ewe or doe is also thin or fat and cannot manage fetal demands that late in pregnancy. This can be done by administering dexamethasone (20 mg, IV or IM). Parturition is expected within 24–72 hr, with most animals giving birth within 36 hr. Does may also benefit by the addition of prosta-

glandin $F_{2\alpha}$ (dinoprost [10 mg, IM] or cloprostenol [75 mcg/45 kg body wt]). Contributing factors (eg, nutrition, housing, illness, other stressors) should be corrected for the group, and feeding management assessed (eg, adequate feeder space, feeding frequency, protection from adverse weather).

Treatment of advanced cases of pregnancy toxemia is frequently unrewarding. If a ewe or doe is already comatose, humane euthanasia is warranted, and treatment should focus on the rest of the flock. However, if the female is valuable and the owner wishes to pursue treatment despite the poor prognosis, then aggressive therapy should be directed against the ketoacidosis and hypoglycemia. Before starting this therapy, it should be determined whether the fetuses are alive (eg, real-time or Doppler ultrasonography). If the fetuses are alive and within 3 days of a calculated due date (gestation length 147 days), then an emergency cesarean section may be considered if economically viable. If the fetuses are dead or too premature to survive a cesarean section, it is less stressful to the ewe or doe to induce early parturition with dexamethasone (as above). Prophylactic antibiotics (usually procaine penicillin G at 20,000 IU/kg/day) are appropriate if the fetuses are thought to be dead.

Hypoglycemia can be treated by a single injection of 50% dextrose, 60–100 mL, IV, followed by balanced electrolyte solution with 5% dextrose. IV drips and lower dextrose levels in solution might cause less of a diuretic effect; however, this is often impractical in a field setting. Repeated boluses of IV glucose should be avoided, because they may result in a refractory insulin response. Insulin can be administered (20–40 IU protamine zinc insulin, IM, every other day). Calcium (50–100 mL of a commercial calcium gluconate or borogluconate solution, SC) can be given safely without serum biochemistry data. If serum biochemistry demonstrates hypocalcemia, ~50 mL of a commercial calcium solution can be given by slow IV injection while monitoring the heart. Oral potassium chloride (KCl) can be given as well, because serum potassium levels are often depressed. Use of flunixin meglumine at 2.5 mg/kg improved survival rate of ewes and their lambs, although the mechanism is unknown. Although aggressive therapy and intensive nursing care may be successful, it is not unusual to see case fatality rates $>40\%$. Given the cost, it is prudent to share the guarded prognosis with owners before undertaking treatment.

A sample of late-gestation ewes or does can be tested for serum BHB levels to determine the extent of the risk in the rest of the flock. Generally, 10–20 animals in late gestation should be sampled (3%–20% of the pregnant flock). The risk of the flock can be determined based on the mean value of these results: normal (low risk) 0–0.7 mmol/L, moderate underfeeding (moderate risk) 0.8–1.6 mmol/L, and severe underfeeding (high risk) 1.7–3.0 mmol/L. Other diseases should be treated (eg, footrot). Females off feed should be separated from the group and hand fed, keeping in mind they should be able to see the group to feel comfortable.

Prevention: Ewes or does should not enter the last 6 wk of gestation with a BCS <2.5; this can be prevented by good feeding management, eg, adequate feeder space for pregnant animals, sorting (based on BCS, fetal numbers, and animal size), forage analysis (for energy, digestible fiber, and protein levels), and ration formulation. During the last 6 wk of gestation, grain is required as a source of carbohydrates in the ration to maintain the health of multiple-bearing females. Amount varies depending on forage quality, adult body weight and condition score, and number of fetuses, but protein must also be balanced for rumen microbes to make optimal use of available carbohydrates.

Producers should ideally assess BCS at breeding and midgestation, usually at the time of pregnancy scanning, so that thin animals can be fed as a separate group. It takes ~6 wk to raise BCS by 1 point, so early intervention is important to avoid late-gestation problems. If real-time ultrasound scanning allows for fetal number determination, then animals should also be managed based on fetal numbers. Producers may find

it convenient to feed pregnant ewe-lambs or doelings with twin-bearing females and thin, single-bearing females because of the added energy young animals need for growth. With prolific breeds, triplet-bearing ewes and thin, twin-bearing ewes can be fed together. Overconditioned females (ie, BCS ≥ 4) are not as common but may be seen in small hobby flocks. Fat females are much less responsive to therapy, and owners should be advised on how to avoid the problem through proper feeding management. However, late pregnancy is not the time to reduce BCS in overconditioned females. BHB serum levels can be used as a flock screening test to detect flocks at risk of pregnancy toxemia. In flocks with values ranging from >0.8–3 mmol/L, feeding management should be corrected quickly to avoid clinical disease.

Research has supported the use of ionophores, particularly monensin, in transition dairy cows to prevent subclinical ketosis and other early postpartum diseases. Ionophores improve feed efficiency by changing microflora populations in the rumen, resulting in increased feed efficiency and production of propionic acid, followed by improved gluconeogenesis. There is some evidence that monensin may be beneficial for late-gestation ewes (although not for dairy goats); it improved feed efficiency by lowering feed intake. Treated ewes also showed lower serum BHB levels in late gestation, with no adverse effects on lamb birth weights. It may help prevent ketosis in postpartum dairy goats. Lasalocid has been similarly studied. Again, feed intake was suppressed, but lamb survival was better in the treatment group. More work needs to be done with both drugs to assess their use in preventing pregnancy toxemia in prolific ewes.

KETOSIS IN CATTLE

(Acetonemia, Ketonemia)

Ketosis is a common disease of adult cattle. It typically occurs in dairy cows in early lactation and is most consistently characterized by partial anorexia and depression. Rarely, it occurs in cattle in late gestation, at which time it resembles pregnancy toxemia of ewes (see p 1021). In addition to inappetence, signs of nervous dysfunction, including pica, abnormal licking, incoordi-

nation and abnormal gait, bellowing, and aggression, are occasionally seen. The condition is worldwide in distribution but is most common where dairy cows are bred and managed for high production.

Etiology and Pathogenesis: The pathogenesis of bovine ketosis is incompletely understood, but it requires the

combination of intense adipose mobilization and a high glucose demand. Both of these conditions are present in early lactation, at which time negative energy balance leads to adipose mobilization, and milk synthesis creates a high glucose demand. Adipose mobilization is accompanied by high blood serum concentrations of nonesterified fatty acids (NEFAs). During periods of intense gluconeogenesis, a large portion of serum NEFAs is directed to ketone body synthesis in the liver. Thus, the clinicopathologic characterization of ketosis includes high serum concentrations of NEFAs and ketone bodies and low concentrations of glucose. In contrast to many other species, cattle with hyperketonemia do not have concurrent acidemia. The serum ketone bodies are acetone, acetoacetate, and β -hydroxybutyrate (BHB).

There is speculation that the pathogenesis of ketosis cases occurring in the immediate postpartum period is slightly different than that of cases occurring closer to the time of peak milk production. Ketosis in the immediate postpartum period is sometimes described as **type II ketosis**. Such cases of ketosis in very early lactation are usually associated with fatty liver (*see* p 1018). Both fatty liver and ketosis are probably part of a spectrum of conditions associated with intense fat mobilization in cattle. Ketosis cases occurring closer to peak milk production, which usually occurs at 4–6 wk postpartum, may be more closely associated with underfed cattle experiencing a metabolic shortage of gluconeogenic precursors than with excessive fat mobilization. Ketosis at this time is sometimes described as **type I ketosis**.

The exact pathogenesis of the clinical signs is not known. They do not appear to be associated directly with serum concentrations of either glucose or ketone bodies. There is speculation they may be due to metabolites of the ketone bodies.

Epidemiology: All dairy cows in early lactation (first 6 wk) are at risk of ketosis. The overall prevalence in cattle in the first 60 days of lactation is estimated at 7%–14%, but prevalence in individual herds varies substantially and may exceed 14%. The peak prevalence of ketosis occurs in the first 2 wk of lactation. Lactational incidence rates vary dramatically between herds and may approach 100%. Ketosis is seen in all parities (although it appears to be less common in primiparous animals) and does not appear to have a genetic predisposition, other than being associated with dairy breeds. Cows

with excessive adipose stores (body condition score ≥ 3.75 out of 5) at calving are at a greater risk of ketosis than those with lower body condition scores. Lactating cows with subclinical ketosis (*see* p 1027) are also at a greater risk of developing clinical ketosis and displaced abomasum than cows with lower serum BHB concentrations.

Clinical Findings: In cows maintained in confinement stalls, reduced feed intake is usually the first sign of ketosis. If rations are offered in components, cows with ketosis often refuse grain before forage. In group-fed herds, reduced milk production, lethargy, and an “empty” appearing abdomen are usually the signs of ketosis noticed first. On physical examination, cows are afebrile and may be slightly dehydrated. Rumen motility is variable, being hyperactive in some cases and hypoactive in others. In many cases, there are no other physical abnormalities. CNS disturbances are noted in a minority of cases. These include abnormal licking and chewing, with cows sometimes chewing incessantly on pipes and other objects in their surroundings. Incoordination and gait abnormalities occasionally are seen, as are aggression and bellowing. These signs occur in a clear minority of cases, but because the disease is so common, finding animals with these signs is not unusual.

Diagnosis: The clinical diagnosis of ketosis is based on presence of risk factors (early lactation), clinical signs, and ketone bodies in urine or milk. When a diagnosis of ketosis is made, a thorough physical examination should be performed, because ketosis frequently occurs concurrently with other peripartum diseases. Especially common concurrent diseases include displaced abomasum, retained fetal membranes, and metritis. Rabies and other CNS diseases are important differential diagnoses in cases exhibiting neurologic signs.

Cow-side tests for the presence of ketone bodies in urine or milk are critical for diagnosis. Most commercially available test kits are based on the presence of acetoacetate or acetone in milk or urine. Dipstick tests are convenient, but those designed to detect acetoacetate or acetone in urine are not suitable for milk testing. All of these tests are read by observation for a particular color change. Care should be taken to allow the appropriate time for color development as specified by the test manufacturer. Handheld instruments designed to monitor

ketone bodies in the blood of human diabetic patients are available. These instruments quantitatively measure the concentration of BHB in blood, urine, or milk and may be used for the clinical diagnosis of ketosis.

In a given animal, urine ketone body concentrations are always higher than milk ketone body concentrations. Trace to mildly positive results for the presence of ketone bodies in urine do not signify clinical ketosis. Without clinical signs, such as partial anorexia, these results indicate subclinical ketosis. Milk tests for acetone and acetoacetate are more specific than urine tests. Positive milk tests for acetoacetate and/or acetone usually indicate clinical ketosis. BHB concentrations in milk may be measured by a dipstick method that is available in some countries, or by the electronic device mentioned above. The BHB concentration in milk is always higher than the acetoacetate or acetone concentration, making the tests based on BHB more sensitive than those based on acetoacetate or acetone.

Treatment: Treatment of ketosis is aimed at reestablishing normoglycemia and reducing serum ketone body concentrations. Bolus IV administration of 500 mL of 50% dextrose solution is a common therapy. This solution is very hyperosmotic and, if administered perivascularly, results in severe tissue swelling and irritation, so care should be taken to ensure that it is given IV. Bolus glucose therapy generally results in rapid recovery, especially in cases occurring near peak lactation (type I ketosis). However, the effect frequently is transient, and relapses are common. Administration of glucocorticoids, including dexamethasone or isoflupredone acetate at 5–20 mg/dose, IM, may result in a more sustained response, relative to glucose alone. Glucose and glucocorticoid therapy may be repeated daily as necessary. Propylene glycol administered orally (250–400 g/dose [8–14 oz]) once per day acts as a glucose precursor and is effective as ketosis therapy. Indeed, propylene glycol appears to be the most well documented of the various therapies for ketosis. Overdosing propylene glycol leads to CNS depression.

Ketosis cases occurring within the first 1–2 wk after calving (type II ketosis) frequently are more refractory to therapy than cases occurring nearer to peak lactation (type I). In these cases, a long-acting insulin preparation given IM at 150–200 IU/day may be beneficial. Insulin

suppresses both adipose mobilization and ketogenesis but should be given in combination with glucose or a glucocorticoid to prevent hypoglycemia. Use of insulin in this manner is an extra-label, unapproved use. Other therapies that may be of benefit in refractory ketosis cases are continuous IV glucose infusion and tube feeding. (See also p 1018.)

Prevention and Control: Prevention of ketosis is via nutritional management. Body condition should be managed in late lactation, when cows frequently become too fat. Modifying diets of late lactation cows to increase the energy supply from digestible fiber and reduce the energy supply from starch may aid in partitioning dietary energy toward milk and away from body fattening. The dry period is generally too late to reduce body condition score. Reducing body condition in the dry period, particularly in the late dry period, may even be counterproductive, resulting in excessive adipose mobilization prepartum. A critical area in ketosis prevention is maintaining and promoting feed intake. Cows tend to reduce feed consumption in the last 3 wk of gestation. Nutritional management should be aimed at minimizing this reduction. Controversy exists regarding the optimal dietary characteristics during this period. It is likely that optimal energy and fiber concentrations in rations for cows in the last 3 wk of gestation vary from farm to farm. Feed intake should be monitored and rations adjusted to meet but not greatly exceed energy requirements throughout the entire dry period. For Holstein cows of typical adult body size, the average daily energy requirement throughout the dry period is between 12 and 15 Mcal expressed as net energy for lactation (NE_L). After calving, diets should promote rapid and sustained increases in feed and energy consumption. Early lactation rations should be relatively high in nonfiber carbohydrate concentration but contain enough fiber to maintain rumen health and feed intake. Neutral-detergent fiber concentrations should usually be in the range of 28%–30%, with nonfiber carbohydrate concentrations in the range of 38%–41%. Dietary particle size will influence the optimal proportions of carbohydrate fractions. Some feed additives, including niacin, calcium propionate, sodium propionate, propylene glycol, and rumen-protected choline, may help prevent and manage ketosis. To be effective, these supplements should be fed in the last 2–3 wk of gestation, as well as during the period of ketosis susceptibility.

In some countries, monensin sodium is approved for use in preventing subclinical ketosis and its associated diseases. Where approved, it is recommended at the rate of 200–300 mg/head/day.

SUBCLINICAL KETOSIS

Subclinical ketosis is defined as high serum ketone body concentrations without observed clinical signs. Subclinically affected cows are at increased risk of clinical ketosis and displaced abomasum and are also less fertile than those with normal serum ketone body concentrations. Furthermore, they appear to have reduced milk production. Determination of serum β -hydroxybutyrate (BHB) concentrations is considered the best way to detect and monitor subclinical ketosis, because the cow-side tests mentioned above are insufficiently sensitive and specific in detecting subclinical increases in serum BHB concentrations. Serum concentrations may be determined spectrophotometrically by traditional clinical laboratory means. The BHB concentrations in blood or serum samples are reasonably stable; thus, rigorous sample handling precautions are not necessary to transport the specimens to the laboratory. The test is sensitive to hemolysis, however, so hemolysis should be avoided during sample collection, and serum should be separated from the clot before shipment to the laboratory.

In addition to laboratory determination by spectrophotometry, handheld devices manufactured to monitor blood ketone body concentrations in human diabetic patients have been evaluated for use in monitoring subclinical ketosis in cows. These instruments use whole blood rather than serum for BHB determination, making them particularly practical for on-farm use. The whole blood BHB concentration is very close to the serum concentration, so the interpretation of results obtained from either the handheld device or laboratory analysis is similar.

Diagnosis of subclinical ketosis requires definition of a concentration above which cows are considered to be subclinically ketotic. Concentrations between 1,000 μ M (10.4 mg/dL) and 1,400 μ M (14.6 mg/dL) are used. Recommended strategies for herd-level testing are to test at least 12 animals in the first 60 days of lactation. If >10% are subclinically ketotic, it should be considered evidence of a herd-level problem and prompt a review of nutritional management. Some farms use the handheld BHB meters to test all cows in early lactation. Cows diagnosed with subclinical ketosis are treated with propylene glycol. Such an approach is labor intensive but has been demonstrated to reduce further disease occurrence in subclinically ketotic animals and to improve milk production in treated animals. Such an approach should not replace sound nutritional management procedures.

MALIGNANT HYPERTHERMIA

(Porcine stress syndrome)

Malignant hyperthermia (MH) is a rare, life-threatening, inherited disorder that can lead to metabolic disease of skeletal muscles in susceptible animals after exposure to triggering agents such as halogenated inhalation anesthetics, depolarizing neuromuscular blocking drugs, stress, and/or exercise. A mutation in the ryanodine receptors (RYR1 locus) on the sarcoplasmic reticulum that surrounds myofibrils of skeletal muscles alters the function of calcium release channels, which results in massive release of calcium into the cytoplasm of the myofibrils. As a result, generalized, extensive skeletal muscle

contraction occurs, leading rapidly to a potentially fatal hypermetabolic state known as an MH episode. More than 300 RYR1 variants have been identified, and 31 of those mutations have been confirmed to cause MH according to the molecular genetic guidelines of the European Malignant Hyperthermia Group. Different mutation loci within the RYR1 receptors have been shown to be responsible for MH syndrome in different species.

Etiology and Clinical Findings: MH is considered to be a clinical syndrome rather than a single disease, because research

indicates that multiple environmental and genetic factors cause a complex of pathophysiologic events. Contrary to general belief, a full-fledged MH episode, with a sudden and rapidly progressive course of symptoms, does not occur frequently. In most cases, MH is a subtle disorder. Pigs and people seem to be most susceptible, but MH has also been reported in dogs, cats, and horses. In people and dogs, both parents must carry the mutant chromosome for the autosomal recessive gene to result in clinical expression in offspring. In pigs, the mutant autosomal gene is dominant, so that a single copy of the mutant chromosome, carried by either parent, can result in clinical expression in the offspring, ie, 50% of offspring are susceptible to MH.

Interestingly, most MH-susceptible animals, including people, do not suffer from signs of muscle disease in everyday life. In people, the incidence of MH episodes during anesthesia is between 1:5,000 and 1:50,000 per 100,000 anesthetic events. The MH episode may develop at first exposure to an anesthetic triggering agent, but in some cases, as many as three exposures must occur before a full-fledged MH crisis develops. In domestic animals, it is unclear whether multiple exposures to the triggering agent are required before developing a full-fledged episode. This is because the clinical signs of MH can be so subtle that the episode goes unrecognized.

MH can occur at any time during anesthesia or in the early postoperative period. The clinical signs of MH are often a sudden and dramatic rise in body temperature and end-tidal CO_2 (ETCO_2), followed by muscle fasciculation, muscle rigidity, tachypnea, tachycardia, arrhythmias, myoglobinuria, metabolic acidosis, renal failure, and often death. The prognosis is usually poor once clinical signs are recognized. Triggering agents of MH include stress (eg, excitement, transportation, and preanesthetic handling), exercise, halogenated inhalation anesthetics (eg, halothane, isoflurane, sevoflurane, and desflurane), and depolarizing neuromuscular blocking drugs (eg, succinylcholine). Of the halogenated inhalation anesthetics, halothane is claimed to be the most potent triggering agent, and it is no longer used in western countries. The use of succinylcholine, another potent triggering agent, has been gradually restricted by international anesthesia societies.

In **pigs**, MH is also referred to as porcine stress syndrome. Breed susceptibility varies, with Pietrain, Portland China, and Landrace pigs very susceptible to MH, and Large White, Yorkshire, and Hampshire pigs much less so. In the past, halothane was the most frequently reported trigger of MH in pigs. Isoflurane has been reported to trigger MH in pigs of susceptible breeds, but only one instance of isoflurane-induced MH has been reported in a potbellied pig. Sevoflurane-induced MH also has been reported in purebred Poland Chinapigs. Episodes of MH induced by desflurane have been reported in Large White, Pietrain, and Pietrain-mixed pigs. There have been no reports of isoflurane- or sevoflurane-induced MH in cattle.

In **dogs**, MH syndrome has been reported in Pointers, Greyhounds, Labrador Retrievers, Saint Bernards, Springer Spaniels, Bichon Frises, Golden Retrievers, and Border Collies. There are distinct differences in the clinical signs of MH seen in dogs and those in pigs and people. The first obvious indication of an imminent MH episode in dogs is the rapid and dramatic increase in CO_2 production, as evidenced by a sudden increase in ETCO_2 concentration. Body temperature may increase during the episode, but this occurs much later than the increased ETCO_2 . In a study in which a colony of Doberman-German Shepherd-Collie dogs were challenged with halothane/succinylcholine, the dogs that developed MH syndrome all had a mutation on the calcium-release channels in the RYR1 receptors. However, this mutation was identified on a different loci (T1640) than that responsible for MH syndrome in pigs (R614C) and in people (CFA01). Another mutation, RYR1V547A, has also been shown to be involved in MH syndrome in dogs. The incidence rate of MH syndrome associated with anesthesia in dogs is reported to be 2.1% in Canada, 0.43% in the USA, and 0.23% in England, with a mortality rate of 0.11% in both Canada and the USA.

MH syndrome in **horses** is difficult to recognize, because it can easily be confused with other myopathies commonly associated with anesthesia in horses. Unlike in pigs, dogs, and people, signs of MH syndrome in horses tend to be slow to develop and are often observed only after ≥ 3 hr of anesthesia. In addition to the clinical signs of anesthetic-related MH seen in other species, intraoperative cardiac arrhythmia (eg, premature ventricular contraction),

postanesthetic myositis, and increased serum potassium and CK have also been seen in MH-affected horses. Clinical signs similar to those of MH syndrome such as hypercarbia, increased body temperature, and hyperkalemia, are also seen in horses with hyperkalemic periodic paralysis (*see* p 1047), a genetic mutation of sodium channels. Thus, a definitive diagnosis should be confirmed by *in vitro* contracture test (IVCT) or DNA analysis. Prognosis of horses suffering an MH episode during or after anesthesia is usually poor because of the lack of response to symptomatic treatments and difficulty in management of complications such as myositis, fractures, and/or seizures.

Diagnosis: Currently, the gold standard for diagnosis of MH is IVCT, which is based on muscle fiber contracture in response to triggering agents such as halothane or caffeine. However, IVCT requires a surgical procedure (ie, muscle biopsy), is expensive and available only at specialized testing centers, and may produce equivocal as well as false-positive and false-negative results. DNA analysis is an alternative to the IVCT; it requires only a small blood sample to be sent to an accredited diagnostic laboratory to screen for RYR1 mutation. An animal is diagnosed as MH susceptible if 1 of the 31 known causative mutations is detected. However, the diagnostic classification of many RYR1 mutations remains difficult because their pathophysiologic impact with regard to initiating an MH episode is not yet clear. Therefore, an IVCT is required to exclude MH susceptibility in case of an unclassified RYR1 mutation or if RYR1 mutation is absent. Other minimally invasive diagnostic tests for identification of MH susceptibility are in development

Treatment and Prevention: Because of few effective drugs available to treat MH, stress before anesthesia should be minimized, and using anesthetics that are known triggering agents should be avoided to prevent an MH episode in susceptible animals. Total IV anesthesia and/or regional/local anesthetic techniques can be safely used as alternative procedures to allow surgery on MH-susceptible animals. Drugs that can be safely administered to MH-susceptible animals include phenothiazine derivatives (eg, acepromazine), butyrophenone derivatives (eg, droperidol, azaperone), benzodiazepine derivatives (eg, diazepam, midazolam, zolazepam), α_2 -agonists (eg, xylazine,

detomidine, dexmedetomidine, romifidine), dissociative anesthetics (eg, ketamine, tiletamine-zolazepam), propofol, etomidate, opioids (eg, morphine, hydromorphone, fentanyl, butorphanol, buprenorphine), N_2O , nondepolarizing neuromuscular blocking drugs (eg, atracurium, vecuronium, rocuronium), and local anesthetics (eg, lidocaine, mepivacaine, bupivacaine). MH-susceptible animals should be kept calm and stress minimized by administering effective preanesthetic medication before induction and maintenance of anesthesia. Azaperone at 0.5–2 mg/kg, IM, provided 100% protection against MH in susceptible Pietrain pigs.

Treatment of MH is most effective when signs of MH (eg, muscle rigidity, sudden rise in body temperature and $ETCO_2$) are recognized early and treated aggressively. Treatment is largely symptomatic and includes immediate discontinuation of inhalation anesthetic and use of ice packs and alcohol baths. Controlled ventilation using a machine flushed free of anesthetic agent should also be instituted as soon as possible to remove excessive CO_2 and maintain normal blood pH and acid-base status. Dantrolene (a specific ryanodine receptor antagonist) has proved effective for treatment (1–3 mg/kg, IV) and prophylaxis (5 mg/kg, PO, up to 10 mg/kg) of MH. Animals with cardiac arrhythmias, such as tachycardia or severe premature ventricular contractions, can be treated with lidocaine (1–2 mg/kg, IV), if needed. Calcium chloride and calcium gluconate are not recommended. Hyperkalemia should be treated with controlled ventilation, and 50% dextrose (0.5 mL/kg, IV) and/or insulin (0.25–0.5 U/kg, IV) can be administered to promote movement of extracellular potassium into cells. Sodium bicarbonate (1–2 mEq/kg, IV) can be administered to maintain normal blood pH in the presence of metabolic acidosis. Balanced electrolyte solutions, 5% dextrose in water, and normal saline are acceptable for supportive fluid therapy; Ringer's lactate with added calcium should not be used. Dantrolene should be administered to affected animals. Testing for disseminated intravascular coagulation, which often results when body temperature exceeds 41°C (131.4°F), is prudent, as well as observation of the urine for myoglobinuric renal failure due to severe muscle damage. Affected animals should be closely monitored for signs of MH for 48–72 hr, because 25% may experience recrudescence.

TRANSPORT TETANY IN RUMINANTS

(Railroad disease, Railroad sickness, Staggers)

Transport tetany occurs after the stress of prolonged transport, typically in cows and ewes in late pregnancy, although it is also seen in lambs transported to feedlots and in cattle and sheep transported to slaughter. Crowded, hot, poorly ventilated transport vehicles (railroad cars or trailers) with minimal or no access to feed or water appear to predispose animals to the condition; however, prolonged travel by foot is also a risk factor. The disease is characterized by recumbency, GI stasis, and coma, and is generally fatal.

Although cows in late gestation are most commonly affected, the disease is also seen in cows that have recently calved, as well as in bulls, steers, and dry cows. Risk factors include heavy feeding before shipment, deprivation of feed and water for >24 hr during transit, and unrestricted access to water and exercise immediately after arrival. Exposure to hot environmental conditions is also associated with an increased incidence. Although the specific cause of tetany is unknown, the condition may be a form of acute hypocalcemia precipitated by late pregnancy and early lactation, or by fasting before or during transit. Physical stress is undoubtedly related. Hypomagnesemia may be a precipitating factor in cattle and a contributing factor in sheep.

Clinical signs in cattle may occur while in transit or as long as 48 hr after arrival. Early clinical signs include restlessness and excitement, trismus, and grinding of teeth. A staggering gait may be seen, and later, if recumbent, cattle often demonstrate paddling of the hindlegs. Rumen hypomotility and GI stasis are seen, and animals become completely anorectic. Tachycardia and rapid, labored respiration may develop. Abortion may be a complication. Cattle that do not recover gradually become more obtunded to the point of coma and die within 3–4 days. Moderate hypocalcemia and hypophosphatemia may be seen in cattle. Some sheep are hypocalcemic and

hypomagnesemic, but others show no measurable biochemical abnormalities. No specific lesions are found at necropsy other than lesions associated with prolonged recumbency, most commonly ischemic muscle necrosis. In lambs, early signs include restlessness, staggering, and partial hindlimb paralysis followed by lateral recumbency. Death can occur rapidly or after 2–3 days of recumbency. In lambs, mild hypocalcemia may be noted. Recovery rates are fair even with treatment. The relationship of clinical signs with transport or forced, prolonged exercise is diagnostic.

Some animals respond to treatment with combinations of parenteral calcium, magnesium, and glucose. IV injections of calcium borogluconate (25% solution at 400–800 mL/cow or 100 mL/ewe) or calcium borogluconate with magnesium sulfate (5% solution, same volumes) can be administered slowly. A dose of 50 mL/day can be given SC to affected lambs in feedlots. Repeated injections may be warranted, but failure to respond is common (50%) and most likely due to concurrent muscle necrosis. Additional treatment considerations include IV administration of large volumes of polyionic fluids such as lactated Ringer's solution. Animals should be offered good quality feeds (eg, alfalfa hay), fresh water, and soft bedding with good footing underneath. Sedation may be necessary if animals are hyperexcitable or convulsing.

If prolonged transport times of cows or ewes in advanced pregnancy is unavoidable, animals should be fed a restricted diet several days before shipment, then provided adequate feed, water, and rest periods during transport. Administration of ataractic agents (unless transport is to slaughter) such as promazine hydrochloride before loading is recommended, especially for nervous animals. Upon unloading at the destination, animals should be allowed limited access to water for the first 24 hr and minimal exercise for 2–3 days.

MUSCULOSKELETAL SYSTEM INTRODUCTION

The musculoskeletal system consists of bones, cartilage, muscles, ligaments, and tendons. Primary functions of the musculoskeletal system include support of the body, provision of motion, and protection of vital organs. The skeletal system serves as the main storage system for calcium and phosphorus and contains critical components of the hematopoietic system. Many other body systems, including the nervous, vascular, and integumentary systems, are interrelated, and disorders of one of these systems may also affect the musculoskeletal system and complicate diagnosis.

Diseases of the musculoskeletal system most often involve motion deficits, functional disorders, and lameness. The degree of impairment depends on the specific problem and its severity. Skeletal and articular disorders are by far the most common and have the greatest economic impact. In horses and dogs, musculoskeletal injuries are a major source of debilitating pain, economic loss, and loss of athleticism. Degenerative joint disease is much more common and has a greater economic importance than acute traumatic injuries or respiratory diseases in performance horses. Several studies estimate that problems involving the fetlock and carpal joints account for 25%–28% of horses lost from training. In addition, tendon injury is a common debilitating injury in performance horses. The healing response is prolonged, and the resultant repair tissue is usually of inferior mechanical strength. Consequently, the prognosis for return to previous levels of performance is poor. In dogs, cranial cruciate ligament injury with resulting osteoarthritis is the most common musculoskeletal injury resulting in lameness. Although perhaps less common, primary muscular diseases, neurologic deficits, toxins, endocrine aberrations, metabolic disorders, infectious diseases, blood and vascular disorders, nutritional imbalances or deficits, and occasionally congenital defects are diagnosed as well.

DISORDERS OF MUSCLE

The structural and functional unit of skeletal muscle is the motor unit. It consists of a ventral motor neuron with its cell body in the central horn of the spinal cord and its

peripheral axon, the neuromuscular junction, and the muscle fibers innervated by the neuron. Each of these components must be functionally intact for the muscle to contract properly. The ventral motor neuron is the final common pathway conducting neural impulses from the CNS to the muscle.

The transmission of a nerve impulse at the neuromuscular junction involves massive release of acetylcholine from small synaptic vessels, where it is stored. The acetylcholine fills the synaptic cleft between the nerve terminal and the muscle fiber membrane, where most of it is destroyed by cholinesterase within a fraction of a second. This short period of activity is sufficient to excite the muscle fiber membrane, which results in a significant increase in membrane permeability to sodium ions and allows rapid influx of sodium into the muscle fiber. The sodium ion increases the endplate potential, which elicits electrical currents that spread to the interior of the fibers, where they cause a release of calcium ions from the sarcoplasmic reticulum. The calcium ions initiate, in turn, the chemical events of the contractile process. When this occurs in all the muscle fibers innervated by each motor neuron (possibly thousands), muscle contraction results.

Normal muscle, comprising many motor units, is dynamic, and its function and structure can be influenced by many diseases. Complete paralysis, paresis, or ataxia may be caused by primary muscular dysfunctions of infectious, toxic, or congenital origin. However, in most instances the primary disorder can be attributed to the nervous system (eg, tetanus, rhinopneumonitis, canine distemper, protozoal myelitis), with the muscular system merely representing the effector organ. Disorders that affect the neuromuscular junction (eg, myasthenia gravis, hypocalcemia, hypermagnesemia) can result in muscle fatigue, weakness, and paralysis. The neuromuscular junction can also be affected by muscle-relaxing drugs (eg, curare, succinylcholine, M99), certain antibiotics, and toxins (eg, botulism, tetanus, venoms).

Disorders primarily of the muscle membrane and, to some extent, of the

actual muscle fibers are called myopathies. Muscle membrane disorders may be hereditary (eg, myotonia congenita in goats) or acquired (eg, vitamin E and selenium deficiencies, hypothyroidism, and hypokalemia). Myopathies involving the actual muscle fiber components include muscular dystrophy, polymyositis, eosinophilic myositis, white muscle disease, and exertional rhabdomyolysis. Various laboratory tests, eg, histopathologic examination, determination of serum enzyme levels, electromyographic studies, thermography, and determinations of conduction velocity, are very useful in confirmation of a specific diagnosis.

DISORDERS OF TENDONS

Tendons act as bridging and attachment structures for the muscles; some bridge long gaps between the muscle bellies and target bone and, therefore, are prone to injury themselves, especially because they are often loaded to the extreme and are only minimally capable of elastic elongation. A prime example is the superficial flexor tendon of horses, which is frequently injured by partial tearing that leads to tendinitis. Another acquired injury of tendons involves traumatic disruptions. Because of the relatively poor blood supply of both tendons and ligaments, healing is always prolonged with inelastic scar tissue, and the injured tendon never returns to its original strength. Therefore, management of tendon and ligament injuries requires patience with conservative long-term rehabilitation. Reinjury is common.

DISORDERS OF BONE

Bone diseases are generally congenital or hereditary, nutritional, or traumatic. Congenital disorders include in utero malformations and atavisms, such as polydactyly or persistent ulnae or fibulae in foals; examples of genetic defects are atlanto-occipital malformations in Arabian horses or certain cases of spinal ataxia (*see* p 1228), canine hip dysplasia, and abnormal bone formation such as that caused by parathyroid hypoplasia.

Bone defects due to nutrition are caused primarily by imbalances or deficiencies in minerals, particularly the trace minerals such as copper, zinc, and magnesium. Calcium and phosphorus concentrations must also be present in the correct ratio. Osteomalacia represents the classic example of imbalanced or deficient calcium and phosphorus intake. Other nutritional

disorders are caused by excessive protein intake of growing animals. Either deficiency or excess intake of certain vitamins, particularly vitamins A and D, may influence growth and development of bone. Aseptic physisitis or special osteochondrotic conditions of the physes may be caused by zinc toxicity or copper deficiency.

Traumatic causes of bone disorders represent the vast majority of cases and include fractures, fissures, periosteal reactions as a result of trauma, sequestrum formation, and insertion desmopathies or tendinopathies, respectively. Lack of weight bearing, lameness, reduced motion, instability, pain, heat, or swelling usually accompany these disorders.

DISORDERS OF JOINTS

Articulations are divided into synarthrodial joints and diarthrodial joints. Synarthrodial joints are osseous components united by fibrous tissue or cartilage. Synarthrodial joints are practically immovable and are rarely associated with joint disease other than fractures. Diarthrodial joints are mobile; the opposing bone ends are covered by articular hyaline cartilage and are separated by a joint cavity filled with synovial fluid. Articular cartilage serves to distribute weight-bearing forces and to minimize friction between adjacent skeletal components during movement. Normal synovial fluid and articular cartilage express a glycoprotein to provide boundary lubrication to the articular cartilage and synovial membrane during weight bearing. The synovial fluid also nourishes the articular cartilage.

Diarthrodial joints are most frequently involved in pathologic changes. These changes can involve the joint capsule, synovial membrane, hyaline articular cartilage, and subchondral bone. Damage to intra-articular ligaments and the menisci in the stifle joint can affect the stability of the joint and propagate damage to the joint. Joint disorders may be caused by trauma, chronic inflammation, developmental factors, or infections. Severe trauma frequently results in luxation, subluxation, fracture, or instability of a joint. Direct penetration of the joint capsule may also lead to septic arthritis, which is characterized by an increase in synovial WBCs resulting in an increased concentration of proteolytic enzymes within the synovial fluid. The severe inflammatory response within the joint can quickly lead to breakdown of the articular hyaline cartilage. Bacterial and fungal infections

involving synovial structures are typically recognized based on their extreme heat, swelling, pain localized to the joint, and lameness that is often severe. All cases of synovial sepsis require immediate and aggressive treatment to preserve the joint.

Developmental defects include osteochondritis dissecans, equine ataxia, angular limb deformities, and lumbar disc syndrome in certain breeds of dogs. Extension of physisitis into the adjacent joint and damage due to continuous abnormal weight bearing in animals with angular limb deformities are other inciting causes of joint disease.

Chronic inflammation of joints and surrounding structures is most common in articulations associated with locomotion. Joint homeostasis involves the simultaneous synthesis and degradation of extracellular matrix components of the cartilage. The responses of the synovial membrane and articular cartilage are critical to accommodate the mechanical and chemical demands placed on the joint. In pathologic conditions, the biosynthetic activity of the cells does not compensate for the loss of matrix components through mechanical and enzymatic degradation. This results in a net loss of cartilage and compromised joint function.

Osteoarthritis is a degenerative, progressive disease of diarthrodial joints. It has a multifactorial etiology; aging, trauma, mechanical forces, conformation, hormonal, and genetic factors contribute to varying degrees. It is a major cause of musculoskeletal pain, morbidity, and decreased performance in all species. Although pathologic changes occur in multiple joint tissues, loss of articular cartilage is the hallmark of the disease.

Cartilage damage is recognized clinically when sufficient joint damage occurs to cause synovitis or lameness. As damage accumulates, cartilage fibrillation or complete eburnation can occur at areas of high stress. Histologically there is loss of proteoglycan staining, decreased cell viability, and advancement of the tidemark of calcified cartilage. The loss of proteoglycans is accompanied by an increase in cartilage matrix water content and a reduction in stiffness. The biomechanically compromised cartilage is more susceptible to further damage.

Corticosteroids and NSAIDs have been widely used for symptomatic treatment of osteoarthritis. The benefit of these drugs is minimized in extensive cartilage loss in which chondrocyte replacement is an issue, and their inappropriate use may exacerbate the progression of degenerative change.

Several medications have specific chondroprotective actions to treat articular cartilage damage. Structure-modifying osteoarthritides drugs (eg, glycosaminoglycans, pentosan polysulfate, hyaluronic acids) slow down the progression of osteoarthritis by mitigating the rate of cartilage degradation and enhancing matrix synthesis. Intra-articular hyaluronic acid administration reduces synovial inflammatory effects and may also reestablish boundary lubrication within the joint cavity. The autogenous substance interleukin receptor antagonist protein (IRAP) has been used effectively to control joint inflammation in some horses.

DIAGNOSIS AND TREATMENT OF MUSCULOSKELETAL DISORDERS

In all cases of musculoskeletal pain and lameness, diagnostic procedures to determine the nature, extent, and exact location of the injury must be performed. Evaluation of the source of pain and lameness always starts with a thorough history, inspection, and physical examination to look for sources of heat, swelling, and pain on manual palpation. Hoof testers should be applied to determine whether pain is present within the hoof capsule. Next, the gait and locomotion of the animal are evaluated. In a weight-bearing lameness, the lame leg always bears less weight and often has a shorter duration of bearing weight. In swinging leg lameness, the lame leg abducts or adducts to avoid flexion of a painful joint. These findings can be measured objectively using a force plate or a gait analysis system. In horses, flexion tests of joints followed immediately by lameness evaluation at a trot may help localize pain. After determining which limb is lame, diagnostic analgesia (intra-articular or perineural) can be used to localize the painful gait to a specific anatomic structure or a region of the affected limb. After localization, diagnostic imaging techniques can be performed to evaluate the soft-tissue structures and bones. These diagnostic procedures include radiography, ultrasonography, MRI, CT, nuclear imaging, and thermography. When joint sepsis is suspected, synovial fluid analysis of affected joints is necessary for diagnosis. After these procedures, a diagnosis can be made, treatment instituted, and a prognosis given based on the diagnosis, extent of disease, and expected response to therapy.

Therapeutic options for diseases of the musculoskeletal system include rest,

restricted or modified activity, immobilization of diseased or injured structures in splints and casts, NSAIDs, corticosteroid administration, physical therapy, acupuncture, extracorporeal shock wave therapy, and surgical repair. Therapeutic options for management of musculoskeletal disorders have greatly expanded

during the past few years with the use of regenerative medicine, in which growth factors and mesenchymal cell therapy have been used to augment healing. A return to a useful life for many animals is possible when diagnosis and subsequent treatment is done early in the disease process.

CONGENITAL AND INHERITED ANOMALIES OF THE MUSCULOSKELETAL SYSTEM

Congenital and inherited anomalies can result in the birth of diseased or deformed neonates. Congenital disorders can be due to viral infections of the fetus or to ingestion of toxic plants by the dam at certain stages of gestation. The musculoskeletal system can also be affected by certain congenital neurologic disorders.

MULTIPLE SPECIES

Contracted Flexor Tendons

Contracted flexor tendons are probably the most prevalent abnormality of the musculoskeletal system of newborn foals and calves. An autosomal recessive gene causes this condition. In utero positioning may also affect the degree of disability.

At birth, the pastern and fetlocks of the forelegs and sometimes the carpal joints are flexed to varying degrees due to shortening of the deep and superficial digital flexors and associated muscles. A cleft palate may accompany this condition in some breeds. Slightly affected animals bear weight on the soles of the feet and walk on their toes. More severely affected animals walk on the dorsal surface of the pastern and fetlock joint. If not treated, the dorsal surfaces of these joints become damaged, and suppurative arthritis develops. Rupture of the common digital extensor can occur as a sequela. This condition should be differentiated from arthrogryposis.

Mildly affected animals recover without treatment. In moderate cases, oxytetracycline may be administered to relax the flexor muscles, and a splint can be applied to force the animal to bear weight on its toes. The pressure from the splint must not compromise the circulation, or the foot may undergo ischemic necrosis. Frequent manual extension of the joints, attempting

to stretch the ligaments, tendons, and muscles, helps treat these intermediate cases. Severe cases require tenotomy of one or both flexor tendons. A bandage cast may sometimes be indicated. Extreme cases may not respond to any treatment.

Dyschondroplasia

Dyschondroplasia of genetic origin is seen in most breeds of cattle. The forms range from the so-called Dexter "bulldog" lethal,

Ruptured common digital flexor tendon as a sequela of contracted flexor tendons in a foal. Courtesy of Dr. Reid Hanson.

in which the calf is invariably stillborn, to mildly affected animals.

The **brachycephalic dwarfs** common in Hereford cattle in the 1950s largely have been eliminated through genetic selection. Short faces, bulging foreheads, prognathism, cleft palate, large abdomens, and short legs are characteristic. They are approximately half normal size. The **dolichocephalic dwarf**, most commonly seen in Angus cattle, is of the same general body conformation as the brachycephalic dwarf, except that it has a long head and does not have either a bulging forehead or prognathism. The short-faced calves are frequently referred to as "snorter" dwarfs because of their labored and audible breathing. Both types are of low viability and susceptible to bloat. Their carcasses are undesirable, and they are rarely kept except for research purposes.

Dyschondroplasia of the appendicular and axial skeletons also is seen in dogs. The former is reported in Poodles and Scottish Terriers, the latter in Alaskan Malamutes, Basset Hounds, Dachshunds, Poodles, and Scottish Terriers. In some breeds (Bassetts, Dachshunds, Pekingese), the appendicular dyschondroplastic characteristics are an important feature of breed type. In Malamutes, the condition is accompanied by anemia.

Dystrophy-like Myopathies

Numerous examples of progressive myopathies have been described in animals; many are heritable, and many resemble various types of muscular dystrophy in people. Affected muscles have a variety of degenerative and atrophic changes. In Meuse-Rhine-Yssel cattle of Holland, a progressive fatal myopathy of the diaphragm and intercostal muscles has been described. Another dystrophy in cattle is weaver syndrome in Brown Swiss. Hyperplasia, commonly called double muscling (see p 1045), is a congenital myopathy found in some European breeds of cattle. Progressive myopathies have been reported in Merino sheep in Australia (an inherited autosomal recessive), in Pietrain pigs (Pietrain creeper syndrome), and in dogs, cats, chickens, turkeys, and mink. Inherited muscular dystrophy of mice and hamsters has been studied extensively; the hamsters have severe myocardial lesions and serve as a model for studies of cardiomyopathy.

Several types of muscular dystrophy are seen in dogs. An X-linked Duchenne-like muscular dystrophy is reported in Golden Retrievers in the USA and in Irish Terriers in

Europe. Affected dogs, generally males, develop progressive muscular weakness, dysphagia, stiffness of gait, and muscular atrophy. Microscopically, the distinctive change is lack of dystrophin, a protein concentrated in the sarcolemma and essential for normal membrane function. Some dogs die with accompanying cardiomyopathy. A similar X-linked dystrophy with a lack of dystrophin is described in cats. A second type of dystrophy involves Labrador Retrievers in North America, Europe, and Australia. Clinical signs, which include stiffness, exercise intolerance, and muscular atrophy, develop by 6 mo of age. Autosomal recessive inheritance is implicated. A further dystrophy was described in dysphagic Bouviers in Europe.

Glycogen Storage Disease

(Glycogenosis)

Glycogen storage disease (GSD) is the result of defects in the processing of glycogen synthesis or breakdown within muscles, liver, and other cell types. GSD can be genetic or acquired. Genetic GSD is caused by an inborn error of metabolism (genetically defective enzymes) involved in these processes. In livestock, acquired GSD is caused by intoxication with the alkaloid castanospermine. Progressive muscular weakness and inability to rise properly may be seen in animals with GSDs. Five of the 11 types of GSDs characterized in people have been identified in animals (types I, II, III, VII, and VIII). Affected species include cattle, sheep, dogs, cats, horses, Japanese quail, rats, and mice. Type II glycogenosis in Shorthorn and Brahman cattle has been well documented and is inherited as an autosomal recessive disorder. Affected cattle develop muscular weakness and die at 9–16 mo of age, often with accompanying cardiomegaly and congestive heart failure. Morphologic and biochemical study reveals extensive intralysosomal and cytoplasmic glycogen deposits. Corriedale sheep and Lapland dogs also develop type II glycogenosis.

Myophosphorylase deficiency (type V glycogenosis) is an autosomal recessive disorder in Charolais cattle. Affected cattle show exercise intolerance and may have increased serum activities of skeletal muscle–origin enzymes.

Muscular Steatosis

Muscular steatosis is a condition in which muscle fibers have been replaced by fatty deposits and is seen occasionally in cattle,

sheep, and pigs at slaughter. Sometimes the occurrence of muscular steatosis is indicated before slaughter by an abnormal gait, but usually the condition is not found until a carcass is butchered. The condition may be difficult to establish, and it is often only the restriction of muscular steatosis to a single muscle group in an otherwise poorly marbled carcass that makes it conspicuous. In pigs, there is evidence that the onset of muscular steatosis is accompanied by lipid accumulation in muscle fibers. No clinical disease results, and the cause is unknown. The gross lesions are symmetric, pale areas in affected muscles, especially of the back, neck, and upper limbs. Microscopically, many muscle fibers are replaced by fat cells.

Myopathy Associated with Congenital Articular Rigidity

(Arthrogryposis)

This syndrome, one of the more common congenital defects of calves, is characterized by rigid fixation of the limbs in abnormal postures; it often produces dystocia. The muscle weakness and imbalance of muscle power around the joints elicits a physiologic compensatory collagenic response, which replaces atrophied muscle fibers with connective tissue and thickens the joint capsule sufficiently to result in prenatal fixation of limb segments at the joint.

Affected animals may have other anomalies, including hydrocephalus, palatoschisis, and spinal dysraphism. The condition may be lethal, but some mildly affected animals recover completely. The muscle lesions may be primary in some types of the disease, but the neural lesions generally are primary, and the muscular alterations represent denervation atrophy. Congenital articular rigidity is seen in cattle, sheep, horses, and pigs. Numerous etiologic factors have been recognized. In cattle, these include viral (Akabane virus [see p 620], bluetongue virus [see p 738]) and plant (*Lupinus* sp, see p 3018) teratogens, and a heritable recessive trait in Charolais (see ARTHROGRYPOSIS, p 1045). In sheep, plant (locoweed) and viral (Akabane, Wesselsbron [see p 775] teratogens, Rift Valley fever [see p 768]), parabenzazole exposure, and inherited autosomal recessive primary myopathies of Merino and Welsh Mountain lambs may cause congenital articular rigidity. In pigs, the condition may be inherited as an autosomal recessive, or result from deficiency of vitamin A or manganese or from exposure of pregnant sows to plant toxins (eg, tobacco, thornapple, hemlock, and black cherry).

Osteochondrosis

Osteochondrosis is a disturbance in endochondral ossification that is sometimes classified as dyschondroplasia. The immature articular cartilage may separate from the underlying epiphyseal bone, which sometimes dissects completely free and floats loose in the synovial cavity, resulting in accompanying synovitis or the retention of pyramidal cores of physal cartilage projecting into the metaphysis. Often, these two lesions are seen simultaneously in the same bone. The disease develops during maximal growth when the biomechanical stresses are greatest in the immature skeleton (4–8 mo in dogs, 80–120 lb [36–54 kg] in pigs). It is most common in large and giant breeds of dogs (see p 1195) and in rapidly growing pigs (see p 1161), horses (see p 1148), turkeys, and chickens (see p 2932).

Osteogenesis Imperfecta

Osteogenesis imperfecta is a generalized, inherited bone defect in cattle, dogs, and cats, characterized by extreme fragility of bones and joint laxity attributable to any of a large number of possible mutations of type I collagen. The mechanical properties of the “soft” part of the collagen/mineral composite in the bone appear to be altered. The long bones are slender and have thin cortices. Calluses and recent fractures may be present. The sclera of the eyes may be bluish. The inheritance is most likely polygenic.

Osteopetrosis

Osteopetrosis is a metabolic bone disease characterized by a systemic increase in skeletal mass. It is a rare disease that appears to be inherited as a simple autosomal recessive trait in Angus, Simmental, Dutch Holstein-Friesian and Hereford cattle. It is also seen in dogs and foals. It is characterized by premature stillbirth 10 days to 1 mo before term, brachygnathia inferior, impacted molar teeth, and easily fractured long bones. Bone marrow cavities are absent and replaced by primary spongiosa. The fetal-like abnormal intramedullary bone consists of chondroosseous tissue. Foramina of the skull and long bones are hypoplastic or aplastic. The cranium is thickened and compresses the brain. Extensive mineralization is present in vessel walls and neurons of the brain. Diagnosis is confirmed by a longitudinal bisection of long bones revealing the diaphyses filled with a plug of bone instead of marrow.

Syndactyly and Polydactyly

Syndactyly, or mule foot, is the partial or complete fusion of the digits of one or more feet. Reported in numerous cattle breeds, it is most prevalent in Holsteins and is inherited as a simple autosomal recessive condition. The forefeet are affected most often, but one or all four feet may be affected. Animals affected with syndactyly walk slowly, usually have a high-stepping gait, and may be more prone to hyperthermia.

Polydactyly is a genetic defect of cattle, sheep, pigs, and occasionally horses. In its most common form, the second digit is developed but the medial dewclaw is missing. The toes may be fused to give rise to polysyndactyly. Rarely one or all four limbs have the condition. Polydactyly in cattle appears to be polygenic, with a dominant gene at one locus and a homozygous recessive at another.

CATTLE

Arthrogryposis

Arthrogryposis is ankylosis of the limbs, usually combined with a cleft palate and other growth deformities. It is seen in all breeds of cattle, particularly Charolais. At birth, affected calves exhibit joints fixed in abnormal positions and frequently have scoliosis and kyphosis. They are usually unable to stand or nurse. Muscle changes, notably atrophy, have also been seen. In the spinal cord, necrosis of neurons and lesions of the white matter may be seen. Arthrogryposis has more than one etiology and pathologic entity. The arthrogryposis syndrome in Charolais is caused by an autosomal recessive gene with complete penetrance in the homozygous state. Teratogens identified as causing arthrogryposis include plants such as lupines (anagryne as the toxic agent) that are ingested by pregnant cows between day 40 and 70 of gestation. Prenatal viral infections with the Akabane (*see* p 620) or bluetongue (*see* p 738) virus can also cause arthrogryposis.

Brown Atrophy

(Xanthosis, Lipofuscinosis)

In dairy cattle with brown atrophy, the skeletal muscles and myocardium are yellow-brown to bronze. The masseter muscles and the diaphragm are affected most frequently. No clinical disease results. Certain breeds (eg, Ayrshire) are more predisposed than others. Microscopically,

brown lipofuscin pigment granules accumulate under the sarcolemma or centrally in the muscle fibers. The inheritance pattern of one affected and three normal offspring suggests that this condition may result from inheritance of a simple recessive gene.

Double Muscling

Double muscling is an overdevelopment of the musculature of the shoulder, back, rump, and hindquarters, separated by deep creases, particularly between the semitendinosus and biceps femoris, and between the longissimus dorsi muscles of either side. Necks of double-muscled cattle are shorter and thicker, and their heads appear smaller. Associated disorders include hypoplastic reproductive tracts, delayed reproductive age of maturity, and lengthened gestation and increased birth weights combined with dystocia. The condition is seen in various beef breeds, including Charolais, Santa Gertrudis, South Devon, Angus, Belgian Blue, Belgian White, and Piedmontese. Double muscling is caused by a pair of incompletely recessive genes that result in the inhibition of myostatin activity in various degrees of the condition. Succinic dehydrogenase activity is significantly decreased in affected calves.

Limber Leg

Limber leg is a hereditary condition of Jersey cattle, apparently controlled by a simple lethal autosomal recessive gene. Some affected calves are born dead. Living calves appear normal at birth but are unable to stand because of incompletely formed muscles, ligaments, tendons, and joints. The shoulder and hip joints can be rotated in any direction without apparent discomfort. Diagnosis is based on signs, necropsy findings, and identification of carrier animals.

Perosomus Elumbis

Perosomus elumbis is an occasionally found congenital anomaly of unknown etiology that is characterized by partial or complete agenesis of the lumbar, sacral, and coccygeal area and accompanied by posterior bimelic arthrogryposis characterized by ankylosis of joints with associated malformations of the musculature. Affected calves cannot use their hindlegs and must be euthanized. The defect is suspected to be inherited. A reduced number of vertebrae has been reported rarely but also has been claimed to be a genetic defect. The condition has also been reported in sheep and pigs.

Spine Defects

There are several defects of the spinal column that include short spine lethal, atlanto-occipital fusion, kyphosis (dorsal arching of the back), lordosis (ventral), scoliosis (lateral), and torticollis (twisted). These defects may occur alone, in combination with, or associated with defects of other body systems, particularly of the CNS.

HORSES

Angular Limb Deformities

In these congenital or acquired skeletal defects, the distal portion of a limb deviates laterally or medially early in neonatal life. In utero malposition, hypothyroidism, trauma, poor conformation, excessive joint laxity, and defective endochondral ossification of the carpal or tarsal and long bones have been implicated. One to four limbs may be affected, depending on the severity of the condition.

The carpus is affected most frequently, but the tarsus and fetlocks are occasionally involved. The deviation is obvious but varies in severity. A lateral deviation (valgus) of up to 6° of the distal portion of a limb may be regarded as normal. Most foals are asymptomatic, but lameness and soft-tissue swelling can accompany severe deviations. Outward rotation of the fetlocks invariably accompanies carpal valgus. Foals with defective ossification of the carpal cuboidal bones or excessive joint laxity are frequently lame as the legs become progressively deviated. Affected limbs must be palpated carefully to detect ligament laxity and specific areas that may be painful.

Diagnosis should include a precise determination of the site and cause for the deviation. The distal radial metaphysis, physis, epiphysis, or cuboidal bones may be the site of deviation. Radiography helps detect physal flaring, epiphyseal wedging, and deformation of carpal bones. Mildly affected foals frequently improve spontaneously.

Treatment depends on the severity of the condition and tissues affected. Excessive joint laxity, with or without cuboidal carpal bone involvement, requires tube casts or splints. The fetlock and phalangeal region should not be included in the casts, which should protect the weak joint from trauma but allow restricted exercise to maintain tendon and ligament tone. Such limb support may be required for as long as 6 wk.

Physal and epiphyseal growth disturbances are also amenable to surgical correction through hemircumferential

transection and periosteal elevation of the distal radius on the concave side of the defect or through transphysal bridging of the physis on the convex side. These surgeries must be performed before the physal growth plates close (as early as 2–4 mo of age for fetlocks), and success depends on continued growth and development of the bones. Sequential examinations and radiographs are necessary to follow spontaneous improvement or to establish a need for surgery.

Without treatment, the prognosis for severe carpal valgus is poor. The conformational anomaly leads to early degenerative joint disease. Likewise, deformity of the cuboidal carpal bones contributes to a poor prognosis. However, with early detection, careful evaluation, and proper surgical treatment, most foals respond favorably.

Digit Malformation

Digital malformations include supernumerary digits (polydactyly), hypoplasia of phalanges, such as the navicular bone, and bipartite and tripartite navicular bone in which there is incomplete ossification of the navicular bone.

Dwarfism

Dwarfism is the lack of appropriate growth, resulting in a smaller horse. A dwarf horse can be proportionate or disproportionate. Proportionate dwarfs are a result of a deficiency in growth hormone, whereas disproportionate dwarfs are a result of abnormal thyroid hormone levels. The latter results in a foal with musculoskeletal immaturity, characterized by delayed cuboidal bone development, a large head, silky hair coat, floppy ears, and mandibular brachygnathia. Determination and interpretation of either growth hormone assays or thyroid hormone function is not entirely developed or understood in horses, hence the importance of clinical diagnosis. Efforts toward characterizing thyroid function and growth hormone levels should be undertaken to prevent overdiagnosis of this condition. A nitrate toxicity theory has been confirmed in certain foals born with “congenital hypothyroid syndrome.”

Glycogen Branching Enzyme Deficiency

Glycogen branching enzyme (GBE) deficiency may be a common cause of neonatal mortality in Quarter horses and related breeds that is obscured by the variety of clinical signs that resemble other equine

neonatal diseases. Affected foals lack the enzyme necessary to store glycogen in its branched form and therefore cannot store sugar molecules. The disease is fatal; heart muscle, brain, and skeletal muscles are unable to function. Clinical signs of GBE deficiency may include transient flexural limb deformities, stillbirth, seizures, respiratory or cardiac failure, and persistent recumbency. Leukopenia, high serum CK, AST, and γ -glutamyl transferase are present in most affected foals. Gross postmortem lesions are inconclusive. Muscle, heart, or liver samples contain abnormal periodic acid-Schiff-positive globular or crystalline intracellular inclusions in amounts proportional to the foal's age at death. Accumulation of an unbranched polysaccharide in tissues is suggested by a shift in the iodine absorption spectra of polysaccharide isolated from the liver and muscle of affected foals. Skeletal muscle total polysaccharide concentrations are reduced, but liver and cardiac muscle glycogen concentrations are normal. Several glycolytic enzyme activities are normal, whereas GBE activity is virtually absent in cardiac and skeletal muscle, as well as in liver and peripheral blood cells. GBE activities in peripheral blood cells of dams of affected foals and several of their half-siblings or full siblings are ~50% of controls. GBE protein in liver is markedly reduced to absent in affected foals. Pedigree analysis supports an autosomal recessive mode of inheritance.

Hernias

Hernias are defects in the muscle wall that permit intestines/organs to move into an abnormal location. An umbilical hernia is the incomplete closure of the abdominal wall at the umbilicus. Larger umbilical hernias should be surgically repaired to prevent incarceration of bowel. A congenital diaphragmatic hernia is an opening in the thoracic diaphragm, permitting the displacement of abdominal organs into the thorax. These hernias usually go undetected until the horse is presented for GI signs (colic) rather than respiratory issues. Inguinal hernias are commonly seen in certain breeds, particularly Standardbred and draft horses. They are most common in male foals, and a large scrotal sac is seen. Affected horses rarely present with signs of colic. The hernia should be reduced on a daily basis, and most cases will resolve in 4–6 mo. In cases presented with signs of colic or when there is edema in the inguinal/ventral area (ruptured hernia), surgical repair is advised.

Hyperkalemic Periodic Paralysis

Hyperkalemic periodic paralysis (HYPP) is marked by sudden attacks of paralysis which, in severe cases, may lead to collapse and sudden death. It is an inherited missense mutation in the gene encoding the alpha chain of the adult skeletal muscle sodium channel, resulting in increased sodium permeability across the skeletal muscle cell membrane. Quarter horse, Paint horse, and Appaloosa progeny tracing back to the Quarter horse sire "Impressive" can be affected with this disease and must be eliminated from any reproductive program. Most affected horses are heterozygotes. A sequela of HYPP in horses that undergo general anesthesia is malignant hyperthermia syndrome (*see* p 1027).

Spine Defects

Skeletal malformations include scoliosis (lateral deviation of the back), synostosis (fusion of vertebrae), lordosis (ventral dorsal deviation of the back), kyphosis (dorsal deviation of the back), torticollis (twisted neck), and wry nose (twisted nose). Although all of these conditions are uncommon in foals, congenital scoliosis is encountered most frequently. On clinical examination, it is often difficult to assess the severity. A better appreciation of the condition can be obtained by radiographic examination. In mild cases, improvement is spontaneous and may be complete. Even in the more severe cases, there is rarely any obvious abnormality in gait or maneuverability. However, these foals frequently are not raised because they appear unlikely to be able to withstand being ridden or worked.

Another occasional congenital deformity is that of synostosis (fusion of vertebrae), which may be associated with secondary scoliosis. Radiography is necessary for confirmation.

Congenital lordosis (swayback) is associated with hypoplasia of the intervertebral articular processes. In adult horses, degrees of acquired lordosis and kyphosis (roachback) are occasionally seen, which contribute to back weakness. Diagnosis is based on the clinical appearance and can be confirmed by radiography, which reveals an undue curvature of the vertebral column, usually in the cranial thoracic region (T5–10) in lordosis and in the cranial lumbar region (L1–3) in kyphosis.

Other, less common skeletal malformations include incomplete closures of the bony spinal canal (cervical meningocele, spina bifida) and hydrocephalus (abnormal accumulation of fluid in the cranial vault with resultant enlargement of the head).

Tying-up Syndrome

(Equine rhabdomyolysis syndrome, Exertional rhabdomyolysis, Myoglobinuria)

See also p 1178. Tying-up syndrome in Thoroughbreds is an inherited abnormality in the way calcium is regulated by membrane systems in the skeletal muscle. The narrow genetic origin of Thoroughbreds and the common lineage of the pedigrees of horses with tying-up would support the possibility of an inherited trait. The disease might lie dormant unless specific factors trigger the calcium regulatory system to malfunction. Initiating events include stress, excitement, lameness, high-grain diets, and exercise at submaximal speeds.

A different form of tying-up is **polysaccharide storage myopathy** (PSSM). It is characterized by the accumulation of glycogen polysaccharides in skeletal muscle. The recent identification of a genetic mutation for PSSM revealed that there are actually no less than two forms of this disease. A form of PSSM called type 1 PSSM is caused by a mutation in the glycogen synthase gene. Type 1 PSSM occurs in many Quarter horses and related breeds, draft breeds, some Warmblood breeds, and several other breeds. It has not been identified in Thoroughbreds to date. This mutation causes the muscle to continually make glycogen. Consequently, when beginning exercise, horses have trouble switching over to burn glycogen for energy rather than storing glycogen in their muscles. Affected horses develop stiffness, muscle cramping, and soreness with light exercise probably due to a deficit of energy generation in their muscles. Some horses with this disorder also have an increased sensitivity to insulin, further increasing storage of glycogen in the muscle. PSSM type 1 horses are often calm, sedate horses that tie-up after a lay-up, especially when fed grain. They tend to be found in disciplines such as halter and pleasure horse performance and do not usually perform well at speed.

Type 2 PSSM has a slightly different microscopic appearance, and the genetic cause is yet unknown. It occurs in Quarter horse-related breeds, Warmbloods, and likely other light horse breeds, possibly including Thoroughbreds. Whereas type 1 PSSM can be diagnosed by a DNA-based blood or hair root test, type 2 PSSM requires examination of a muscle biopsy. Treatment of both forms of PSSM involves supplying horses with an alternative source of energy such as fat rather than sugar. Eliminating

grain and sweet feed completely and feeding fats such as rice bran or vegetable oils stabilizes blood sugar and provides fat for energy metabolism. It is essential that horses with PSSM be turned out as much as possible and exercised often, even if only for 10 min/day. Horses with mild to moderate clinical signs might be able to return to full athletic performance with careful dietary and management changes, which include regular daily exercise without extended periods of inactivity. Breeding horses with PSSM has at least a 50% chance of passing the trait on to offspring.

SHEEP

Spider Lamb Syndrome

Hereditary chondrodysplasia, or spider lamb syndrome, is an inherited, semilethal, musculoskeletal disease affecting lambs primarily of Suffolk or Hampshire breeds. Because the syndrome is a recessive genetic disorder, a lamb is afflicted only if both parents pass on the mutation. Thus, it is critical to identify carriers, which are structurally normal animals with only one copy of the mutation. The location of the locus causing spider lamb syndrome is along the distal end of ovine chromosome 6. This mutation causes an inactivation of normal fibroblast growth factor receptor 3, which produces skeletal overgrowth in animals homozygous for the gene. Lambs have pronounced medial deviation of the carpus and hock and are unable to stand without distress. Pathologic changes in the skull reveal a rounding of the dorsal silhouette, producing a "Roman nose" appearance and a narrowed elongation of the occipital condyles. The thoracic and lumbar vertebrae are moderately kyphotic, which causes a dorsal rounding of the backline. The sternbrae are dorsally deviated, leading to a flattening of the sternum. The forelimbs have a medial deviation of the carpal joints with a bowed radius and ulna and irregular thickening of the growth plate cartilage. The hindlimbs have medially deviated hocks and bowed tibiae, which also have thickened, irregular growth plates. Muscle atrophy is also predominant. The regulation of liver insulin-like growth factor (IGF) and IGF-binding proteins may be involved in the physical manifestations of this disorder. It is suggested that the condition is inherited in a simple autosomal recessive pattern.

PIGS

Splayleg

(Spraddleleg, Myofibrillar hypoplasia)

In splayleg, a condition of neonatal pigs, the hindlegs are spread apart or extended forward because of weakness of the adductor muscles relative to the abductors. The condition is seen at or soon after birth and can present in a number of forms. In the "stars" form, both sets of limbs are splayed out sideways, such that the pig cannot stand and can move about only by crawling or shuffling. The most common form of the condition is hindleg splays; the back legs splay out sideways and forward, causing the pig great difficulty in standing on its hind end. Many will "dog sit" and shuffle around on their backsides. This can lead to considerable skin trauma and secondary infection. Front leg splays also occur. The hindlimbs work normally, but the front legs splay out sideways such that the pig moves around with its chin on the ground. Such pigs have great difficulty nursing, and mortality levels are high. The incidence of splayleg is greater in the Landrace than in other breeds.

Histologically, there is a continuous gradation in myofibrillar content between normal and severely affected muscles. Myofibrils in affected fibers are scanty and small in cross section. No other morphologic or histochemical abnormalities have been detected. The cause of the condition remains obscure. Newborn piglets of hybrid stock tested for defects of neuromuscular transmission by stimulation electromyography reveal that congenital myofibrillar hypoplasia is not primarily a myasthenia-like syndrome, but that either excitation-contraction coupling or the contractile mechanism itself is primarily affected.

Selection for increased litter size indirectly increases the genetic potential for sows to create a uterine environment more likely to produce litters with splayleg pigs and should be treated as a trait of the sow, rather than of the individual pig. Affected pigs are susceptible to overlaying, starvation, and chilling because of poor mobility. Mortality may reach 50%. Genetic influence has been demonstrated. There are significant differences in the incidence among litters of different sires and breeds. It is seen more frequently in males than females and in pigs of lower birth weight. The syndrome also may be produced if glucocorticoids are administered during pregnancy, and it appears possible that

stress-sensitivity of the heavily muscled parent(s) may be a contributing factor. However, any cause of stretching of the adductor muscles increases the incidence. Stretching can result from slippery or sloping floors, struggling while legs are caught in cracks in the floor, or as the result of damage to nerve pathways from intrauterine viral infections. Mycotoxins have been suggested to play a role in some cases. The general nutrition of the sow (choline, methionine, and vitamin E levels) may influence the incidence, but benefits from feeding supplements to sows is questionable.

The clinical signs are distinctive. In utero infections with hemagglutinating encephalitis virus, enteroviruses, other viruses, and postpartum bacterial meningeal infection and trauma should be considered. The affected muscles are generally hypoplastic, and the small muscle fibers contain few myofibrils, as would be found in muscles of normal fetuses nearing parturition. Frequently affected muscles include the semitendinosus, longissimus dorsi, and triceps.

Dry, nonslippery floors should be provided, with no cracks in which the legs can become trapped, especially for the first 2 days. Pigs should be protected from injury by the sow, and adequate suckling should be ensured. In affected piglets, the hindlegs should be secured together above the hocks with a loose "figure 8" of adhesive tape for 2-4 days. Appropriately treated pigs usually recover within a week, although few recover if the front legs are also affected. Glucocorticoids should not be administered late in gestation. Highly susceptible blood lines should be eliminated.

SMALL ANIMALS

Apodia

Few reports of apodia have appeared in the literature. It is likely that this condition occurs more frequently than is documented, but affected animals probably either die, are euthanized by breeders without being brought to a veterinarian, or are just not reported. Congenital absence of the forearm or hand is a relatively common abnormality in people. Most defects are transverse (amelia) and unilateral. Lower limb deformities are less common and also usually unilateral. No familial tendencies have been seen, and intrauterine amputation by amniotic bands is thought to be a common cause of amelia. Longitudinal limb

deficiency, or hemimelia, probably results from defective development of the embryonic limb bud.

Few cases of hemimelia in dogs and cats have been reported. Radial agenesis appears to be the most common of these defects. Affected animals have medially directed angular deformities of the affected limbs. There may be complete or partial agenesis of either one or both radii with a compensatory increase in the diameter of the ulna. Tibial agenesis is less common. The fibulae are markedly enlarged in affected animals.

Ectrodactyly Syndrome

Maldevelopment of the central rays of the limbs may produce longitudinal splitting of the extremities. Split hand or foot may be sporadic, but autosomal dominant and recessive forms of this condition, sometimes termed the "lobster claw" defect, have been described. The defect also occurs as part of several syndromes. Splitting is most common between the first and second metacarpals, although all variations have been seen. Other abnormalities associated with this defect include digit contractures, digit aplasia, and metacarpal hypoplasia and

fusion. No breed or sex predilection has been noted. Studies of this defect in cats indicate that it is inherited as an autosomal dominant with variable expressivity.

Polydactyly

In dogs and cats, preaxial polydactyly is by far the more common form (an additional digit or digits on the medial side of the paw). In cats, it is inherited as an autosomal dominant trait with variable expressivity. A similar inheritance pattern appears to apply to the occurrence of multiple dewclaws in dogs, as is seen in Great Pyrenees. Lateral polydactylism occurs less frequently. There is no apparent clinical significance to these conditions, other than an increased propensity for traumatic injury of the partial supernumerary digits.

Syndactyly

Syndactyly involves bony and/or soft tissue union of two or more digits, with varying degrees of involvement. Few cases of syndactyly in dogs and cats have been reported. Because few clinical problems are associated with the malformation, this syndrome is probably more common than reported.

DYSTROPHIES ASSOCIATED WITH CALCIUM, PHOSPHORUS, AND VITAMIN D

The principal causes of osteodystrophies are deficiencies or imbalances of dietary calcium, phosphorus, and vitamin D, as well as dysregulation of parathyroid hormone (PTH) activity. Their interrelationships are complex and not easily defined.

The primary source of calcium and phosphorus is the diet. These elements are absorbed in amounts depending on the source of the minerals, intestinal pH, and dietary levels of vitamin D, calcium, phosphorus, iron, and fat. If vitamin D or its activity is decreased, calcium and phosphorus absorption are reduced. Vitamin D is obtained either through the diet or by production when the skin is exposed to sunlight (ultraviolet radiation). Before vitamin D can be used, it must be processed into its metabolically active form in two consecutive hydroxylation steps by the liver and kidney. Vitamin D₃ (cholecalciferol)

acts primarily on the GI tract to increase absorption but also affects the bone, thereby increasing availability of elemental calcium. Through a negative feedback loop, it also contributes to the regulation of PTH secretion.

PTH secretion occurs in response to a low circulating calcium ion concentration and depends on the availability of magnesium. The target organs of PTH are the kidneys, bones, and intestines. In the kidneys, PTH promotes renal tubular absorption of calcium while enhancing the renal excretion of phosphorus, as well as the activity of 1 α -hydroxylase, the enzyme responsible for activation of vitamin D₃ in the kidney. In the intestine, PTH promotes absorption of calcium. PTH also facilitates mobilization of calcium and phosphorus from bone by allowing utilization of calcium from the osteoid matrix. In ruminants, PTH

increases the salivary excretion of phosphorus in exchange for bicarbonate.

Specific bony lesions are associated with abnormalities in absolute or relative amounts of vitamin D, calcium, phosphorus, and PTH. Often, in addition to the deficiency or excess in one element, this also causes a secondary pathology due to feedback mechanisms, altered ratios, or concomitant metabolic deficiencies. Specific disease syndromes can be classified as nutritional, metabolic, or genetic in nature. Classic examples of nutritional osteodystrophies are rickets, osteomalacia, enzootic calcinosis, or hypervitaminosis D. Fibrous osteodystrophy and hyperparathyroidism are common metabolic osteodystrophies. Genetic osteodystrophies can be caused by defects in phosphate transporters or genetic abnormalities in the hormonal regulation of phosphorus homeostasis. Examples of genetic defects associated with osteodystrophies include X-linked hypophosphatemia and hereditary hypophosphatemic rickets.

NUTRITIONAL OSTEODYSTROPHIES

RICKETS

Rickets is a disease of the bony growth plate and thus only affects young, growing animals. The most common causes are dietary insufficiencies of phosphorus or vitamin D. Calcium deficiencies can also cause rickets, and while this rarely occurs naturally, poorly balanced diets deficient in calcium have been said to cause the disease. As in most diets causing osteodystrophies, the abnormal calcium:phosphorus ratio is most likely the cause.

Clinical Findings and Lesions: The characteristic lesions of rickets are failure of both vascular invasion and mineralization in the area of provisional calcification of the physis. This pathology is most obvious in the metaphyses of the long bones. There may be a wide variety of clinical signs, including bone pain, stiff gait, swelling in the area of the metaphyses, difficulty in rising, bowed limbs, and pathologic fractures. On radiographic examination, the width of the physes is increased, the nonmineralized physal area is distorted, and the bone may show decreased radiopacity. In advanced cases, angular limb deformity can be seen due to asynchronous bone growth.

Animals fed all-meat diets are commonly affected. Kittens fed beef heart exclusively

develop locomotor disturbances within 4 wk, even though the high content of digestible protein (>50% on a weight basis) and fat promotes rapid growth, the animals appear well nourished, and their coat maintains a good luster. The predominant clinical signs are reluctance to move, posterior lameness, and ataxia. The kittens often stand with characteristic deviation of the paws. The skeletal disease becomes progressively more severe after 5–14 wk. The kittens become quiet and reluctant to play; they assume a sitting position or sternal recumbency with the hindlimbs abducted. Normal activities may result in the sudden onset of severe lameness due to incomplete or folding fractures of one or more bones. Lameness is the initial functional disturbance in growing dogs and may vary from a slight limp to inability to walk. The bones are painful on palpation, and folding fractures of long bones and vertebrae are common.

Swine kept in confined housing are susceptible to rickets because of their rapid growth rate combined with lack of exposure to sunlight. Furthermore, diets for market swine are formulated to maximize growth of lean muscle mass with little consideration of requirements for bone formation.

Diets with excessive amounts of calcium (three times normal concentrations) have caused rickets-like signs in growing Great Danes. Several other bone pathologies such as retained cartilaginous cores, osteochondrosis, and stunted growth were seen in these dogs as well.

Diagnosis: Typical microscopic lesions associated with rickets are impaired endochondral ossification, which are most prominent in fast-growing bones. Growth plates are widened and irregular, and joints appear enlarged. Trabeculae of the spongiosa are thinner, predisposing to infarctions and hemorrhage. Radiographic examination of large bones and joints is the most reliable *in vivo* diagnostic tool for rickets. The radiopacity of rachitic bones is characteristically less than that of normal bone. Growth plates appear widened and irregular.

Plasma alkaline phosphatase activity is commonly increased. Concentrations of serum phosphorus and vitamin D may be altered depending on the primary cause of rickets. In cases associated with phosphorus or vitamin D deficiencies, concentrations of these compounds in serum are subnormal. Hypocalcemia is seen in advanced stages.

Treatment: Correction of the diet is the primary treatment for rickets. The prognosis is good in the absence of pathologic fractures or irreversible damage to the physes. If the animals are housed, exposure to sunlight (ultraviolet radiation) will also increase production of vitamin D₃ precursors.

Many homemade diets for dogs are deficient in minerals and have altered calcium:phosphorus ratios. Therefore, a high-quality commercial food, or one designed by a credentialed veterinary nutritionist, is recommended.

OSTEOMALACIA

(Adult rickets)

Osteomalacia has a pathogenesis similar to that of rickets but is seen in mature bones and associated with disruption of normal bone remodeling. Because bones mature at different rates, both rickets and osteomalacia can be seen in the same animal. Osteomalacia is characterized by an accumulation of excessive unmineralized osteoid on trabecular surfaces.

Clinical Findings: Animals with osteomalacia are unthrifty and may exhibit pica. Nonspecific shifting lamenesses are common. Fractures can be seen, especially in the ribs, pelvis, and long bones. Spinal deformation such as lordosis or kyphosis may be seen.

In horses, nutritional osteodystrophy is known as **bran disease**, **millers' disease**, and **"big head."** The diet of pampered horses is often too high in grains and low in forage; such a diet is high in phosphorus and low in calcium. Many of the obscure lamenesses of horses have been attributed to nutritional osteodystrophy. The pathologic changes are similar to those in other species, with the provisos that the bones of the head are particularly affected in severe cases and that gross or microscopic fractures of subchondral bone (with consequent degeneration of articular cartilage and tearing of ligaments from periosteal attachments) are dominant clinical signs. Unilateral facial deformity due to secondary (nutritional) hypoparathyroidism has been reported in a 1-yr-old filly.

Nutritional osteodystrophy can occur in cattle grazing on arid, infertile soils deficient in phosphorus if they are not given adequate mineral supplementation. Affected animals are unthrifty and have a rough hair coat. Weight loss, shifting limb lameness, limb deformities, and spontaneous fractures are

the most common clinical findings. Pica may predispose affected animals to esophageal obstruction, reticuloperitonitis, botulism, or other intoxications.

Diagnosis: To establish a firm diagnosis of osteomalacia, the diet should be evaluated for calcium, phosphorus, and vitamin D content. There is radiographic evidence of generalized skeletal demineralization, loss of lamina dura dentes, subperiosteal cortical bone resorption, bowing deformities, and multiple folding fractures of long bones due to intense localized osteoclast proliferation. Levels of hydroxyproline, an amino acid released into blood during bone mineralization, can be determined to assess the extent of ongoing bone mobilization. If dietary calcium and phosphorus content cannot readily be determined (eg, in grazing animals), soil or fecal samples can be analyzed as crude proxies for dietary intake of these minerals.

Laboratory values used to assess renal function should be within normal limits in animals with nutritional osteodystrophy.

Treatment: Animals with osteomalacia should be confined for several weeks after initiation of the supplemental diet. Response to therapy is rapid; within 1 wk the animals become more active, and their attitude improves. Jumping or climbing must be prevented, because the skeleton is still susceptible to fractures. Restrictions can be lessened after 3 wk, but confinement with limited movement is indicated until the skeleton returns to normal (response to treatment should be monitored radiographically). Complete recovery can be achieved within months in animals with no or only minor limb and joint deformities.

ENZOOTIC CALCINOSIS

(Enteque seco, Enteque ossificans, Espichamento, Espichacao, Manchester wasting disease, Naalehu disease, Weidekrankheit)

Enzootic calcosinosis is a disease complex of ruminants and horses caused by plant poisoning or mineral imbalances and characterized by extensive calcification of soft tissues. The prevalence of the disease in cattle varies widely (10%–50%) in areas of Argentina, Brazil, Papua-New Guinea, Jamaica, Hawaii, and Bavaria. It is said to cause up to 60% mortality and affect 17% of the sheep in southern Brazil and Mattewara (India), respectively. Incidence elsewhere (Australia, Israel, South Africa, and

southern USA) is less well documented, and in many areas enzootic calcinosis is rare or nonexistent.

Etiology and Pathogenesis: Known causes of enzootic calcinosis fall into two categories: plant poisonings and mineral imbalances in the soil, the first probably being the more important. *Cestrum diurnum* (wild jasmine, day-blooming jessamine, king-of-the-day), *Trisetum flavescens* (golden oats or yellow oat grass), *Nierembergia veitchii*, *Solanum esuriale*, *S torvum*, and *S malacoxylon* contain 1,25-dihydroxycholecalciferol (calcitriol) glycoside or a substance that mimics its calcinogenic action. Studies indicate that *S malacoxylon* has the required enzyme systems for synthesis of calcitriol from vitamin D₃.

The imbalance of minerals in certain soils, as well as at higher altitude (up to 1,500 m above sea level), have been thought to be the main etiologic factors; higher altitude is considered to favor the growth of plants like golden oats at the expense of other plants less suited for this location.

Osteodystrophy of bulls after prolonged intake of excessive calcium is a similar condition; calcification of the cardiovascular system associated with aging and such cachectic diseases as tuberculosis is not identical. Excessive vitamin D₃ and normal or excessive calcium intake induces aortic calcification and atherosclerosis in ruminants.

Normally, the conversion of 25-hydroxycholecalciferol (calcifediol) to calcitriol in the kidneys is controlled by a feedback mechanism. The calcitriol-like factor in the leaves of plants bypasses this mechanism, and more calcium is absorbed than can be accommodated physiologically. Hypercalcemia promotes calcitonin production, calcinosis, and osteoporosis.

Changes in plasma calcium, phosphorus, and magnesium are different in different species. Horses develop hyperphosphatemia; plasma calcium remains normal but rises with excess doses of calcitriol. In cattle and small ruminants, high serum inorganic phosphorus with increased or normal serum calcium concentrations have been reported in animals with enzootic calcinosis.

Clinical Findings: Enzootic calcinosis is progressive and chronic, extending for weeks or months. The earliest signs are stiffness and shifting limb lameness, most pronounced when the animal rises after prolonged rest. Forelimbs are particularly

affected, and some animals even walk or graze on their knees. The distal joints become abnormally straight. When affected animals are forced to walk, their gait is awkward, stiff, and slow, and their steps are short. After walking only short distances, breathing becomes shallow and diaphragmatic, the nostrils are flared, and the head and neck are extended. Tachycardia is a common finding, and heart murmurs may be audible on auscultation. Jugular venous pulse is prominent in some cases.

As the disease progresses, the animal loses weight and becomes weak, listless, reluctant to stand, or even recumbent. The coat becomes shaggy, dull, and faded, particularly in cattle. There is wasting of muscles, a prominent skeleton, tucked up abdomen, kyphosis, and raised tailhead. Appetite is usually unimpaired but sometimes becomes depraved. Calcification of vessels is sometimes palpable on rectal examination.

Osteodystrophy is seen in calcinosis due to *T. flavescens* and *C. diurnum* toxicities in Bavarian cattle and Florida horses, respectively. Severely affected horses stand with forelimbs somewhat abducted and luxated caudally at the shoulder joints. The flexor tendons, particularly the suspensory ligaments, are painful. Fetlock joints are overextended to varying degrees.

Lesions: Degeneration and calcification of soft tissues are seen, with emaciation and varying amounts of excess fluid in the thoracic and abdominal cavities and pericardial sac. The cardiovascular system is the first to be involved, followed by lung, kidney, and tendons. The heart and aorta show the most pronounced abnormalities. The left side of the heart is more affected than the right. Calcification of the bicuspid valves results in valve insufficiency and systolic heart murmurs. White, elevated plaques of irregular size and shape are seen on the luminal surface; in advanced cases, these are seen throughout the length of the aorta and its main branches. Mineral deposits are found on the pleura, on the surface and edges of the diaphragmatic and apical lobes of lungs, in the renal artery and pelvis of the kidney, and on the ligaments and tendons (particularly of the forelimbs). Capsular thickening and irregular erosions of articular surface of cartilage and joints are seen, especially of the carpus and hock.

The basic histologic evidence is necrosis and calcification of connective tissue, followed by cellular proliferation in the affected area.

Diagnosis: Diagnosis of enzootic calcinosis is usually based on the history, combined with clinical signs such as emaciation, lameness, and listlessness, as well as cardiac and respiratory abnormalities, but may be difficult at early stages. Abnormal serum calcium, phosphorus, and magnesium concentrations and increased activity of alkaline phosphatase in combination with the presence of plants with calcinogenic action in the feed or on pasture are further clues.

Imaging techniques such as radiography and ultrasonography can be used to visualize soft-tissue calcification.

Treatment and Control: No practical treatment reversing soft-tissue calcification is currently available. Removal of the causal factor(s) is essential, but when the disease is associated with the mineral content of the soil, control may be difficult. Change of pasture, forage, and environment may effect clinical improvement. Careful pasture management to limit the density of calcinogenic plants can effectively reduce the disease prevalence. Feeding oat grass hay cut after blooming rather than having animals graze on oat grass pasture may reduce the problem, because calcinogenicity of the plant decreases with maturity and with drying. Experimentally, daily administration of 15 g of aluminum hydroxide, PO, prevented the development of calcinosis in sheep fed *T. flavescens*.

VITAMIN D₃ TOXICITY

Iatrogenically induced calcinosis, in the form of vitamin D₃ toxicity, is a condition occasionally reported in cattle that is very similar to enzootic calcinosis. Parenteral administration of vitamin D₃ 10–14 days before the predicted calving date is considered an effective strategy to prevent periparturient hypocalcemia (milk fever) in dairy cows. Because of the narrow margin between therapeutic and toxic doses, vitamin D₃ toxicity can occur either after a single overdose or after repeated therapeutic doses injected at short intervals. Commonly, toxicity is due to the repeated injection of therapeutic doses in cows that did not calve within 2 wk of the initial treatment and thus are considered at increased risk of developing periparturient hypocalcemia.

Clinical Findings: Animals with vitamin D₃ intoxication become anorectic, lose weight, and develop acetoneuria within 2–3 wk after the overdose. Tachycardia, shallow

breathing, and lameness, followed by weakness, recumbency, and even death can be seen in animals with vitamin D₃ toxicosis.

Lesions: Lesions are consistent with soft-tissue calcification described under enzootic calcinosis (see p 1053).

Diagnosis: Diagnosis of vitamin D₃ toxicity is usually based on a history of repeated vitamin D₃ injections in combination with the clinical signs mentioned above.

Treatment and Control: No practical treatment for vitamin D₃ toxicity is currently available. Education of producers concerning the risks and toxic dose of parenterally administered vitamin D₃ will help avoid accidental overdoses.

METABOLIC OSTEODYSTROPHIES

FIBROUS OSTEODYSTROPHY

(Rubber jaw syndrome)

Primary Hyperparathyroidism

In primary hyperparathyroidism (see p 564), there is excess production of parathyroid hormone (PTH) by an autonomous functional lesion in the parathyroid gland. The normal control mechanisms for PTH secretion by the concentration of blood calcium are lost, and the parathyroid produces excess PTH despite increased levels of blood calcium. This disease is encountered infrequently in older dogs, and it does not appear to be a sequela of renal secondary hyperparathyroidism (see p 1056).

PTH acts on cells of the renal tubules initially to promote the excretion of phosphorus and retention of calcium. A prolonged increased secretion of PTH results in accelerated osteocytic and osteoclastic bone resorption. Mineral is removed from the skeleton and replaced by immature fibrous connective tissue. Fibrous osteodystrophy is generalized throughout the skeleton but is accentuated in local areas such as the cancellous bone of the skull. The increased PTH levels also inhibit the renal tubular resorption of phosphorus.

The lesion in the parathyroid gland in dogs is usually an adenoma, occasionally a carcinoma, composed of active chief cells. Usually, adenomas are single, light brown-red, and located in the cervical region near the thyroid gland.

Clinical Findings: In primary hyperparathyroidism, lameness follows severe osteoclastic bone resorption, and fractures of long bones occur after minor physical trauma. Compression fractures of weakened vertebral bodies may exert pressure on the spinal cord and nerves, resulting in motor and sensory dysfunction.

Facial hyperostosis with partial obliteration of the nasal cavity (by poorly mineralized woven bone and highly vascular fibrous connective tissue) and loss or loosening of teeth has been seen in dogs. This may result in an inability to close the mouth properly and development of gingival ulcers. The maxillae and rami of the mandibles often are coarsely thickened by the excess woven bone. Bones of the skull are markedly thinned by the increased resorption and have a characteristic "moth-eaten" appearance radiographically. In advanced cases, the mandible can be twisted gently due to loss of osteoid and severe fibrous osteodystrophy—hence the name "rubber jaw" syndrome.

Lesions: Histologic demonstration of a rim of normal tissue and a partial to complete fibrous capsule in an enlarged parathyroid suggests an adenoma rather than focal hyperplasia. Chief-cell carcinomas tend to be larger than adenomas and fixed to the underlying tissues due to local infiltration of neoplastic cells.

Diagnosis: Although other laboratory findings may be variable when diagnosing primary hyperparathyroidism, hypercalcemia is consistent and results from accelerated release of calcium from bone. The blood calcium in healthy dogs is $\sim 10 \pm 1$ mg/dL, depending on age and diet (and assay method). Serum calcium values consistently >12 mg/dL indicate hypercalcemia. Dogs with primary hyperparathyroidism usually have a serum calcium of ≥ 12 – 20 mg/dL. The blood phosphorus is low or in the low-normal range (≤ 4 mg/dL). The urinary excretion of phosphorus, and often of calcium, is increased and may result in nephrocalcinosis and urolithiasis. Accelerated bone matrix metabolism is reflected by increased urinary excretion of hydroxyproline. Serum alkaline phosphatase activity may be increased in animals with overt bone disease. Demonstration of increased levels of PTH by a species-specific assay in an adult to aged dog with hypercalcemia, hypophosphatemia, and evidence of generalized bone disease provides conclusive evidence of primary hyperparathyroidism. PTH can be measured by

sensitive radioimmunoassays or immunoradiometric assays.

The intact PTH assay or dual-site assays can be performed using either serum (preferred) or plasma that has been separated and frozen (-70°C [-94°F] in either glass or plastic tubes) as soon as possible after collection. Using this method, circulating levels of PTH in most animals are near 20 pg/mL (dogs, 20 ± 5 pg/mL; cats, 17 ± 2 pg/mL), with levels in nonhuman primates being slightly lower (normal values also vary among laboratories). PTH assays that use antibody generated against the carboxy terminal end of the human molecule usually give less consistent results in animals other than people.

Differential diagnoses include other causes of hypercalcemia, such as vitamin D intoxication (overdosage), enzootic calcinosis (see p 1052), malignant neoplasms with osseous metastasis, and humoral hypercalcemia of malignancy (see p 563). The hypercalcemia of hypervitaminosis D may be as high as that in primary hyperparathyroidism but is accompanied by varying degrees of hyperphosphatemia and normal serum alkaline phosphatase activity. Skeletal disease usually is absent, because the increased concentrations of blood calcium and phosphorus are derived principally from augmented intestinal absorption rather than from bone resorption.

Malignant neoplasms with osseous metastases may cause moderate hypercalcemia and hypercalciuria, but the alkaline phosphatase activity and serum phosphorus level usually are normal or only slightly increased. These changes are believed to be due to the release of calcium and phosphorus into the blood from areas of bone destruction at rates greater than can be cleared by the kidneys and intestine. Bone involvement is more sharply demarcated and localized to the area of metastasis. Osteolysis associated with tumor metastases results not only from a physical disruption of bone by proliferating neoplastic cells but also from local production of humoral substances that stimulate bone resorption, such as prostaglandins and interleukin-1.

Primary parathyroid hyperplasia has been described in German Shepherd pups. The condition was associated with hypercalcemia, hypophosphatemia, increased immunoreactive PTH, and increased fractional clearance of inorganic phosphorus in the urine. Clinical signs include stunted growth, weakness, polyuria, polydipsia, and a diffuse reduction in bone

density. IV infusion of calcium fails to suppress the autonomous secretion of PTH by the diffuse hyperplasia of chief cells in all parathyroids. Lesions include nodular hyperplasia of thyroid C cells and widespread mineralization of the lungs, kidneys, and gastric mucosa. The disease is inherited as an autosomal recessive.

Hypercalcemia also may be associated with multifocal osteolytic lesions associated with septic emboli, complete immobilization, osteosarcoma, hypoadrenocorticism (Addison-like disease), hypocalcetonism due to a destructive thyroid lesion, chronic renal disease, hemoconcentration, or hyperproteinemia. Hypercalcemia is detected occasionally in dehydrated animals but usually is mild. It is attributed to fluid volume contraction that results in hyperproteinemia and increased concentrations of ionized and nonionized calcium; it resolves rapidly after fluid therapy.

Treatment: The objective in treating primary hyperparathyroidism is to eliminate the source of excessive PTH production. An attempt should be made to identify all four parathyroid glands before excising any tissue. Single or multiple adenomas should be removed in toto. If all identifiable parathyroids in the cervical region appear to be of normal or smaller size, and the diagnosis is reasonably certain, surgical exploration of the thorax near the base of the heart may be necessary to localize the parathyroid neoplasm.

Removal of the functional parathyroid lesion results in a rapid decrease in circulating PTH levels, because the half-life of PTH in plasma is <15 min. Because plasma calcium levels in animals with overt bone disease may decrease rapidly and be subnormal within 12–24 hr after surgery, they should be monitored frequently. Postoperative hypocalcemia (≤ 6 mg/dL) can result from the following: 1) depressed secretory activity of chief cells due to suppression by the chronic hypercalcemia or injury to the remaining parathyroid tissue during surgery, 2) abruptly decreased bone resorption due to decreased PTH levels, and 3) accelerated mineralization of osteoid matrix formed by the hyperplastic osteoblasts, which was previously prevented by the increased PTH levels (known as “hungry-bone syndrome”). Infusions of calcium gluconate to maintain the serum calcium between 7.5 and 9 mg/dL, plus feeding high-calcium diets and supplemental vitamin D therapy, corrects this serious postoperative complication. If hypercalcemia persists for ≥ 1 wk after

surgery, or recurs after initial improvement, a second adenoma or metastases from a carcinoma should be suspected.

Renal Secondary Hyperparathyroidism

Renal secondary hyperparathyroidism is a complication of chronic renal failure characterized by increased endogenous levels of parathyroid hormone (PTH). It is more common than primary hyperparathyroidism. In contrast to primary hyperparathyroidism, renal secondary hyperparathyroidism tends not to be autonomous. It is seen frequently in dogs, occasionally in cats, and rarely in other species.

With progressive renal disease, serum hyperphosphatemia develops as the glomerular filtration rate decreases. Hyperphosphatemia leads to lower serum concentration of ionized calcium. Renal synthesis of calcitriol is also reduced. Calcitriol normally acts on the intestine and kidneys to maintain normal calcium levels. Decreased ionized calcium and calcitriol concentrations cause an increase in serum PTH concentrations. As glomerular filtration rate decreases with advancing renal disease, PTH concentrations progressively increase, leading to the clinical manifestations of renal secondary hyperparathyroidism.

Clinical Findings: The predominant signs of renal insufficiency (eg, vomiting, dehydration, polydipsia, polyuria, and depression) are usually present. Skeletal lesions range from minor changes with early (or mild) renal disease to severe fibrous osteodystrophy of advanced renal failure. The volume of affected bones usually is normal (isostatic), particularly in older dogs because of the slow onset of renal failure and lower metabolic activity of bones. Hyperostotic bone lesions, such as facial swelling, may be seen in younger dogs in which deposition of unmineralized osteoid by hyperplastic osteoblasts and production of fibrous connective tissue exceed the rate of bone resorption.

Skeletal involvement is generalized but not uniform. Lesions become apparent earlier and reach a more advanced stage in certain areas, such as cancellous bones of the skull. Resorption of alveolar bone occurs early and results in loose teeth, which may be dislodged easily and interfere with mastication. As a result of accelerated resorption of cancellous bone of the maxilla and mandible, bones become softened and

pliable ("rubber jaw" syndrome), and the jaws fail to close properly. This often results in drooling and protrusion of the tongue. Severely demineralized mandibles are predisposed to fractures and displacement of teeth from alveoli. Long bones are less dramatically affected. Lameness, stiff gait, and fractures after minor trauma may result from increased bone resorption.

Lesions: All parathyroid glands are enlarged, initially due to hypertrophy of chief cells and subsequently by compensatory hyperplasia. Although the parathyroids are not autonomous, the concentration of PTH in the peripheral blood often exceeds that of primary hyperparathyroidism. Changes such as osteoclastosis, marrow fibrosis, and a higher concentration of woven osteoid may be seen histologically. Severe hypercalcemia, hyperphosphatemia, and high concentrations of PTH seen in advanced disease may cause osteosclerosis.

Diagnosis: Renal secondary hyperparathyroidism is diagnosed by laboratory abnormalities consistent with renal insufficiency accompanied by an increase in serum PTH. Radioimmunoassay of PTH that must be species specific is commercially available for most companion animal species and horses. Assays that measure fragments of the PTH molecule should not be used, because the concentration of biologically inactive metabolites of PTH increases with renal failure.

Treatment: Treatment options for renal secondary hyperparathyroidism include dietary modification, administration of calcitriol (the bioactive metabolite of vitamin D₃) in combination with oral supplementation of phosphate binders, and management of the underlying renal disease. Prescription diets with restricted dietary phosphorus are available. Oral calcitriol (1.5–3.5 ng/kg/day) has reversed hyperparathyroidism of chronic renal failure, but calcitriol therapy is contraindicated with hyperphosphatemia or hypercalcemia. (Special compounding of calcitriol is needed, because the dosages currently available commercially are much larger than those needed clinically.) Dietary phosphorus binders are used to decrease the amount of phosphorus available for absorption in the intestines and should be administered with meals. This therapy is especially important during calcitriol supplementation, because calcitriol increases the absorption of phosphorus and calcium.

Prognosis: If untreated, secondary hyperparathyroidism results in irreversible hypertrophy of the parathyroid glands, a condition also known as tertiary hyperparathyroidism. In this stage, hyperparathyroidism becomes unresponsive to treatment and requires surgical extirpation of the hypertrophic parathyroid glands.

HYPOPARATHYROIDISM

In hypoparathyroidism (*see* p 570), either subnormal amounts of parathyroid hormone (PTH) are secreted, or the hormone secreted is unable to interact normally with target cells. It has been recognized primarily in dogs, particularly in smaller breeds such as Miniature Schnauzers, but other breeds may be affected.

Various pathogenic mechanisms can result in inadequate secretion of PTH. Parathyroid glands may be damaged or inadvertently removed during thyroid surgery. After damage to the glands or their vascular supply, adequate functional parenchyma often regenerates, and clinical signs subsequently disappear.

Idiopathic hypoparathyroidism in adult dogs usually is the result of diffuse lymphocytic parathyroiditis that causes extensive degeneration of chief cells and replacement by fibrous connective tissue. Other possible causes of hypoparathyroidism include destruction of parathyroids by primary or metastatic neoplasms in the anterior cervical area, and atrophy of parathyroids associated with chronic hypercalcemia. The presence of numerous distemper virus particles in chief cells of the parathyroid gland may contribute to the low blood calcium in certain dogs with this disease. Agenesis of the parathyroids is a rare cause of congenital hypoparathyroidism in pups. Certain cases of idiopathic hypoparathyroidism in animals (including people) with histologically normal parathyroids may be due to lack of the specific enzyme in chief cells that converts the pro-PTH molecule to the biologically active PTH secreted by the gland. In other cases, an immune-mediated mechanism may be involved, because a similar destruction of secretory parenchyma and lymphocytic infiltration has been produced experimentally in dogs by repeated injections of parathyroid tissue emulsions.

Pseudohypoparathyroidism is a variant seen in people, but it is uncertain whether it is seen in other animals. Target cells in kidney and bone are unable to respond to normal or increased amounts of PTH, and

severe hypocalcemia develops even though the parathyroid glands are hyperplastic.

Clinical Findings and Lesions: The functional disturbances and clinical manifestations of hypoparathyroidism primarily are the result of increased neuromuscular excitability and tetany. Bone resorption is decreased because of the lack of PTH, and blood calcium levels diminish progressively (4–6 mg/dL). Affected dogs are restless, nervous, and ataxic, with weakness and intermittent tremors of individual muscle groups that progress to generalized tetany and convulsions. Blood phosphorus levels are increased substantially, owing to increased renal tubular reabsorption. Calcification of microvasculature, intracerebral calcification, decreased mental function, cataracts, osteopenia, and ligamentous ossification have been associated with chronic hypoparathyroidism.

In the early stages of immune-mediated lymphocytic parathyroiditis in dogs, there is infiltration of the gland with lymphocytes and plasma cells and nodular regenerative hyperplasia of remaining chief cells. Later, the parathyroid gland is replaced by lymphocytes, fibroblasts, and capillaries, with only an occasional viable chief cell.

Diagnosis: Diagnosis of hypoparathyroidism is based on clinical signs of increased neuromuscular excitability, severe hypocalcemia, and often moderate hyperphosphatemia in a nonparturient animal, as well as on the response to therapy. Some of the signs (eg, tetany) and laboratory data (eg, hypocalcemia) are similar to those of puerperal hypocalcemia (see p 992). However, puerperal

hypocalcemia usually is accompanied by hypophosphatemia and a low-normal or subnormal blood glucose concentration as a result of the associated intense muscular activity.

Treatment: The neuromuscular tetany should be treated initially by restoring blood calcium levels to near normal by IV administration of calcium gluconate. One recommended therapeutic regimen is 10 mL of 10% calcium gluconate in 250 mL of 0.9% saline administered at 2.5 mL/kg/hr for 8–12 hr. Care must be taken not to administer the calcium too rapidly because of its cardiotoxic properties. Longterm maintenance of blood calcium levels in the absence of normal PTH secretion should be attempted by feeding diets high in calcium and low in phosphorus and that are supplemented with calcium (gluconate or lactate) and vitamin D₃.

Large doses of vitamin D₃ (≥25,000–50,000 U/day, depending on the weight of the dog) may be required initially to increase the blood calcium level in hypoparathyroid animals, because the lack of PTH diminishes the rate of formation of the biologically active vitamin D metabolite in the kidney. To prevent hypercalcemia and extensive soft-tissue mineralization, the dosage of vitamin D should be carefully adjusted after frequent determination of the serum calcium level. After adjusting the dosage of vitamin D, a 4- to 5-day interval should precede the next blood calcium determination. Once the blood calcium level has returned to normal, substantially lower dosages of vitamin D are indicated for longterm maintenance; in some dogs, only dietary calcium supplementation is required for longterm stabilization.

SARCOCYSTOSIS

In sarcocystosis, the endothelium and muscles and other soft tissues are invaded by Apicomplexan protozoans of the genus *Sarcocystis*. As the name implies, *Sarcocystis* spp (from Greek *sarkos*: muscle and *kystis*: cysts) form cysts in muscles of various intermediate hosts—people, horses, cattle, sheep, goats, pigs, birds, rodents, camelids, wildlife, and reptiles. The cysts vary in size from a few micrometers to

centimeters, depending on the host and species. Most *Sarcocystis* spp infections are distributed worldwide.

Etiology, Transmission, and Pathogenesis: *Sarcocystis* spp normally develop in two-host cycles consisting of an intermediate host (prey) and the final host (predator). Species-specific prey-predator life cycles have been demonstrated for

cattle-dog (*S cruzi*), cattle-cat (*S hirsuta*), cattle-human (*S hominis*), sheep-dog (*S capracanis*, *S hircicanis*), sheep-cat (*S gigantea*, *S medusiformis*), goat-dog (*S capracanis*, *S hircicanis*), goat-cat (*S moulei*), pig-dog (*S meischeriana*), pighuman (*S suihominis*), pig-cat (*S porcifelis*), horse-dog (*S fayeri*), llama-dog (*S aucheniae*), pigeon-hawk (*S calchasi*), and others. *S sinensis* has been detected affecting muscles of buffalo and cattle, but its final host remains unknown. Some wildlife may serve as intermediate hosts (such as raccoons, rodents, birds, etc) or final hosts (coyotes, opossums, snakes, etc) for some species of *Sarcocystis*.

About 1–2 wk after ingesting muscle tissue that contains *Sarcocystis* cysts (sarcocysts), the final host begins to shed infective sporocysts in the feces; shedding continues for several months. After ingestion of sporocysts by a suitable intermediate host, sporozoites are liberated and initiate development of schizonts in vascular endothelia of mesenteric arterioles and mesenteric lymph nodes. Merozoites are liberated from the mature schizonts and produce a second generation of endothelial schizonts in capillaries from several organs. Merozoites from this second generation subsequently invade the muscle fibers and develop into the typical sarcocysts. Initially, sarcocysts contain only a few merozoites—round, noninfective parasites that give rise to the banana-shaped infective bradyzoites found in mature cysts beginning 2–3 mo after infection. Sarcocysts of some species are easily visible with the unaided eye (*S aucheniae*, *S hirsuta*, *S gigantea*). The presence of such sarcocysts as well as those of zoonotic species can cause condemnation of the carcass during meat inspection. Sarcocysts of other species remain microscopic, even though tremendous numbers of cysts may be present in the muscles. The identification of different species could be achieved by molecular studies and cyst wall morphology (mainly ultrastructure).

S cruzi produce microscopic cysts, principally in myocardium, and can affect 100% of some cattle populations. *S hirsuta* has been primarily responsible for cattle condemnation for visible sarcocysts. *S meischeriana* is the most important species affecting pigs and may affect meat quality. Microscopic cysts of *S aucheniae* are an important cause of condemnation of llama meat. Sarcocysts are easily recovered from esophagus, diaphragm, and heart muscle.

In general, *Sarcocystis* spp infections are considered of low pathogenicity except

induced infection with *S cruzi* sporocysts from canine feces, which may cause acute disease in calves; eosinophilic myositis in cattle; and abortions, stillbirths, and deaths in pregnant cows. Two cases of necrotic encephalitis in heifers have been reported. Similar pathogenicity has been demonstrated for *S tenella* in lambs and ewes and for *S meischeriana* in pigs. An outbreak of myositis affecting 20 ewes with flaccid paralysis was a result of heavy *Sarcocystis* infection. Immune status of the host and the dose of sporocysts may be the most important factors for the development of clinical disease. Pathologic changes in myocardium and skeletal muscles were more pronounced in cows with lymphatic leukemia. "Inmunization" using small doses of sporocysts appears to prevent development or reduce severity of clinical disease in sheep when challenged with large doses later (premunitive immunity). In dogs, a longer prepatent period and shortened patent period resulted after repeated infection. Pigs can also have persistent acquired immunity after immunization infections.

People may also serve as intermediate hosts and suffer myositis and vasculitis, but this tissue phase is rare, and the source of such human infection has never been determined. Human intestinal illness as final host, with clinical signs of nausea, abdominal pain, loss of appetite, vomiting, and diarrhea that lasted as long as 48 hr, has followed ingestion of sarcocysts of *S suihominis* in uncooked pork and *S hominis* in uncooked beef. Differentiation between cysts of *S sinensis* and *S hominis* in beef is extremely important to avoid unjustified rejections.

Clinical Findings: *Sarcocystis* spp infections are quite prevalent in farm animals; however, there have been few outbreaks of clinical disease. Most animals are asymptomatic, and the parasite is discovered only at slaughter. In cattle severely affected by *S cruzi*, the signs include fever, anorexia, cachexia, decreased milk yield, diarrhea, muscle spasms, anemia, loss of tail hair, hyperexcitability, weakness, prostration, and death. Cows infected in the last trimester of pregnancy may abort. After recovery from acute illness, calves failed to grow well and eventually died in a cachectic state. Anemia, hepatitis, and myocarditis were the primary lesions in acute ovine sarcocystosis after experimental challenge with *S tenella* sporocysts. Cases of encephalomyelitis in sheep were associated with a *Sarcocystis*

sp infection. After recovery from acute illness, some sheep may lose their wool. *S tenella* may also induce abortion in sheep. At necropsy, acutely affected animals have hemorrhage of the serous membranes of the viscera and myocardium. *Sarcocystis* spp infections are probably most important in growing ruminants and swine, in which they can result in subclinical anemia and reduced weight gain.

Equine protozoal myeloencephalitis (EPM, see p 1309) is caused principally by *S neuroma* in American horses. Only asexual stages of this parasite have been found in horses, and they may be located in neurons and leukocytes of the brain and spinal cord. Opossums (*Didelphis virginiana* and *D albiventris*) are its definitive hosts. Clinical signs in horses include gait abnormalities such as ataxia, knuckling, and crossing over. Muscle atrophy of the hindlimb, which is usually unilateral, is frequent. The lesions are typically focal, and brain-stem involvement is common. Depression, weakness, head tilt, and dysphagia are other possible signs. EPM can mimic many neurologic diseases. Horses may also develop a myopathy. Multifocal myositis has been reported and is possibly due to another *Sarcocystis* species with horses as the intermediate host, *S fayeri*. PCR is an important diagnostic method. *S calchasi* can

produce pigeon protozoal encephalitis with severe brain lesions and muscle cysts at the same time.

Control: Livestock become infected by sporocysts from the feces of carnivores. Because most adult cattle, sheep, and many pigs harbor cysts in their muscles, dogs and other carnivores should not be allowed to eat raw meat, offal, or dead animals. Supplies of grain and feed should be kept covered; dogs and cats should not be allowed in buildings used to store feed or house animals. Amprolium (100 mg/kg/day for 30 days), fed prophylactically, reduced illness in cattle inoculated with *S cruzi*. Prophylactic administration of amprolium or salinomycin also protected experimentally infected sheep. Therapeutic treatment of the chronic stage (tissue cysts) has been ineffective. Vaccines are not available. Experimental work demonstrated that infected pork and beef could be made safe for consumption by cooking at 70°C (158°F) for 15 min or by freezing at -4°C (24.8°F) for 2 days or -20°C (-4°F) for 1 day.

Pyrimethamine and sulfadiazine (1 mg/kg/day and 20 mg/kg/day, respectively, for 120 days or longer) is the traditional therapy to treat horses with EPM. Diclazuril and toltrazuril (5 mg/kg) are potentially useful prophylactic agents against *S neuroma*.

ARTHROPATHIES IN LARGE ANIMALS

See also LAMENESS IN CATTLE, p 1066; HORSES, p 1096; SHEEP, p 1166; GOATS, p 1092; and PIGS, p 1151.

ARTHRITIS

Arthritis is a nonspecific term denoting inflammation of a joint. All joint diseases of large animals have an inflammatory component to varying degrees. Arthritic entities of importance include traumatic arthritis, osteochondritis dissecans, subchondral cystic lesions, septic (or infective) arthritis, and osteoarthritis (also called degenerative joint disease).

Traumatic Arthritis

Traumatic arthritis includes traumatic synovitis and capsulitis, intra-articular chip fractures, ligamentous tears (sprains)

involving periarticular and intra-articular ligaments, meniscal tears, and osteoarthritis. Traumatic arthritis is seen in all breeds of horses worldwide.

Clinical Findings and Diagnosis: Traumatic synovitis and capsulitis is inflammation of the synovial membrane and fibrous joint capsule associated with trauma. Typically, the horse is an athlete and presents with synovial effusion in the acute stage, along with general thickening and fibrosis in the more chronic stage. Lameness varies from a mild gait change to severe lameness. Traumatic synovitis and capsulitis is differentiated from other traumatic entities by use of radiography to exclude osteochondral fractures or disease. Tearing of ligaments or menisci (in

femorotibial joints) can often be excluded only by diagnostic arthroscopy. Osteochondral fractures are diagnosed with radiographs. Osteoarthritis is the progressive loss of articular cartilage and can be the consequence of any or all of these traumatic entities (see also p 1063). Osteoarthritis is diagnosed with radiographs when the changes are sufficiently severe to demonstrate loss of joint space (associated with articular cartilage loss), subchondral sclerosis, and osteophyte or enthesophyte formation. Lesser degrees of osteoarthritis can be defined only with diagnostic arthroscopy. Clinical signs of osteochondral fractures are similar to those of synovitis and capsulitis, as well as those of osteoarthritis; differential diagnosis of these entities is based on radiographs and, in some cases, arthroscopy.

Arthritis generally results in pain and altered function of the joint. If the process is active or acute, there is usually synovial effusion, and the surrounding tissues are swollen and warm. In more severe cases, manipulation of the joint causes pain. In more subtle cases, flexion tests are required to elicit lameness. As the disease process becomes chronic, the range of motion is reduced with fibrous thickening of the joint capsule. Radiographic evaluation is necessary for positive confirmation of a number of disease entities. Arthroscopy is used to accurately assess the amount of damage to the articular cartilage and to establish a prognosis.

Treatment: Treatment of acute traumatic synovitis and capsulitis includes rest and physical therapy regimens such as cold water treatment, ice, passive flexion, and swimming. NSAIDs (usually phenylbutazone) are used routinely. In more severe cases, the joint is lavaged to remove inflammatory products produced by the synovial membrane, as well as articular cartilage debris that exacerbates the synovitis. Joint drainage alone, without lavage or injection of medication, provides only short-term relief.

Various intra-articular medications have been used. Corticosteroids are the most potent anti-inflammatory agents and are effective in acute traumatic arthritis. However, there are differences in the adverse effects between various corticosteroids and various dosages. Betamethasone products and triamcinolone acetonide are effective with no deleterious adverse effects. Methylprednisolone acetate is more potent and longer acting than the other two drugs but has significant adverse effects

that cause degenerative changes in the articular cartilage. Intra-articular sodium hyaluronate has been used effectively for mild to moderate synovitis and has a chondroprotective effect, but it is less effective in severe synovitis or when intra-articular fractures are present. Use of an IV formulation of hyaluronic acid (systemic dose 40 mg) in clinical cases appears to be effective, and this is supported by research data in a controlled model of arthritis in horses. Polysulfated glycosaminoglycans (PSGAGs) are also used frequently for traumatic arthritis entities. PSGAG is effective for synovitis and can help prevent ongoing degeneration of articular cartilage. Although effectiveness of PSGAG when used intra-articularly (250 mg) has scientific support, effectiveness when used IM (500 mg) is less certain. The use of pentosan polysulfate (PPS) at 3 mg/kg, IM, has been shown to be effective as a disease-modifying drug with experimental equine osteoarthritis and has been extensively used in clinical cases outside the USA. Biologic therapies such as autologous conditioned serum are also becoming more commonly used.

Horses with osteochondral chip fragmentation (most commonly seen in the carpus and fetlock joints) are treated with arthroscopic surgery to minimize the ongoing development of osteoarthritis. Fragments are removed, and defective bone and cartilage debrided. Rest periods of 2–4 mo follow, and physical therapy regimens are instituted in the convalescent period. The success rate in returning horses to previous performance level is high when secondary osteoarthritic changes are minimal at the time of surgery. Osteochondral chip fragments that are amenable to arthroscopic surgery and have successful results include those associated with the distal radius or carpal bones; dorsoproximal first phalanx; proximal palmar/plantar first phalanx; apical, abaxial, and basilar fragments of the proximal sesamoid bones; fragmentation of the distal patella in the femoropatellar joint; chip fragments of the tibiotarsal joint; and fragments of the extensor process of the distal phalanx (coffin joint).

Osteochondritis Dissecans

For a complete discussion of equine osteochondrosis, see p 1148.

In osteochondritis dissecans (OCD), a focal area of the immature articular cartilage is retained, and the matrix in the basal area of this region becomes

chondromalacic and acellular. The immature articular cartilage separates from the underlying trabecular bone. The chondral fracture extends horizontally and vertically until a flap is formed. Synovial fluid gains entrance to the underlying medullary space, and subchondral cysts may form (usually only in larger animals). The flap of immature articular cartilage may stay separated and loose, break away completely ("joint mice"), or reattach by endochondral ossification to the underlying bone, especially in pigs, and result in a wrinkled articular surface. The latter occurs only if the joint is rested or protected, which permits reestablishment of the circulation necessary for endochondral ossification. If the flap is torn free by joint motion, it may be ground into smaller pieces during locomotion and disappear, whereas the larger plaques may become attached to the synovial membrane, become vascularized, and ossify. The resultant articular defect, in time, fills with fibrocartilage.

Etiology: The exact cause of OCD is unknown but is assumed to be multifactorial. Factors include genetic predisposition, fast growth, high caloric intake, low copper and high zinc levels, and endocrine factors.

Clinical Findings: The most common sites of OCD, which usually is seen in young animals, are the femoropatellar joint, tibiotarsal (tarsocrural) joint, fetlock (metacarpophalangeal and metatarsophalangeal) joints, and the shoulder.

Animals with OCD of the shoulder usually present when <1 yr old with severe forelimb lameness and possibly some muscular atrophy. Animals with OCD in the other joints usually present with synovial effusion and varying degrees of lameness. Diagnosis is confirmed with radiographs.

Diagnosis: The history, age, breed, sex, and clinical signs provide useful information; however, radiographs are required to substantiate a diagnosis of OCD.

Treatment: Treatment of OCD depends on the location and degree of involvement. Femoropatellar joint lesions are associated with the lateral trochlear ridge of the femur, medial trochlear ridge of the femur, or distal patella. They are amenable to arthroscopic surgery, which is recommended in all cases except early lesions characterized by flattening (without fragmentation) <2 cm long on the lateral trochlear ridge. In the tarsocrural joint, OCD lesions are seen in decreasing frequency on the intermediate

(sagittal) ridge of the tibia, lateral trochlear ridge of the talus, medial malleolus of the tibia, and medial trochlear ridge of the talus. All lesions are amenable to arthroscopic surgery, and the prognosis is usually good. Surgery is recommended when synovial effusion is present. Lesions without fragmentation in the metacarpophalangeal or metatarsophalangeal joints can be treated conservatively, and most affected animals recover well. If a fragment is present, arthroscopic surgery is recommended. In the shoulder, surgery is usually recommended, although milder cases have been managed conservatively with success. The prognosis with arthroscopic surgery is generally less favorable in the shoulder than in other joints.

Subchondral Cystic Lesions

Subchondral cystic lesions are seen in the femorotibial joint and in the fetlock, pastern, elbow, shoulder, and distal phalanx. The diagnosis is usually made on the basis of localization of lameness with intraarticular analgesia (synovial effusion is variable) and confirmed with radiographs.

Subchondral cystic lesions are most frequent in the femorotibial joint, followed by the fetlock joint. Surgery (arthroscopic) is currently recommended in the femorotibial joint whenever a complete cystic lesion is present. Smaller, dome-shaped or flattened lesions are usually treated conservatively in the initial period. Athletic soundness is achieved in 65%–70% of these horses. Intralesional injection of corticosteroids under arthroscopic visualization, in preference to debridement as done previously, achieves superior results. In cases with collapsed edges to the cystic lesion at arthroscopic surgery, or in cases unresponsive to therapy, arthroscopic debridement with augmentation with fibrin, growth factors, and mesenchymal stem cells have been used. Surgery is usually recommended for subchondral cystic lesions of the distal metacarpus in the fetlock but not as consistently as in the femorotibial joint. Single lesions associated with the pastern and elbow joint are treated conservatively and have a fair prognosis. If possible, surgery is recommended for cystic lesions of the distal phalanx (results with conservative treatment are very poor).

Septic Arthritis

(Infective arthritis)

Etiology and Epidemiology: Septic or infective arthritis results from sequestration

of bacterial infection in a joint. Infection of a joint develops in three main ways:

- 1) hematogenous infection, which is common in foals, calves, and lambs (commonly referred to as navel ill);
- 2) traumatic injury with local introduction of infection; or
- 3) iatrogenic infection associated with joint injection or surgery (usually in horses). Navel ill is only one example of a hematogenous route of infection, which can also be gained from GI or pulmonary sources.

Clinical Findings and Diagnosis: Septic arthritis is usually characterized by severe lameness and distention of the joint with cloudy, turbid synovial fluid that contains $>30,000$ WBC/mm³ and a total protein level of >4 g/dL.

In foals, hematogenous osteomyelitis often accompanies septic arthritis. Septic arthritis in foals has been classified into type S (septic joint only), type P (involving osteomyelitis of the adjacent growth plate as well), or type E (involving osteomyelitis of the epiphyseal and subchondral bone). Various organisms may be involved.

In young lambs, *Actinobacillus seminis* causes polyarthritis, as do *Chlamydia psittaci* and *Erysipelothrix insidiosa*. The latter can follow docking, castration, or navel infection. Viruses and mycoplasma may also be etiologic agents in food-producing animals.

In mature goats, caprine arthritis and encephalitis virus (see p 747) is an important cause of infective arthritis. In young goats, *C. psittaci* and *Mycoplasma mycoides* are frequent causes.

Bacterial (including *Mycoplasma*) arthritides are seen in young pigs. In newborn pigs, septic arthritis usually is due to intrauterine or navel infection with *Escherichia coli*, *Corynebacterium*, *Streptococcus*, or *Staphylococcus* spp. Control is best directed toward reducing the possibility of infection from the environment. Older pigs sometimes develop arthritis as a sequela of infection with *Haemophilus*, *Erysipelothrix*, or *Mycoplasma* spp. Although diagnosis in the early stages is not difficult, the more chronic stages can be confused with articular lesions produced by dietary hypervitaminosis A.

Traumatic injury to joints with contamination and progression to infection is common in horses, and various species of bacteria are involved. Infection associated with intra-articular injection or surgery occurs in horses and is usually associated with *Staphylococcus aureus* or *S. epidermidis*.

Treatment: Septic arthritis requires prompt treatment to avoid irreparable damage. Systemic broad-spectrum antibiotics are indicated; the initial choice is based on the most likely pathogen but is subject to change based on culture and sensitivity tests. Systemic antibiotic treatment is often combined with intra-articular antibiotics (to achieve more effective sterilization of the joint) and other local therapy, including joint lavage (initially) and arthroscopic debridement and drainage. Adjunctive treatment with NSAIDs (eg, phenylbutazone) is also done. The effectiveness of treatment is monitored carefully with clinical signs and repeat synovial fluid analyses.

Osteoarthritis

(Degenerative joint disease)

Etiology and Epidemiology: Osteoarthritis is a progressive degradation of articular cartilage and represents the end stage of most of the other diseases discussed above if treatment is ineffective or the initial problem is too severe. For this reason, prompt diagnosis and correct management of traumatic synovitis and capsulitis, intra-articular fractures or traumatic cartilage damage, osteochondritis dissecans, subchondral cystic lesions, and septic arthritis are critical.

Clinical Findings and Diagnosis: Lameness can be localized with analgesia to the affected joint. There are varying degrees of synovial effusion, joint capsule fibrosis, and restricted motion (decreased flexion). Radiographic signs of osteoarthritis include decreased joint space, osteophytosis, enthesitis, and subchondral sclerosis. In less severe cases, articular degradation requires definition with arthroscopy.

Treatment: Treatment of osteoarthritis is most commonly palliative and includes the use of NSAIDs, polysulfated intra-articular glycosaminoglycans, intra-articular corticosteroids, IV hyaluronic acid, and IM pentosan polysulfate. The use of intra-articular autologous conditioned serum has also been validated. Physical therapy regimens may prove useful. Arthroscopy is commonly performed to diagnose the extent of articular cartilage loss, as well as to treat primary conditions such as articular cartilage separation, meniscal tears, and ligamentous injury. In advanced cases of osteoarthritis, surgical fusion (arthrodesis) may be performed on selected joints.

Surgical fusion of the proximal interphalangeal joint (pastern) or distal tarsal joints can effect athletic soundness. Fetlock arthrodesis is also done in valuable animals and makes them comfortable and capable of breeding. Treatment is usually unsuccessful in chronic cases in bulls and cows, but restricted exercise and careful feeding and nursing prolong the life of and can be worthwhile for valuable breeding animals.

BURSITIS

Bursitis is an inflammatory reaction within a bursa that can range from mild inflammation to sepsis. It is more common and important in horses. It can be classified as true or acquired. True bursitis is inflammation in a congenital or natural bursa (deeper than the deep fascia), eg, trochanteric bursitis and supraspinous bursitis (fistulous withers, *see below*). Acquired bursitis is development of a subcutaneous bursa where one was not previously present or inflammation of that bursa, eg, capped elbow over the olecranon process, shoe boil over the point of the elbow, and capped hock over the tuber calcaneus.

Bursitis may manifest as an acute or chronic inflammation. Examples of acute bursitis include bicipital bursitis and trochanteric bursitis in the early stages. It is generally characterized by swelling, local heat, and pain. Chronic bursitis usually develops in association with repeated trauma, fibrosis, and other chronic changes (eg, capped elbow, capped hock, and carpal hygroma). Excess bursal fluid accumulates, and the wall of the bursa is thickened by fibrous tissue. Fibrous bands or a septum may form within the bursal cavity, and generalized subcutaneous thickening usually develops. These bursal enlargements develop as cold, painless swellings and, unless greatly enlarged, do not severely interfere with function. Septic bursitis is more serious and is associated with pain and lameness. Infection of a bursa may be hematogenous or follow direct penetration.

The pain in acute bursitis may be relieved by application of cold packs, aspiration of the contents, and intrabursal medication. Repeated injections may result in infection. Treatment of chronic bursitis is surgical (and is done arthroscopically (bursoscopy)). In infected bursitis, systemic antibiotics as well as local drainage are required.

Capped Elbow and Hock

Capped elbow and hock are inflammatory swellings of the subcutaneous bursae

(acquired bursitis) located over the olecranon process and tuber calcaneus, respectively, of horses. Frequent causes include trauma from lying on poorly bedded hard floors, kicks, falls, riding the tailgate of trailers, iron shoes projecting beyond the heels, and prolonged recumbency.

Clinical Findings and Diagnosis: Circumscribed edematous swelling develops over and around the affected bursa. Lameness is rare in either case. The affected bursa may be fluctuating and soft at first but, in a short time, a firm fibrous capsule forms, especially if there is a recurrence of an old injury. Initial bursal swellings may be hardly noticeable or quite sizable. Chronic cases may progress to abscessation.

Treatment: Acute early cases may respond well to applications of cold water, followed in a few days by aseptic aspiration and injection of a corticosteroid. The bursa may also be reduced in size by application of a counterirritant or by ultrasonic or radiation therapy. Older encapsulated bursae are more refractory. Surgical treatment (usually curettage and drainage) is recommended for advanced chronic cases or for those that become infected. A shoe-boil roll should be used to prevent recurrence of a capped elbow if the condition has been caused by the heel or the shoe. With capped hock, behavioral modification so the horse does not kick the stall offers the only hope of permanently resolving the problem.

Fistulous Withers and Poll Evil

Fistulous withers and poll evil are rare, inflammatory conditions of horses that differ essentially only in their location in the respective supraspinous or supra-atlantal bursae. This discussion is of fistulous withers but, except for anatomic details, also applies to poll evil. In the early stage of the disease, a fistula is not present. When the bursal sac ruptures or when it is opened for surgical drainage, and secondary infection with pyogenic bacteria occurs, it usually assumes a true fistulous character.

Etiology: The condition may be traumatic or infectious in origin. Agglutination titers support an infectious etiology. *Brucella abortus* can sometimes be isolated from the fluid aspirated from the unopened bursa.

Clinical Findings: The inflammation leads to considerable thickening of the bursa wall. The bursal sacs are distended

and may rupture when the sac has little covering support. In more chronic, advanced cases, the ligament and the dorsal vertebral spines are affected, and occasionally these structures necrose.

In the early stage, the supraspinous bursa distends with a clear, straw-colored, viscous exudate. The swelling may be dorsal, unilateral, or bilateral, depending on the arrangement of the bursal sacs between the tissue layers. It is an exudative process from the beginning, but no true suppuration or secondary infection occurs until the bursa ruptures or is opened.

Treatment and Prevention: The earlier treatment is instituted, the better the prognosis. The most successful treatment is complete dissection and removal of the infected bursa. The expense of the protracted treatment required in chronic cases often exceeds the value of the animal. *Brucella* vaccines have not proved helpful. Sodium iodide therapy is of limited value.

CHLAMYDIAL POLYARTHRTIS-SEROSITIS

(Transmissible serositis)

Chlamydial polyarthriti-serositis is an infectious disease that affects sheep, calves, goats, and pigs. Chlamydial polyarthriti of sheep was first described in Wisconsin and has since been recognized in the western USA, Australia, and New Zealand. The disease was identified in calves from the USA, Australia, and Austria, and in pigs from Austria, Bulgaria, and the USA.

Etiology and Epidemiology: Strains of the causal agent, *Chlamydia psittaci*, isolated from affected joints of sheep and calves, are identical, but strain-specific antigens in their cell walls distinguish them from those that cause abortions in sheep and cattle (see p 1332).

The GI tract is of prime importance in the pathogenesis of chlamydial polyarthriti (see p 598). The disease has been reproduced experimentally by oral inoculation. Because chlamydiae can be recovered from the feces of clinically healthy calves and lambs, it is most likely the GI tract wherein the host and parasite stay frequently in balance. If there is a shift in favor of the chlamydiae, then a systemic infection and chlamydenia ensues; the ultimate site of replication is the synovial membrane. The GI tract also has been infected after experimental intra-articular inoculations. Chlamydiae are excreted in the feces and

urine and transmitted via ingestion or, in some cases, inhalation.

Clinical Findings: Chlamydial polyarthriti is seen in lambs on range, on farms, and in feedlots. Morbidity may be 5%–75%. Rectal temperatures are 102°–107°F (39°–41.5°C). Varying degrees of stiffness, lameness, anorexia, and a concurrent conjunctivitis (see p 506) may be seen. Affected sheep are depressed, reluctant to move, and often hesitate to stand and bear weight on one or more limbs, but they may “warm out” of stiffness and lameness after forced exercise. Incidence of the disease in sheep on range is highest between late summer and early winter.

The disease affects cattle of all ages, but calves 4–30 days old are affected more severely. Calves may have fever, are moderately alert, and usually nurse if carried to the dam and supported while sucking. They invariably also have diarrhea, which can be severe. Affected calves assume a hunched position while standing; their joints usually are swollen, and palpation causes pain. Navel involvement and nervous signs are not seen.

Chlamydial polyarthriti has been recognized in older pigs as well as in young piglets. The affected piglets become febrile and anorectic and may develop nasal catarrh, difficulties in breathing, and conjunctivitis. This condition has not been clearly differentiated from other infections that lead to polyserositis and arthritis in pigs.

Lesions: The most striking tissue changes are in the joints. In lambs, enlargement of the joints is not often noticed, but in chronic advanced cases, the stifle, hock, and elbow may be slightly enlarged. In calves, periarticular subcutaneous edema along tendon sheaths and fluid-filled, fluctuating synovial sacs contribute to enlargement of the joints. Most affected joints of lambs or calves contain excessive, grayish yellow, turbid synovial fluid. Fibrin flakes and plaques in the recesses of the affected joints may adhere firmly to the synovial membranes. Joint capsules are thickened. Articular cartilage is smooth, and erosions or evidence of marginal compensatory changes are not present. Tendon sheaths of severely affected lambs and calves may be distended and contain creamy, grayish yellow exudate. Surrounding muscles are hyperemic and edematous, with petechiae in their associated fascial planes.

Diagnosis: The history and careful examination of the pathologic changes in the joints and other organs can be of

diagnostic value. Cytologic examination of synovial fluids or tissues may reveal chlamydial elementary bodies or cytoplasmic inclusions. Isolation and identification of the causative agent from affected joints confirms the diagnosis. Bacteriologic cultures of affected joints are usually negative, but *Escherichia coli* or streptococci occasionally may be isolated. If the joints of young calves are arthritic, and if navel lesions are absent, chlamydial polyarthritis should be considered.

Clinical and pathologic features distinguish chlamydial polyarthritis from most other conditions that cause stiffness and lameness in lambs. Lambs with mineral deficiency or osteomalacia usually are not febrile. The abnormal osteogenesis in these two conditions and the distinct lesions of white muscle disease are virtually pathognomonic. In arthritis caused by *Erysipelothrix rhusiopathiae*, there are deposits on and pitting of articular surfaces, periarthral fibrosis, and osteophyte formation. Laminitis due to bluetongue virus infection (see p 738) can be differentiated clinically and etiologically. Detailed microbiologic investigations are required to differentiate chlamydial arthritis from mycoplasmal arthritis.

Treatment and Prevention: If begun early, therapy with long-acting penicillin, tetracyclines, or tylosin appears to be beneficial. More advanced lesions do not respond satisfactorily. Feeding chlortetracycline at 150–200 mg/day to affected lambs in feedlots reduces the incidence of chlamydial polyarthritis. No approved vaccines are available.

TENOSYNOVITIS

Tenosynovitis, an inflammation of the synovial membrane and usually the fibrous

layer of the tendon sheath, is characterized by distention of the tendon sheath due to synovial effusion. It has a number of possible causes and clinical manifestations. The various types of tenosynovitis include idiopathic, acute, chronic, and septic (infectious). Idiopathic synovitis refers to synovial distention of tendon sheaths in young animals, in which the cause is uncertain. Acute and chronic tenosynovitis are due to trauma. Septic tenosynovitis may be associated with penetrating wounds, local extension of infection, or a hematogenous infection.

Clinical Findings and Diagnosis: There are varying degrees of synovial distention of the tendon sheath and lameness, depending on the severity. Horses are markedly lame in septic tenosynovitis. Chronic tenosynovitis is common in horses in the tarsal sheath of the hock (thoroughpin) and in the digital sheath (tendinous windpuffs). These two entities must be differentiated from synovial effusion of the tarsocrural and fetlock joints, respectively.

Treatment: In idiopathic cases, no treatment is initially recommended. Acute cases with clinical signs may be treated symptomatically with cold packs, NSAIDs, and rest. Tenoscopic surgery is often used to treat specific conditions within the tendon sheath that give rise to tenosynovitis symptoms. Application of counterirritants and bandaging has been used in more chronic cases. Septic tenosynovitis requires systemic antibiotics and drainage. If adhesions develop between the tendon sheath and the tendon, persistent effusion and lameness is the rule.

LAMENESS IN CATTLE

DIAGNOSTIC PROCEDURES

The lesions that cause lameness in dairy cows result in intense pain and are a major animal welfare issue. Lameness also causes stress, which debilitates and reduces productivity. The financial impact of lameness includes losses from decreased production, cost of treatment, prolonged calving interval, and possibly nursing labor.

Loss of milk of 1.7–3 L/day for up to 1 mo before and 1 mo after treatment (because of pain) plus milk discarded because of antibiotic therapy must also be considered. Lame cows are more reluctant to use automatic milking systems and show visible signs of stress when forced to do so.

At least 10% of cows in a herd are culled for reasons related to lameness. Rearing replacement heifers is expensive, and

replacement animals are not initially as productive as mature cows. Cows in poor condition have a greater predisposition to lameness. Cows that are lame before breeding have a reduced ability to conceive, and cystic ovaries are much more common in lame cows. Lame cows are less aggressive in their struggle for feed and are more likely to die early or be culled.

Considerable funds are being invested in bovine lameness research; within the next decade, national databases detailing bovine lameness are expected to become increasingly available as a management tool. Although the lameness data are being collected primarily by hoof trimmers, veterinarians should be familiar with this information to continue to play a leading role in management of bovine lameness.

PHYSICAL EXAMINATION OF A LAME COW

Visual Appearance of the Standing Animal:

Abrasions or swellings on the limbs suggest a prior traumatic event. Decubital lesions (to the knee or more often the hock) might indicate prolonged periods of recumbency or difficulty when rising. Cubicle design should be reviewed. Muscular atrophy, particularly noticeable in the gluteal region, can be associated with a painful condition such as arthritis. Cows experiencing extreme pain can lose body condition rapidly.

Stance or posture can change as the bearing surface of the claw wears or there is a painful lesion in the foot. In a normal stance, the point of the hock (tuber calcanei) lies directly beneath the pin bone (ischial tuber) when viewed either from the side or from behind. Approximately 60% of the body weight is borne by the forelimbs. A lame animal adjusts its posture to relieve pain.

The following principles illustrate specific examples of changes in stance or posture related to lameness: 1) A painful abscess in a lateral hind claw causes the cow to abduct that limb. 2) Pain in the heel of the hind foot forces the cow to hold its foot to the rear, a posture known as "camping back" or retraction. 3) After a cow has spent much time walking on concrete, the lateral hind claw may become overburdened (excessive buildup of solebar horn). This forces the hock to turn inward, a posture referred to as "cow hocked." 4) Pain in the toe, which occurs in laminitis, causes the cow to hold its hind feet further forward than normal, a posture referred to as "camping forward" or protraction. This

posture can be confused with a conformational defect referred to as "sickle hock," in which the angle of the hock is $<160^\circ$. 5) When the angle of the hock is $<180^\circ$, the posture is referred to as "post leg," an undesirable conformational characteristic associated with arthritis. 6) When the hind feet are held closer together than normal (adducted), pain in the medial claw is indicated. The cow is said to be "standing narrow." This posture is often confused with a trait of conformation called "bow leg." Standing narrow can be a sign of laminitic-related lesions in the medial claw.

These principles of abnormal posture can be used to deduce the region of the foot in which the seat of lameness is located. Use of hoof testers may be one way to confirm the observation. For example, if there is pain in the toe, the retraction phase of the stride (when the foot passes behind the phase of vertical weight-bearing) is reduced considerably. In contrast, if there is pain in the heel, the protraction phase of the stride is reduced, or the foot is not carried as far forward as normal. Usually, the gait of one limb can be compared with that of the contralateral limb when viewed from the side. However, lameness simultaneously present in contralateral limbs tends to appear less severe than is actually the case. It is not unusual in cases of subacute laminitis for all limbs to be affected more or less equally. In these cases, no specific gait change is seen, but the cows tend to place their feet carefully with each step, ie, they "plod" or have a stilted gait.

Examination of the Claw: In cows exposed to concrete surfaces for a prolonged period, the sole of the lateral claw is likely to be worn flat and become much wider than that of the medial claw. Such soles are highly subject to trauma.

To facilitate examination of a completely flat claw, the surface of the sole should be washed and examined carefully for black marks by exploring with a hoof knife. If the sole is heavily caked with mud or manure (eg, cows at pasture or confined in corrals or straw yards), it is quicker and easier to cut off a layer of superficial horn together with the caked material to expose fresh horn beneath. Particular attention should be paid to the abaxial white line area. Removal of large amounts of sole horn is contraindicated in the diagnostic phase of an examination. The interdigital space should be evaluated by separating the claws and examining carefully for evidence of a foreign body, fibroma, footrot, interdigital dermatitis, or digital dermatitis.

LOCOMOTION SCORING

Locomotion scoring is a useful tool as part of a routine herd health evaluation or in a detailed herd lameness investigation.

Most farmers will detect between only 25% and 40% of truly lame cows; this underestimation of lameness prevalence means that the economic consequences of lame cows are less obvious to farmers than those caused by mastitis (loss of milk) and fertility problems. Cows in the early stages of sole ulcer, white line disease, and toe necrosis syndrome show only slight signs of lameness; if these lesions can be identified in their early stages, they can be treated and preventive measures instituted.

Locomotion scoring identifies slightly lame cows as well as those more obviously lame. Therefore, use of locomotion scoring can demonstrate the real extent of the problem.

Herd assessments should be done when the cows are walking on level, unobstructed walkways that give the observer a clear view. Locomotion scoring is frequently performed when the cows are leaving the milking parlor. In addition, milkers should note any cow standing in the milking parlor with an arched back, because it is highly probable that such cows are lame. Any cow lying down for an abnormally long time (>70–80 min/vout) should also be noted for special attention.

Locomotion scoring is a 5-point system based on both gait and posture: 1) Normal: The cow is not lame; the back is flat. 2) Mildly lame: The back is slightly arched when walking. 3) Moderately lame: The back is arched when both standing and walking. The cow walks with short strides in one or more legs. 4) Lame: The lame cow can still bear some weight on the affected foot. 5) Severely lame: The back is arched; the cow refuses to bear weight on the affected foot and remains recumbent. (Some observers use a 4-point scoring system, referring to normal as zero.) The repeatability of locomotion scoring is acceptably high among experienced observers.

As the locomotion score increases, milk yield decreases; however, the composition of the milk (fat, protein) remains unaffected.

COMPUTERIZED RECORDING OF DIGITAL LESIONS

Recording foot lesions by hoof trimmers is one of the most valuable advances in hoof health care and can be used to demonstrate the seriousness of the problem. In many cases, the data indicate the risk factors to be investigated. Any defect in the animal's environment that leads to some stress or

foot abnormality is considered a risk factor. When a risk factor has been identified, control measures can be instituted before the problem becomes difficult to control. Lameness in cattle is a clinical sign of pain with many possible causes that require investigation. Methods to record lesions and rating severity are not yet standardized, but computer programs are available. In many countries, as many as one-third of hoof trimmers can provide this service and accurately identify and describe the severity of foot lesions.

In one survey, 86% of lesions recorded were found in the lateral claw of hindlimbs and 14% in the forelimbs; 73% of forelimb lesions were observed in the medial claw.

The National Database in Denmark also contains information about milk yield, reproductive status, health, etc. The prevalence of lesions must be interpreted carefully, because not every cow with a lesion will show signs of lameness. However, an abnormally high incidence of lesions may forecast lameness to come. The findings would indicate the urgency with which preventive measures should be implemented. The incidence of lesions varies considerably between countries and between regions of the same country. Lesion incidence also changes with different management system practices (eg, tie stall and free stall) as well as with variations during seasons of the year.

The annual herd incidence of lameness can be extremely high; in unique cases as many as 60% of the cows are affected at least once. However, even a 10%–15% incidence represents a significant economic loss.

DISTAL DIGITAL ANESTHESIA FOR DIAGNOSTIC AND SURGICAL PROCEDURES

For distal digital analgesia (used for surgical or diagnostic procedures), the dorsal site is located on the dorsal axis proximal to the interdigital space close to the metacarpal or metatarsal phalangeal joint. The needle should be placed with care (because the proper digital artery can be found at the dorsal site), and 10 mL of 2% lidocaine injected. If the needle is inserted deep into the interdigital space, the nerves of the flexor surface can be reached. This obviates the necessity of a flexor site block for simple procedures. The distribution of the nerve supply to the axial face of the digits of the forelimb is not constant, which makes this technique unreliable for digital analgesia of the forelimb.

The preferred flexor site is a little lower than the dorsal site because it is difficult to

pass a needle through the partially cartilaginous palmar/plantar ligament. The medial and lateral sites are located at the level of the dewclaws, and the needle is inserted dorsally (horizontal in the standing animal) from a point 2.5 cm slightly proximal to the dewclaws. For the flexor site and the medial and lateral sites, ~5–8 mL of 2% lidocaine is injected. For surgery of the digit (eg, amputation), the dorsal, palmar/plantar, and medial or lateral sites are used, depending on the claw. For interdigital surgery (eg, removal of corns), both the dorsal and palmar/plantar sites are used. Differential diagnosis can be aided by selective anesthesia of the nerves of the digit.

The diagrams above illustrate the sites for four regional nerve blocks in the front and hind feet. The site selected should be perfused with 10 mL of 2% lidocaine using an 18–20 gauge needle.

Intravenous regional analgesia is frequently used for lengthy surgical procedures such as arthrodesis. Sedation and restraint is advised. A tourniquet is applied just below the hock or knee, the hair is clipped, and the skin sterilized from a site over a vein. Lidocaine (10–30 mL) without epinephrine is injected to produce analgesia within ~10 min. The tourniquet should never be kept in place for >60 min. When surgery is complete, the tourniquet should be loosened gradually to prevent a flood of anesthetic suddenly entering the general circulation. Concurrent injection of antibiotic may be helpful.

RADIOGRAPHY

Radiography of the Digital Region:

Radiography can help identify the site of lameness and provide information about the stage to which the pathology has progressed. This helps to determine the most advantageous treatment. When pathologic changes are seen in the region of the distal interphalangeal joint, tissue damage is often rapid and severe.

Before a radiograph is taken, the interdigital space and both claws should be cleansed thoroughly, and both claws lightly trimmed. If this is not done, false images or shadows may mask abnormalities present in the claws. The digits can be viewed radiographically using four angles or projections.

In the dorsopalmar/plantar projection, the image produced shows all of the major bones and joints without overlap. This view allows diagnosis of many diseases of the bovine foot.

In the oblique projection, the plate is positioned beneath the claw, and the head of the machine is placed dorsad to the digits

and rotated backward at a 45° angle. Because cattle have two digits that overlap one another when viewed radiographically from the side, an abnormality may be unclear or obscured. The oblique view allows the digit to be viewed from such an angle that one claw appears to be behind the other, which gives a much clearer picture than can be obtained when the digits are superimposed. Because each digit is projected differently on an oblique view, it is best to compare two radiographs of oblique views taken at comparable but opposite angles.

The lateromedial or mediolateral projection is generally of much less value than the oblique view. However, because positioning is relatively easy, this view is useful to evaluate fractures, fracture repairs, and luxations.

In the axial projection, a lateromedial or mediolateral view of a single claw is accomplished by placing a nonscreen film (eg, a paper "cassette") between the digits. This view produces a good image of the affected distal phalanx and, if interdigital soft-tissue swelling is not too great, the distal interphalangeal joint.

Radiographic Analysis and Interpretation:

A number of factors should be considered in radiographic analysis and interpretation. Age differences can be seen radiographically as differences in skeletal development. In calves, physes are present in the distal metacarpus and metatarsus and at the proximal ends of the proximal and middle phalanges. In a very young calf, the distal phalanges may be incompletely ossified so that the bones appear small, and their distal ends are rounded and indistinct. The subchondral bone may appear indistinct and finely irregular; this should not be mistaken for the subchondral bone lysis seen in septic arthropathy.

Diseases stimulating periosteal new bone in cattle (such as corkscrew claw and postrecovery septic arthritis) can cause marked changes in bone contour and increased bone opacity.

Slight bony changes at articular margins and musculotendinous attachments are commonly seen on radiographs of older cattle. Roughening of the distal surface of the distal digit is a normal sign of aging. Changes that occur during the normal aging process should not be confused with active bony changes.

Reactive new bone (osteophyte, enthesiophyte, or exostosis) that has been present for some time has a distinct border and a rough outline, and the opacity is normally even. Active new bone has an

indistinct border and a rough outline, and the opacity is uneven.

Diffuse loss of bone opacity occurs in subacute laminitis, nutritional bone disease, and after limb immobilization. Focal or localized loss of bone opacity occurs in bone infection (osteomyelitis) or inflammation (osteitis), early fracture healing, and with defects in endochondral ossification (osteochondrosis).

Increase in joint width is caused by the presence of increased fluid in the joint. However, this is less evident if the animal is bearing weight at the time the radiograph is taken. To confirm that the joint is in fact wider than normal, it may be compared with the contralateral joint.

Indistinctness and loss of opacity of the subchondral bone are often associated with joint infections. Loss of opacity is often irregular. For this reason, a single radiograph is unlikely to detect this pathology; therefore, several radiographs taken from different angles are usually advised. Comparison between suspect and known normal joints is recommended. Subchondral bone may be indistinct in a young animal.

Radiography is important to evaluate the progress of a fracture repair. A radiograph taken immediately after a fracture has been realigned is the basis for future evaluations, and subsequent radiographs are essential if nonunion or bone infection is suspected.

Loss of bone opacity is difficult to recognize with certainty in metabolic and nutritional diseases. Because all of the bones in the body may be equally affected, it is not helpful to compare one bone with another. In an adult animal, cancellous regions in the bone ends may become coarser or "granular" in appearance as smaller bone trabeculae are resorbed. In the diaphysis of a normal bone in both immature and adult animals, the cortex is thickest at midshaft and becomes thinner toward both ends. If the cortex at midshaft approaches the thinness of the proximal and distal diaphyses, generalized osteopenia must be suspected.

Soft-tissue swelling can be demonstrated on radiographs only in the early stages of a septic disease. The characteristics of a soft-tissue swelling may indicate the location of a lesion and the tissues involved, muscle or tendon disease, cellulitis or edema, or dark gas shadows (eg, a sinus or a cap of an abscess).

ARTHROCENTESIS AND ARTHROSCOPY

Arthroscopy enables visualization of the interior surfaces of a joint for diagnostic or

surgical purposes. Arthrocentesis is a procedure by which synovial fluid may be removed from a joint for examination. Local anesthetic can be introduced to ascertain whether painful lesions are present in the joint. Intra-articular therapy permits medication to be deposited into the joint. Because this procedure may be painful, a nerve block at a higher level is recommended.

For the distal interphalangeal joint, the needle is inserted lateral to the common or long extensor tendon, which inserts into the extensor process of the distal phalanx. The entry point is just proximal to the coronary band. For the pastern joint (proximal interphalangeal joint), the needle is inserted lateral to the extensor tendon. For the fetlock joint (metacarpophalangeal or metatarsophalangeal joint), the needle is directed downward close to the bone and between it and the interosseous (suspensory) ligament. The joint can also be entered from the dorsal surface in a similar manner to the distal joints; however, the flexor pouch is more capacious than the dorsal one. For the digital synovial sheath (sheath of the deep flexor tendon), the needle is directed downward behind the interosseous ligament.

For the stifle joint, it is advisable to use two sites because in some animals the lateral femorotibial compartment may not communicate with the rest of the joint. The first site is close behind the lateral patellar ligament (lateral femorotibial compartment), and the needle should be directed caudally. The needle is inserted in the second site between the medial and middle patellar ligaments and directed slightly down and toward the large medial lip of the trochlea (femoropatellar and medial femorotibial compartments).

RISK FACTORS INVOLVED IN HERD LAMENESS

Lameness is a clinical sign of different diseases or disorders. For each condition, the range of causal risk factors and their severity varies; therefore, each condition has its own epidemiologic study. The importance of each factor differs depending on the system of management, be it total confinement, less restrictive systems, or totally pastoral. Management factors can usually be controlled, whereas factors such as ambient temperature, humidity, and rainfall must be taken into consideration but cannot be controlled entirely.

The diseases and disorders that affect the feet of dairy cows fall into two broad

categories: those caused by infectious agents and those attributable to management.

The following variables can be controlled: nutrition/water, walking surfaces, resting and stress (cow comfort, social confrontation, stocking density), cleanliness/hygiene (prevalence of infectious agents/moisture/irritants), human care (hoof trimming, footbathing, lesion recording, farmer education), and genetic considerations.

If lameness has become a significant problem on a farm, it is invariably too late for a quick resolution. The first step is to immediately obtain the services of a competent hoof trimmer who preferably uses a chute side computerized lesion recording system (see p 1068).

Objective methods to assess risk factors have been developed; progress is needed to develop more objective methods to assess human care, farmer awareness, facility hygiene, and the stressors to which cows are subjected.

Heritability: Correlations between genetics and lameness are being investigated in several European countries. It is thought that different lesions may have different degrees of heritable susceptibility. There is even some proof that the benefits of hoof trimming have a heritable component.

In Sweden a "Bull Index" has been created so that farmers may select sires whose progeny have a low predisposition for lameness.

Nutrition: Subacute ruminal acidosis (SARA) is a common problem in high-producing dairy herds. Volatile fatty acids (VFAs) produced by microorganisms in the rumen are absorbed by rumen papillae. The papillae shrink during the dry period and need to be developed by lead feeding. If the surface of the papillae is inadequate, the pH of the rumen contents drops.

Successfully managing SARA depends on the quantity and digestibility of the carbohydrate fed. The more rapidly carbohydrate is digested, the more rapidly rumen acidosis will develop. Finely ground or moist grains are more digestible than dry, cracked grain. Corn silage is frequently used in dairy production. Sometimes the energy content of the silage is completely underestimated, with disastrous results. Slug feeding once a day is contraindicated, and the more frequently concentrates are fed the better. Sudden changes in the diet or formulation of the diet are extremely dangerous. Component-fed cows should be given up to 7.5% of their body wt in concentrates around calving. After calving, it is safest if rations are not

increased by more than 0.25 kg/day for multiparous cows and by 0.20 kg/day for primiparous cows to a maximum of 14–16 kg (30–36 lb).

The quality and quantity of fiber fed could be more important than the carbohydrate component of the diet. Fiber can, depending on its physical characteristics, stimulate rumination. If the carbohydrate:fiber ratio is >50% carbohydrate, the animal is increasingly at risk of ruminal acidosis. If the percentage of acid detergent fiber for the complete ration is <20%, risk of ruminal acidosis also increases. If the particle length of silage is cut too short (25% cut <5 cm long), the contribution of effective fiber is reduced.

If a nutritional problem is suspected, a "walk around" should be done. Feed storage facilities should be evaluated for clues. For example, different batches of feed may be of different textures or colors. Changing from one silage storage unit to another can indicate a possible sudden change in diet characteristics. Sometimes feed is purchased off-farm even from several different suppliers.

The manure should not contain fiber particles <1 cm of undigested grain. This can be checked by placing 2 cups of manure in a fine mesh kitchen sieve and washing the material through with water from a hose. Feces should not contain mucin/fibrin casts, be foamy, or contain gas bubbles. The feces in the same feeding group should not vary from firm to diarrhea. Rumencentesis can be performed as a last resort.

There should be a drinking station for every 15 cows. The water supply should be clean and free of static electricity. A high level of iron in drinking water can affect palatability.

Walking Surfaces: Walking surfaces are another important contributing cause of lameness. The Nordic countries have pioneered the use of rubber matting. One UK study showed that cows enter and exit the milking parlor more rapidly on rubber matting than on concrete. In addition, sole horn wears less on rubber than on concrete. Of course, rubber is fully effective only if kept free of slurry. Installing rubber matting is expensive but a reasonable recommendation. The best flooring system from the perspective of lameness is slats with rubber caps, but this is reasonable only for new installations or major upgrades.

Resting, Stress, Cow Comfort, Social Confrontation, Stocking Density:

These risk factors together with other physical stressors have been referred to as

ecopathologic factors or an Animal Suitability Index. These terms refer to an assessment tool for housing conditions based on seven spheres of influence: walking, feeding, socializing, resting and comfort, behavior, hygiene, and care. Ecopathology, therefore, is evaluation of space allowance, cubicle dimensions, stall base, bedding, stall and pen measurements, type of flooring, slipperiness, stocking density, cleanliness, hoof trimming and footbathing, feed bunk space, water supply, walking surface conditions, and mobility locomotion score.

Under normal conditions, a healthy cow rests 10–11 hr/day. Resting periods usually last just longer than 1 hr, during which time the cows ruminate and thus digest their feed. Lameness, depending on its severity, tends to increase both the lying time and the number of lying bouts.

Anything that inhibits a cow from lying down is of particular concern. This can be assessed rapidly by use of the Cow Comfort Index (CCI), which should be calculated 1 hr before milking. The number of cows lying in a stall should be divided by the number of cows standing or in any way touching the stall. It is assumed that cows standing and touching the stall are showing a desire to rest; thus, the higher the CCI, the more probable there is a problem. If the incidence of noninfectious lameness is also high, then cow comfort is a risk factor to be dealt with. Cows not involved in calculating the CCI are those drinking, eating, or just walking. Unwillingness to lie down because of remembered discomfort is another reason for prolonged standing. However, inability to exercise reduces the amount of oxygen and nutrition delivered to the claw.

Stall size is important but varies depending on the frame size of the cows in a herd. The partitions must be of space-sharing design. If the overall slope of the stalls is adequate, the cows will lie with their hindlimbs all running in the same direction.

Cows prefer sand stalls above all other surfaces. The sand keeps cows cool and provides good footing to rise. Mattresses filled with rubber crumbs are acceptable; concrete covered with straw or sawdust and hard rubber mats are less desirable.

When a cow rises, she is forced to lunge forward; anything that makes that difficult should be corrected. Neck rails (never cables) should be 37–43 in. above the stall. A brisket board is important, and flexible structures are available to reduce the risk of hematomas of the brisket. Loose house stalls built facing a wall are a poor configuration. Cows should not be forced to lie or stand with their hindlimbs in the alley.

Stress is a factor that can and has been measured in cows. Stress may play a role in causing lameness, and lameness itself is a cause of stress. Stress may also be an etiologic factor in both reproductive failure and in some types of mastitis infections. Social confrontation may be a surprising cause of stress. The matriarch cows dominate the pecking order. Presumably, a submissive animal is somewhat stressed when confronted by a dominant animal in a narrow alley. Prolonged standing, waiting in line to drink, or spending >3 hr in the holding yard each day are commonly overlooked factors. Overstocking increases the occasions on which cows of significantly different dominance will face one another. This is particularly noticeable when heifers are first admitted to the milking herd. This may also be the first time heifers ever encounter concrete. Heifers should always be given 1 mo to adapt to concrete before the added stress of facing dominant cows. Alleys should never be <12 ft wide, feed alleys 13 feet wide, and loafing alleys 14 feet. There must be more cubicle stalls and feeding standings than there are cows. All too commonly, a building built to hold 50 cows is modified to take 100–150 cows, with resulting catastrophic overstocking.

Cleanliness and Hygiene: When the prevalence of digital dermatitis is unacceptably high, contamination should be reduced, especially if the hind ends of the cows are caked in muck. Possibly the most commonly used slurry removal system is the scraper fixed to the front of a tractor. Although this system is acceptable, it is commonly not done often enough. Automatic scrapers are costly to install and subject to mechanical breakdowns. The overall effectiveness of flushing systems remains questionable.

The presence of any slurry during a clinician visit should evoke comment.

Farmer Education: Priority must be given to improving farmers' knowledge and increasing their willingness to implement recommendations, including routine examination (by the farmer) of the herd for lame cows. However, in the UK and France, lack of time and labor are reported as the most important barriers to detecting and treating lameness.

Special efforts should be made to help farmers understand the gravity and complexity of an increasing herd lameness problem. Information pamphlets, regional seminars, and hands-on on-farm

demonstrations with a hoof trimmer and nutritionist involved can all be useful.

PREVENTIVE PROCEDURES

FOOTBATHS

Dry cows (and infected heifers) should be included in the footbathing routine.

Permanent, concrete footbaths may measure 3 m (10 ft) long and 0.2–0.6 m (8–24 in.) wide. The sides of the bath should not slope inward and should be 15–25 cm (6–9 in.) deep. Cows prefer to use footbaths that have a bottom close to floor level; therefore, a built-up block “rounded lip” could be considered in the design. The medicated solution should be a minimum of 8–10 cm (3–4 in.) deep. Drainage from the bath should be provided to ensure the foot can be properly cleansed. To avoid blockage, the drain hole should be 10–20 cm in diameter and located at the lowest point of the bath.

Footbaths should be located in relation to the exit from the milking parlor in a frost-free environment with, ideally, an area suitable to drain chemicals from the feet to avoid contaminating the bedding. At all costs, deviation from the normal free flow of cow progression should be avoided.

Prewashing the feet before entering the footbath has been increasing in popularity. Ideally, the wash bath should be located before the cows enter the milking parlor. This allows time for washing fluid to drain before cows enter the chemical bath. The dimensions should be similar to those of the medication bath.

Use of a footbath is not a substitute for either good hygiene or claw trimming. However, if digital dermatitis is endemic on a farm, regular use of a footbath is mandatory.

Plastic, fiberglass, or metal portable footbaths should be avoided. A hoof mat, consisting of a sheet of foam plastic encased in a perforated plastic cover, is also available. The foam is soaked in medication that squirts up between the claws when the cow walks on the mat. There are no recent reports on the effectiveness of this device.

Fully automated power spray washers are claimed to be extremely economical in the use of water, and they require no operator. They deliver soapy water, and some users believe this device alone reduces the incidence of foot disease.

Chemical Agents for Footbaths:

Formalin 4% is the least expensive footbath solution for the control of interdigital

phlegmon (footrot). Some cows will refuse to enter a formalin footbath if the solution is stronger than 4%. Formalin has been found of value to control digital dermatitis. The solution should be changed after the passage of ~200 cows, more frequently if the bath is heavily contaminated with manure. Formalin has good bacteriostatic activity and some potential to harden the epidermis. However, it is ineffective at temperatures < 13°C.

Formalin generates strong fumes that irritate the lungs of milkers and can taint milk. It should never be used in baths located near the milking parlor.

The stronger the formalin solution used, the more effective it is, but the danger of a chemical burn on the cow's skin is also greater. If the hair on the foot appears to be standing on end or the skin is pink, bathing should be suspended. Normally, cows can tolerate twice daily baths for 3 days using a 3% solution. The treatment should be repeated every 3 wk. Higher concentrations should only be used for the most resistant conditions.

Formalin is regarded as a hazardous waste, and land disposal restrictions should be checked and followed. Formalin must never be released into sewer systems, because sewer treatment plants may have problems and contaminated drinking water could be released. However, formalin is said to break down in 7 days in sludge or slurry; even then, it is wise to wait until it is diluted to one part formalin in three parts sludge before spreading it on arable land.

Preferably, the land selected should not have a high water table. Unused formaldehyde concentrate should be returned to the vendor.

Footbathing with a 5% solution of **copper or zinc sulfate** controls interdigital dermatitis and is of some value in controlling footrot (interdigital phlegmon). There are two grades of copper sulfate, and the pentahydrate grade should be used. The solution must be prepared 5 hours before use. Prewashing of the cow's feet is advised, and the solution should be changed after the passage of ~200 cows.

Copper has a strong affinity to be bound by soil, the organic matter in manure, and soil minerals. Hence, much of the copper found in soil is unavailable for plant uptake. Once the copper reaches a high level in the soil, the process cannot be reversed. Therefore, plants stunted by high levels of copper have a lower nutritional value to cattle. Copper sulfate footbath solutions may be tagged to slurry at the highest practical dilution and spread widely on the land.

The sulfates are quite rapidly deactivated by combining with the proteins in manure.

The use of **antibiotics** in footbaths has been a popular past strategy for the treatment, control, and prevention of digital dermatitis. Few reports on the use of antibiotics in footbaths appear in the current literature. Antibiotics are expensive and deteriorate in contaminated solutions. The type of antibiotic used in footbaths should be changed at intervals of ~6 mo to avoid development of resistant strains of the causal organisms. However, treatment may be given for 2–3 days and repeated once after 7 days. Formalin footbaths may be used alternately if more aggressive treatment is necessary. Antibiotics used in footbaths do not result in detectable levels of drug in the bloodstream or milk. Antibiotic sprays or powders are still used for topical treatments.

A new generation of chemical agents has been developed for use in footbaths, but claims of effectiveness have not yet been adequately substantiated in controlled trials. Foams are also available but the cost of associated equipment is considerable. Foams keep the chemical agent in contact with lesions better than liquid products.

FUNCTIONAL CLAW TRIMMING

The role of the professional claw trimmer has changed significantly during the past decade. The introduction of chute-side computerized data collection is providing valuable data; however, it also requires additional training in lesion identification. Close collaboration between trimmer and veterinarian is beneficial for both as well as for the dairy industry overall.

Over time, the claws of cows wear, changing the shape of the sole, which in turn makes the foot unstable. The two claws become unbalanced both longitudinally and laterally. As changes develop in the lateral claw, it becomes “overloaded,” the heel horn may become thicker (overburdened), and posture is compromised. Therefore, the objective of trimming is to reduce excessive weight bearing on load-bearing claws.

Under normal circumstances, horn growth keeps pace with wear. The growth/wear rate at the heel is greater than at the toe. Horn that is dry tends to be extremely resistant to wear and may grow longer than normal. Thus, the claws of cattle maintained in straw yards tend to become overgrown. Conversely, the claws of cattle maintained in extremely wet conditions are softer than normal and more prone to wear and damage. If the cows are housed on concrete

surfaces, the lateral hind claw tends to wear less than the medial.

If claws are routinely correctly trimmed, longevity of the herd may be extended. Trimming can be expected to decrease milk yield by up to 2 lb/day for 2 days but should be restored or even increase in a similar period. Decrease in milk yield is partly due to disruption in the cow's feeding routine and handling. To some extent, variations in milk yield reflect on the skill of the trimmer. Trimming should be avoided in any location close to the milking parlor, and individuals handling the cows should never attempt trimming. Unskilled claw trimming will negatively affect the claw health of a herd and should be avoided. All claws should be evaluated before trimming. On average, the front (dorsal surface) wall of a hind claw measures ~7.5 cm long from apex to hair line. When the dorsal wall increases in length, the dorsal surface of the claw tends to become concave (buckles like the instep of a human shoe). This causes greater weight-bearing to be transferred to the posterior aspect of the claw, increasing pressure on the flexor process of the distal phalanx, the point beneath which sole ulcers develop. The longer the toe, the greater the stress on the flexor system. When the claws are short and the dorsal wall is >7.5 cm, there is considerable risk that the thickness of the sole at the apex will be less than the desirable 7 mm. Thinning of the apex of the sole of short-clawed animals should be avoided.

Foot trimming of every cow in a high-production, intensively managed herd is recommended every 5 mo. Recording and reporting (to the veterinarian) the types of lesions observed will prompt early treatment and timely introduction of preventive measures.

PREVALENT LAMENESS DISORDERS IN INTENSIVELY MANAGED HERDS

Although there are many important lesions, most lameness protocols are based on data from digital dermatitis, sole ulcer, white line disease, toe necrosis/apical syndrome, and sole hemorrhage. Early identification of lesions permits early treatment, which significantly reduces the recovery period.

The incidence of lameness in pastured dairy cattle in New Zealand is extremely low; the risk factors associated with housing do not exist in that country. Pasture management is also common in Chile.

DIGITAL DERMATITIS

(Hairly warts)

Digital dermatitis is the most common disease of the feet of mature dairy cattle and is endemic in intensively managed dairy operations worldwide. It tends to mask or overshadow other more painful lesions present concurrently. Incidence is low in pastoral settings such as in New Zealand and Chile. The presence of the disease in beef cattle appears to be minimal.

Clinical Findings: Two main types of lesions are seen. The erosive/reactive form is seen more commonly in Europe, whereas the proliferative or wart-like form is more prevalent in North America. Both forms cause varying degrees of discomfort and may give rise to severe lameness. Both forms can be seen in the same animal. The two forms likely represent different stages of the same disease process.

Explosive outbreaks can occur when affected cows are introduced to previously unaffected herds.

Treponema-like organisms can be observed in microscopic samples isolated from most lesions. However, the number of strains of *Treponema* affecting cattle can be as high as 80, some of which may be oral or rectal. It would be wise not to incriminate just one strain as the cause because of the numerous manifestations of digital dermatitis. Digital dermatitis is likely to be polytreponemal (eg, *T phagedenis*, *T vincentii*, and *T denticola*).

Digital dermatitis is much more prevalent if hygiene is poor and the feet are exposed frequently to slurry. It is widely believed that a number of predisposing bacteria are involved. It has been postulated that the once ubiquitous *Dichelobacter nodosus* may be an important synergizing agent; *Campylobacter* spp and *Prevotella* spp may also be involved in the etiology.

Skin maceration and the presence of a semi-anaerobic environment are important predisposing factors. Many treponemes are found in the deeper layers of the epidermis, some of which are believed to reach these layers of the epidermis via hair follicles.

A relatively weak immune response has been detected in naive cattle.

Lesions: Lesions are most common in the region of the flexor commissure of the interdigital space. Less typically, lesions have been seen on the dorsal surface of the foot as well as around the dewclaws. One or both hind feet are most commonly involved, although forefeet can be affected. Lesions

vary considerably in size and appearance both within a herd and in different parts of the world.

The following system has been developed to classify the stages of this disease: M0 = normal skin; M1 = early, small circumscribed red to gray epithelial defects of <2 cm in diameter preceding the acute stage, appearing between acute episodes or within the margins of a chronic M4 lesion; M2 = acute, active ulcerative ("strawberry-like") or granulomatous (red-gray) lesions >2 cm in diameter and sometimes surrounded by white halo-like tissues, which may be slightly papillomatous; M3 = the healing stage occurring within 1–2 days after topical therapy, with the lesion covered with firm, scab-like material; M4 = the chronic stage in which the epithelium is thickened and/or proliferative (filamentous or scab-like) and several centimeters in diameter.

Treatment: Acute lesions are initially treated topically. The lesion should be scrubbed clean with a stiff brush and soapy water, rinsed, and dried. An antibiotic powder such as oxytetracycline is applied and protected by a gauze pad or a small feminine hygiene pad held in place by a waterproof bandage or a reinforced nylon device (booties) that can be affixed with hook-and-loop-tape closures. Multiple treatments are usually necessary. Oxytetracycline treatment has not resulted in detectable residual levels of the antibiotic in blood or milk. Extremely high parenteral antibiotic dosages have been reported to help resolve severe lesions.

Once a lesion has started to heal, topical dressings may be sprayed on with a pressurized backpack spray unit. Soluble oxytetracycline or lincomycin-spectinomycin (66 g and 132 g/L of water, respectively) produces the best results. Contamination of the lesion must be avoided at this stage. Although apparent resolution can be achieved, recurrence seems almost inevitable, and farmers should be so advised.

Control: There are no effective vaccines. The following methods are used in control: 1) Automatic power washing of the feet with soapy water before entering the milking parlor. 2) Passage through a medicated footbath after passing through the milking parlor with a 30-min drainage period. 3) Diligence in ensuring the environment is regularly freed from slurry and liquid contamination. 4) If digital dermatitis is not present, replacement animals should not be introduced and the

herd should not be exposed to vectors such as unsterilized instruments or visitors' dirty boots.

PODODERMATITIS CIRCUMSCRIPTA

(Sole ulcer)

Sole ulcer is generally regarded as the most important, prevalent, and costly of the noninfectious lesions. All too frequently, it is the cause of culling. Sole ulcers commonly affect one or both lateral hind claws, predominantly in heavy, high-yielding dairy cattle kept under confined conditions. A sole ulcer is a circumscribed lesion located in the region of the sole/bulb junction, usually nearer the axial than abaxial margin. Damage to the dermis is associated with a circumscribed zone of localized hemorrhage and necrosis. The incidence is variable, but in some herds up to 40% of mature cows can be affected.

Recently, *Treponema*-like organisms have been identified in these lesions.

Etiology and Pathogenesis: Sinking of the claw due to activation of matrix metalloproteinase, which is a feature of subclinical laminitis, is the major predisposing factor. As the space between the flexor process of the pedal bone narrows, the corium is crushed, causing ischemic necrosis and compromising horn production. This results in a hole forming in the sole. As the damaged corium undergoes repair, granulation tissues erupt through the hole in the sole. Because this condition is strongly associated with subclinical laminitis, some softening of the sole horn will occur. This increases the rate of horn wear. The sole horn also softens under very unhygienic conditions when horn is exposed to the fluid component in slurry.

Iatrogenic forms of the lesion are produced when inexperienced claw trimmers remove too much horn from beneath the heel (and/or the posterior region of the abaxial wall), resulting in abnormal pressure on the dermis. Excessive wear of the softened sole horn flattens and thins the sole.

Heel erosion is another potential contributing cause of a sole ulcer. Normally, weight is borne by the anticoncussive qualities of the bulb of the heel, but if heel erosion occurs, weight-bearing may be transferred forward to the region beneath the flexor process. Sometimes, a displaced pad of horn slips over to the vulnerable area, causing abnormal pressure over the flexor process of the distal phalanx.

Clinical Findings: The progress and severity of lameness are variable and often masked in bilateral cases, depending on the size of the lesion and extent of the secondary infection. Because the lateral hind digit is usually involved, the limb is often held slightly abducted with weight-bearing on the unaffected medial digit. In tie stalls, the hind toes may be rested on the edge of a curb in an attempt to relieve pressure on the heel-sole junction. On flat surfaces, an affected cow stands with the hindlimbs camped back. Some cows may shake the affected foot frequently, whereas those with bilateral lesions may continually shift weight from limb to limb and frequently lie down.

The earliest stages of this lesion may be discovered during routine claw trimming. As sole horn is removed from over the typical site, a hemorrhagic lesion may be exposed. The clinical lesion varies from a soft, slightly discolored area that may be painful under pressure to a distinct bright red knob of granulation tissue. This is often the stage at which lameness becomes severe enough to be noticed. Once the corium is exposed, infection can invade the deeper structures of the claw and spread proximally to involve the navicular bursa,

Sole ulcer over flexor process of distal phalanx. The heel has been lost due to heel erosion. Courtesy of Dr. Paul Greenough.

resulting in necrosis of the flexor tendon and ligaments of the navicular bone. A retroarticular abscess may develop, which may be further complicated by infection of the distal interphalangeal joint (*see* p 1088). Rupture of the flexor tendon leads to dorsal rotation (upward) of the toe ("cocked toe"). In complicated cases, infection may progress up the deep flexor tendon sheath.

Treatment: Treatment must be aimed at removing pressure from the affected area. Skillful therapeutic claw trimming is highly effective. This procedure lowers the entire bearing surface of the lateral claw, which transfers loading to the sound medial claw. Applying a "lift" has become the accepted treatment for this condition. The simplest form of lift is a wooden or rubber block glued or nailed to the unaffected medial claw, thereby removing all weight-bearing from the ulcer region. Recently, various models of easier-to-apply plastic slippers have been developed. Care must be taken when applying either a block or a slipper to avoid the sharp, hard, rear edge of the device from causing pressure under the sole. Blocks should be removed after ~1 mo to avoid causing damage to the sole.

Protruding granulation tissue need not be excised and must not be treated with any caustic agent, because this can retard healing. Bandages should not be applied, because this results in continued weight-bearing at the ulcer site. Furthermore, covering the lesion causes it to remain moist and promotes maceration and bacterial infection.

Many ulcers never fully resolve, and affected cows may have chronic, low-grade lameness and need corrective foot trimming 3–4 times/yr for their productive lives.

Prevention and Control: Because the development of sole ulcers is intimately related to subclinical laminitis, the latter should be investigated and appropriate control measures instituted (*see* p 1083).

WHITE LINE DISEASE

White line disease is almost as prevalent as sole ulcer and can be just as difficult to treat satisfactorily. Together with sole ulcers, white line disease commonly affects one or both lateral hind claws, predominantly in heavy, high-yielding dairy cattle kept under confined conditions. White line disease is characterized by hemorrhage into or separation (avulsion) of the abaxial wall, most commonly at the heel-sole junction.

The corium becomes infected through this lesion.

White line disease is often referred to as also being present in the apical region. Technically, this is true, but this type of lesion will be described as a component of the toe necrosis syndrome (*see* below).

Clinical Findings: The affected cow may adduct its hindlimb(s). The abaxial wall may seem a little longer than normal, and occasionally there may be slight swelling and erythema of the coronary band above the heels.

The lateral claw of the hind foot (often both) is usually involved. If bilateral, the disease may remain unnoticed until lameness is more pronounced in one limb than the other. Because the outer hind claw is affected, the limb is swung away from the body during each stride. The cow may stand with the medial claw bearing weight. White line separation without complications is frequently seen at claw trimming. The degree of pain and lameness depends on the rate of development and extent of the subsolar abscess. Routine examination of the sole must include the complete exploration of the abaxial white line region. Black marks must be explored with the tip of a hoof knife as potential sites for track formation. Discharge of pus from the skin/horn junction above the abaxial wall is always reason to suspect a white line lesion. In these cases, the white line must always be examined very carefully.

Etiology and Pathogenesis: The lamellar/laminar arrangement is longest behind the wall on the dorsal side of the hoof. This arrangement gets shorter toward the heel and more or less disappears at the abaxial groove. That is not to say that the collagenous fibers cease to exist in the other regions of the dermis; it can be postulated that adhesion between wall and corium could be less intense. At the same time, beneath the bulbar region is the structure known as the digital cushion. During locomotion, the digital cushion is compressed and expands toward the abaxial wall. Thus, this region is not only structurally weaker than more dorsal areas but is also subjected to a different set of pressure and mechanical stresses. The white line is composed of very soft horn, which fills the spaces between the lamella at the most distal extremity of the wall. It is postulated that stretching of collagen fibers, combined with sinking of the pedal bone, accounts for the hemorrhage into the white line so frequently seen.

Solid foreign bodies may lodge in the softened, widened white zone. They may push through to the corium beneath and introduce infection; however, the presence of a foreign body is not essential for the lesion to develop.

There are three possible sequelae of localized infection: 1) a localized abscess may develop; 2) infection may be forced proximally to form a track that may discharge at the coronary band; and 3) the infected track may, as it forces its way proximally, infect other structures, depending on the site of the initial infection. An anterior track can infect the distal interphalangeal joint directly. Tracks forming closer to the heel are likely to cause infection of the bursa of the deep flexor tendon. Invariably, the bursa ruptures into the retroarticular space, and an abscess develops in this location. Infection of the distal interphalangeal joint and the tendon sheath of the deep flexor tendon may follow. Necrosis and avulsion of the insertion of the deep flexor tendon into the distal phalanx are frequent complications. These cases are easily detected as the apex of the pedal bone unrestricted by the flexor tendon tips up.

Swelling of the heel bulb represents the most advanced form of white line disease; it is frequently misdiagnosed as footrot (often presented as a case of footrot resistant to treatment). Footrot causes the whole foot to swell evenly to the fetlock; in contrast, a retroarticular abscess leads to enlargement of only one heel bulb.

Treatment: During a claw examination, any black mark in the white line must be cut out until healthy horn is exposed. For a local abscess, removal of an elliptical segment of the wall adjacent to the lesion aids free drainage by providing a self-cleansing abaxial opening. Cream-colored pus may indicate a corporeal response to tissues tearing as collagen fibers stretch and the pedal bone sinks. In contrast, if the pus is black, it is likely that infection has penetrated from the outside.

Abscessation at the coronary band is usually indicative that white line disease is present. The same applies to a retroarticular abscess. Cases of nonhealing white line disease have been reported.

TOE NECROSIS SYNDROME

The term toe necrosis syndrome covers three different etiologies for a condition having a similar appearance. The three different etiopathologies are not completely

understood. However, *Treponema*-like organisms have been isolated from all of these lesions.

Etiology and Pathogenesis: Lesion 1—As subclinical laminitis progresses, in some cases the distal phalanx will rotate. Movement of the apex of the pedal bone will cause tearing of tissues, with resultant hemorrhage. In extreme instances, the tip of the bone will prolapse through the apex of the sole. Many cows with a rotated digit also have a ridge (the reaction ridge) running around the wall. The ridge is similar in location to a hardship groove and is displaced distally in a similar manner. Osteomyelitis of the distal phalanx can be seen in complicated cases.

Lesion 2—Many cases have been reported anecdotally in which the anterior half of the sole has been worn down almost paper thin. Hemorrhage from bruising is seen through the thin horn at the apex. Breakdown of the horn and formation of an abscess have been reported. One probable cause is a painful lesion in the heel, which forces the cow to throw most of its weight onto the anterior part of the sole.

Lesion 3—The incidence of apical necrosis can be quite high in young feedlot cattle, many of which become recumbent and die of pneumonia. The condition is sporadically reported in mature cows.

The main blood supply to the digit is the very large axial digital artery, which is vulnerable to pressure from the sharp proximal edge of the axial wall. This artery connects with the terminal arch that penetrates across the bone. Necropsy reveals that necrosis occurs distal to this artery, and radiographs tend to suggest the same thing. The terminal artery marks the margin at which pathologic fractures of the distal digit can be seen.

Necrosis of the apex of the pedal bone is extremely common in yearling beef calves after transportation over long distances. In either case, it is suspected that standing for long periods is the cause. Current laws in North America require that cattle be unloaded and watered every 40–52 hr. It is thought that long periods of standing without exercise allow the blood to pool in the feet and damage the tissues. During locomotion, the coronary cushion with the aid of venous valves functions as a pump to return blood to the general circulation.

Treatment and Control: Treatment is cost effective only in animals with no obvious complication. The cavity should be cleansed, dried, and packed with an

antibiotic powder. If no changes occur after a few days, the lesion may be covered with methylmethacrylate. If the bottom of the lesion is black, a probe should be inserted; if necrotic tissue can be detected, 1–2 cm of the apex of the toe should be removed under regional anesthesia with hoof cutters. The condition of the pedal bone should be visible. If necrosis of the bone is confirmed, a further 1–2 cm of toe should be removed. If the wound bleeds profusely, it is likely that necrosis is not extensive. When hemorrhage is minimal, it is probable that necrosis of the bone is extensive or a physiologic fracture is present. There are several reports of the toe (not the claw) having been amputated with satisfactory recovery. Systemic antibiotics and application of a lift to the sound claw is advised. If the wound is obviously contaminated, the lesion should be packed with a hygroscopic mixture (50% magnesium sulfate and 50% glycerin) and bandaged for a maximum of 24 hr, after which the lesion should be thoroughly dried, dressed with antibiotic powder, and closed with methyl methacrylate.

SOLE HEMORRHAGE

Sole hemorrhage is by far the most common noninfectious lesion in lame cows. It is regarded as a typical sign of laminitis but is frequently overshadowed by bruising of the sole. Blood stains in the sole of the hoof are the most commonly seen abnormality of the sole. When subclinical laminitis was first described, sole hemorrhage was considered to be an invariable clinical sign. It was thought that the arteriovenous shunts in the solar papillae were compromised, allowing blood to perfuse down the tubules, giving a brush-like appearance. Since then, solar hemorrhages have increased in prevalence. This may be due to cows being forced to stand on concrete for longer periods than previously. Bruising/trauma is more likely to occur if the horn is softened by moisture, or if the quality of the horn is reduced because of some nutritional error or because the thickness of the sole is reduced too much during hoof trimming. Interpreting the true cause of solar hemorrhages can be important.

THIN SOLE

As the term “thin sole” implies, the anterior region of the sole has worn very thin due to excessive weight bearing on that region. An innovative method to treat “thin sole” begins by drilling a 10-mm hole through the center of a wooden block. The claw to be treated is

thoroughly dried. Next, a fast-setting adhesive is applied along the border of the axial and abaxial wall. The objective is to create a ridge on the wall that does not involve either the white line or sole. This layer is allowed to dry and harden before a second application of fast-acting adhesive is made. The block is set in place and held by a self-adhesive bandage until the fixative has fully set. Sufficient soft setting material is then injected through the hole in the block to entirely fill the space and exert very gentle pressure on the dermis.

HEEL EROSION

(Slurry heel)

Heel horn erosion is seen as a change in the appearance of the surface of the bulb of the heel. Because heel horn erosion alone does not always cause lameness, the true incidence is unknown. However, subjective observations suggest that once cows have been exposed to copious slurry, the incidence of heel erosion rapidly approaches 100%. In some cows, heel horn erosion advances to a point at which complications develop and lameness may be apparent.

Etiology and Pathogenesis: The etiology is unknown. Heel horn erosion is perhaps more commonly seen in herds in which subclinical laminitis has been diagnosed and in herds affected by digital dermatitis. It is also more commonly seen during the winter, particularly when the claws are exposed to an unhygienic, moist environment (eg, intensively managed dairy units).

Clinical Findings: The first lesions seen are small circular erosions <0.5 cm in diameter. As the condition advances, these lesions merge, and ridges form parallel to the hair line on the axial surface of the bulb. Invariably, the color of the roughened area is black. At this stage, the cow is not lame.

In the secondary phase, the appearance of the heel varies. In some cases, there is a buildup of horn beneath the heel. Simultaneously, there may be a loss of horn under the axial part of the bulbs. The excessive accumulation of horn is often more pronounced in the lateral claw and causes the hock to turn in (cow-hocked stance). This stance resolves after therapeutic claw trimming. Generally, the condition is progressive unless corrected. The disturbance interferes with shock absorption, and the animal throws more and more weight forward. A common concurrent lesion is a sole ulcer. In other cases, erosion completely denudes the heel of

Heel erosion with a wide claw and black necrotic horn. Part of the sole over-reaching the interdigital space. Courtesy of Dr. Paul Greenough.

horn—a process that also interferes with shock absorption and can be associated with a sole ulcer. *Treponema*-like organisms have been observed in microscopic samples of heel horn.

Heel horn erosion must not be confused with separation of the heel, which is the result of the escape of pus from an abscess close to the heel.

Treatment and Control: Both heels should be reduced to the same height by paring away excess horn. Careful attention must be paid to maintaining the bearing function of the abaxial wall and sloping the sole toward the axial border.

Attention to hygiene and reduction of slurry are essential. The claws of dairy cows should be trimmed twice each year. A weekly footbath (where permitted, 3%–5% formalin), starting no later than October in the northern hemisphere, should be provided.

OTHER DISORDERS OF THE INTERDIGITAL SPACE

INTERDIGITAL DERMATITIS

(Stable footrot, Slurry heel, Scald)

Since the widespread appearance of digital dermatitis, interdigital dermatitis is rarely reported. This may imply that the causal

organism of interdigital dermatitis may be implicated in the etiology of digital dermatitis.

Etiology and Pathogenesis: Interdigital dermatitis is caused by a mixed bacterial infection, but *Dichelobacter nodosus* has been considered to be the most active component. *D. nodosus* is an anaerobe and exceptionally proteolytic. The source of the infection is the cow itself, and the infection spreads from infected to noninfected cows through the environment. *D. nodosus* cannot survive for >4 days on the ground but can persist in filth caked onto the claws, creating an anaerobic environment. The bacteria first invade the epidermis of the skin between the claws but do not penetrate to the dermal layers. As the condition progresses, the border between the skin and soft heel horn at the posterior commissure disintegrates, producing lesions similar to ulcers or erosions. At this stage, the lesions cause discomfort. In tied systems, the hindlimbs are affected more often than the forelimbs. In loose housing systems, the distribution between fore- and hindlimbs is about equal. Animals on slatted floors are affected less often than animals on solid floors.

Clinical Findings: The early stages of the condition appear as an exudative dermatitis. The exudate oozes to the commissures of the interdigital space and forms a crust or scab, which may be observed occasionally on the dorsal surface of the digits. As the condition progresses, the animal shows discomfort by “padding,” or constantly moving from one foot to the other. If the heels of the hind feet are especially painful, the limbs are held further back than normal. True lameness does not develop until a complicating lesion is present. After a prolonged period, during which the animal has avoided bearing weight on the heel, the horn beneath the heel increases in thickness and some aberrations of gait result. In dairy cows, interdigital hyperplasia (corns, fibroma) may be caused by the chronic irritation of the interdigital space. Often, the fibroma develops on one side of the interdigital space.

Foot-and-mouth disease can be confused with interdigital dermatitis if the interdigital space is not always examined carefully.

Treatment: Systemic therapy, including the use of antibiotics, is not cost effective. In severe cases, the lesions should be cleaned and dried, after which a topical bacteriostatic agent is applied, eg, a 50% mixture of sulfamethazine powder and anhydrous

copper sulfate. Alternatively, an animal can be confined in a footbath for 1 hr, bid for 3 days.

Control: Good management and housing systems that keep claws dry and clean are most important. Regular foot trimming helps avoid complications. Footbathing, beginning in late fall and before clinical cases can be identified during high-risk periods, is essential in herds known to be infected. Weekly footbathing may be sufficient in the late fall, but the frequency may have to be increased in late winter.

INTERDIGITAL PHLEGMON

(Footrot, Foul in the foot)

Footrot is a subacute or acute necrotic infection that originates in the interdigital skin, leading to cellulitis in the digital region. Footrot has a worldwide distribution and is usually sporadic. It may be endemic in intensive beef units or in cattle at pasture. The incidence varies according to weather, season of year, grazing periods, and housing system. Footrot is presented less commonly today than decades ago, partly because more cases are treated by farmers and partly because dairy cows spend much less time at pasture. However, on average, footrot accounts for up to 15% of foot diseases.

The appearance of footrot in loose housing systems has been reported.

Etiology and Pathogenesis: Injury to the interdigital skin provides a portal of entry for infection. Maceration of the skin by water, feces, and urine may predispose to injuries.

Fusobacterium necrophorum is considered the major cause of footrot. It can be isolated from feces, in which it may survive as a saprophyte, which may explain why control is difficult. It can also survive in moist soil.

F. necrophorum is a gram-negative, nonspore-forming, nonflagellated, nonmotile, pleomorphic anaerobic bacteria. It has a lipopolysaccharide endotoxin capable of necrotizing activity. There are three subspecies and a number of genotypes, each of which targets different tissues. When PCR assays become more widely available, the genotypes will be more readily identifiable.

Other organisms, such as *Dichelobacter nodosus*, *Staphylococcus aureus*, *Escherichia coli*, *Trueperella pyogenes*, and possibly *Bacteroides melaninogenicus* can also be involved.

Clinical Findings: Research suggests that the incubation period of footrot can be a

week. The fore- or, more commonly, the hindlimbs can be affected, but more than one foot is rarely involved at the same time in mature cows. However, footrot can occasionally develop in several feet in calves. The first sign is swelling and erythema of the soft tissues of the interdigital space and the adjacent coronary band. The inflammation extends to the pastern and fetlock. Typically, the claws are markedly separated, and the inflammatory edema is uniformly distributed between the two digits. The onset of the disease is rapid, and the extreme pain leads to increasing lameness. In severe cases, the animal is reluctant to bear weight on the affected foot. Fever and anorexia are seen. The skin of the interdigital space first appears discolored; later, it fragments with exudate production. As necrosis of the skin progresses, sloughing of tissue is likely to follow. A characteristic foul odor is produced.

If the disease proceeds unchecked, weight loss is severe and milk yield is significantly reduced. Milk production may not recover during the current lactation. Open lesions can be infected with secondary invaders. If the necrotic lesion is located in the anterior region of the interdigital space, the distal interphalangeal joint can become infected.

Hematogenous infection of the tissues of the interdigital space may account for peracute cases of footrot, which are referred to as either "blind" or "super foul." This form of footrot is characterized by the initial absence of a skin lesion, extreme pain, and the tendency to progress despite aggressive therapy.

Treatment: Most treated animals recover in a few days. Good results are obtained with penicillin G, IM, for 3 days. Treatment should be administered as soon as signs are observed. However, the label dosage may be inadequate to effect a rapid resolution, and increased dosages may be needed, requiring increased withdrawal times. Treatment of "super foul" must be particularly aggressive. Early cases respond well to single doses of long-acting oxytetracycline.

Sodium sulfadimidine solution IV or trimethoprim/sulfadoxine, IV or IM, bid for 3 days, can also be used. A single oral administration of a long-acting bolus containing baquiloprim/sulfadimidine may be suitable to treat beef cattle.

High concentration of an agent in the target tissues can be achieved by a regional IV injection (see p 1068). Positive results have been obtained with penicillin or oxytetracycline.

Local treatment is essential for some longstanding cases and in all instances in which the anterior region of the interdigital space has been compromised. The lesion must be thoroughly cleansed, but it is inadvisable to curette or otherwise remove necrotic tissue surgically. The dorsal pouch of the distal phalangeal joint is very superficial at this point. A nonirritant bacteriostatic agent (such as nitrofurazone or a sulfa preparation) should be applied as a topical dressing. The application of gauze, cotton batting, or bandages is contraindicated. However, the lesion can be protected and immobilized by binding the digits together with a bandage. The entire digital region can be protected from contamination if it is enclosed in a plastic bag fixed in place with an adhesive bandage. However, prolonged protection is not advocated, because the enclosed lesion tends to macerate further. Bandages, if used, should be replaced daily.

Prevention and Control: Animals actively shedding infectious organisms should be isolated until signs of lameness have disappeared. If this is not possible, a waterproof dressing or protective boot should be applied; however, animals wearing protective boots should be monitored carefully to avoid additional damage. Boots should be disinfected between use.

Because busy traffic areas are invariably heavily contaminated, steps should be taken to ensure that areas around drinking troughs, gateways, and tracks are adequately drained. Animals at pasture might be moved to a clean, dry area, or possibly housed during periods of heavy rainfall. Contaminated concrete must be frequently cleaned and scraped free of manure.

Preventive use of a footbath with an antiseptic and astringent solution (eg, copper or zinc sulfate [7%–10% in water]) has given beneficial results. Formaldehyde solution (3%–5% in water) can also be used. Ethylenediamine dihydroiodide has been used as a feed supplement for prevention, but the results are extremely uncertain. Vaccines against *F. necrophorum* have failed because of the weak immune response to the bacterium. High levels of zinc fed as a supplement have a beneficial effect by improving epidermal resistance to bacterial invaders.

INTERDIGITAL HYPERPLASIA

(Corns)

Etiology and Pathogenesis: In heavy beef breeds, the condition is thought to result from stretching of the insertions of

the distal interphalangeal ligament. The claws splay, and the interdigital skin is stretched. When not involved in weight bearing, the skin folds outward and subcutaneous scar tissue develops. In these cases, a mass tends to develop in the axis of the interdigital space. The mass may become so large that it touches the ground and may become necrotic. There may be a heritable disposition in some breeds such as Herefords.

Corns are reported frequently in dairy cows when their feet are continually exposed to slurry, chronic irritation, or have interdigital dermatitis. Organization of areas of irritated skin on one side or other of the dorsal commissure accounts for development of corns in dairy cows.

Interdigital hyperplasia affects forelimbs. Lameness results more often than not. As the lesion becomes larger, its surface may become excoriated, sore, and infected.

Treatment: In simple cases, treatment may be unnecessary. For surgical removal, the animal should be sedated, and dorsal and flexor regional nerve blocks administered (see p 1068). Surgery can be performed with the animal standing or in lateral recumbency. After preparation of the surgical site, a tourniquet is applied and the claws separated manually or with retractors. The mass is removed, leaving as much of the interdigital skin as possible. If any fat protrudes when the claws are pressed together, it should be removed. Care must be taken to avoid cutting deep structures such as the distal interphalangeal ligament. After surgery, the wound should be dressed with an antibiotic powder and the claws bandaged closely together. Some field reports suggest considerable success with wiring the toe together. Movement of the wound or separation of the claws must be avoided until ~10 days after surgery. Cryosurgery is also an option.

DISORDERS OF THE HORN CAPSULE AND CORIUM

The genetic relationships between what are now considered to be laminitic-related claw disorders have been found to be moderate to high.

LAMINITIS

Equine and bovine laminitis are distinctly different. Although acute laminitis occurs in both species and can be caused by grain overload, other etiologies can affect the equine laminae. A major difference between

the two species is anatomic, in that the lamellar/laminal surface of the equine hoof is considerably more extensive than that of the cow.

For **chronic laminitis**, see p 1086.

Subclinical laminitis is almost certainly an incorrect descriptor for the disorder(s) observed. The condition has been referred to as claw horn disruption, but use of this term is misleading.

Subclinical laminitis is of considerable economic importance to the dairy industry, because it predisposes mature animals to sole ulcer, white line disease, or the toe necrosis syndrome. It has been seen in most developed countries and is of greatest concern in high-production, intensively managed herds.

Clinical Findings: There are no definitive clinical signs of subclinical laminitis. However, in any group of cows presented with the same set of insults, a few cows may show slight signs of the subacute form of the disorder. Some cows with subacute laminitis may walk in a deliberate, careful manner with the legs carried beneath the animal when walking. When standing, such animals tend to draw all four feet under the body. Erythema and edema (puffy foot) of the skin above the coronary band and around the dewclaws in freshly calved cows may indicate a transitory laminitis-like insult and that the cows are being introduced to concentrate too rapidly. Hoof testers may evoke some response.

Sole hemorrhages are an invariable clinical sign of clinical laminitis, but such hemorrhages due to trauma are more common; therefore, this sign must be interpreted carefully (see p 1079).

Etiology: The etiology of subclinical laminitis in cattle is not understood. The classic hypothesis suggests that high levels of carbohydrate in the diet (see p 225) invoke an increase of *Streptococcus bovis* and *Lactobacillus* spp, which induce a state of acidosis in the rumen. This causes gram-negative organisms to die and release vasoactive endotoxins. Rumenitis is frequently associated with ruminal acidosis. High levels of histamine in the blood have been found in the early stages of the disorder. It is probable that subacute ruminal acidosis is one key factor in development of laminitis, because managing subacute ruminal acidosis (SARA) helps control the incidence of subclinical laminitis.

Contemporary thinking is that as production levels increase, cows become more sensitive to risk factors. A risk factor

in this case is any physical insult causing stress. This probably leads to the release of bioactive messengers into the bloodstream. One important risk factor is trauma; many clinicians are convinced that hard flooring is equal in importance to nutritional problems. Care must be taken when dry cows and heifers are introduced to concrete after being accustomed to soft flooring.

Pathogenesis: Although the release of biologic messengers into the bloodstream is known, identification of the agents that play a part in laminitis is ongoing. Epidermal growth factor (EGF) receptors are present in the basement membrane of the corium of the claw. EGF is liberated in large quantities from the GI tract when it is damaged (eg, rumenitis) and could be involved in the pathogenesis of laminitis. In addition to its mitogenic effect, EGF can inhibit the differentiation of keratinocytes in vitro. Inhibited differentiation of keratinocytes of the hoof matrix is a dominant morphologic feature in the early stages of laminitis. This supports the hypothesis that laminitic histopathologic changes result from an inadequate regulation of gelatinase activity, resulting in selective degradation of basement membrane components due to failure of the basement membrane-epidermis attachment.

More recent investigations have studied the role of matrix metalloproteinase (MMP) activity in the pathophysiology of laminitis. It is not known which endotoxins are involved in releasing MMPs. It is known that MMPs play some part in allowing collagen fiber supporting the distal phalanx to stretch. During the peripartum period, hormones such as relaxin are generated. Correct management of nutrition around calving is critical. In early calving heifers, it is possible growth hormones could have a complicating role.

Whatever the biologic messengers, they appear to affect two different types of tissues: the papillary or solear dermis and the collagen fibers of the laminae. This results in two distinctly different pathologies. The first is disruption of normal keratogenesis, and the second, abnormal MMP activity, results in sinkage and/or rotation of the digit.

The pathophysiologic process associated with compromised horn production starts when vasoactive toxins or other biologic agents reach the corium. Arteriovenous shunts may be paralyzed, pressure inside the claw rises, and the walls of the vessels are damaged. Blood or blood fluids escape and soak into the claw horn, staining it either

pink or yellow. Hemorrhagic staining of the horn tubules of the sole give a "brush mark" appearance. Mural thrombi form, reducing blood flow and causing oxygen deprivation and an insufficient nutrient supply to the keratin-producing cells. Thrombus formation is a characteristic feature of laminitis. The resulting horn is soft and prone to damage, infection, and scar formation.

The second pathophysiologic process involves MMP release and stretching of the collagen fibers of the suspensory apparatus of the digit. Collagen fibers originate in horny corrugations (lamellae) on the inner surface of the hoof wall and insert into those areas of the distal phalanx that have no periosteum. Thus, the pedal bone is "suspended" from the wall of the hoof. The lamellae are arranged to increase the surface area from which the fibers originate. The vascular tissue and germinal layer, the laminae, are interleafed between the lamellae. In areas of the wall and sole where there are no lamellae, the tissues of the dermis are referred to as corium. Whether laminitis is truly an inflammatory process could be questionable.

As the collagen fibers stretch, the pedal bone is displaced. Occasionally, the pedal bone will rotate and the apex of the bone will prolapse through the apex of the sole. Perhaps more frequently, the whole bone will "sink," causing the space between the flexor process and the sole of the claw to narrow and increasing the possibility of a sole ulcer developing.

Frequently, young animals appear to recover from laminitis. This may be because new blood vessels develop to form collateral circulation and take over the function of those that have been damaged. Nevertheless, each time an animal has a bout of laminitis, more scar tissue is formed and the animal is less able to recover from the next insult.

Treatment and Control: Treatment for subclinical laminitis is impractical, because diagnosis in an individual animal is not possible at the time of the causative insult(s).

Controlling subclinical laminitis (see p 1083) in a high-production, intensively managed dairy herd requires a systematic epidemiologic study.

DOUBLE SOLE

In double sole, one sole is present while a new sole grows beneath, ie, there is complete shut-down of horn production for an undetermined short period of time.

Etiology and Pathogenesis: A new sole grows beneath an existing one when fluid forms between the dermis and epidermis. This fluid can result from bruising of the sole under conditions such as prolonged walking on rough roads. The fluid may be pus from a subsolar abscess. Double sole has been seen in cattle suddenly changed from a mainly forage diet to one rich in concentrates. Double sole can be confused with underrunning of the heel, which is a frequent sequela of white line disease. Double sole has also been seen after feeding moldy hay.

Treatment and Control: Treatment is simple unless mismanaged. The abaxial wall must remain completely intact and only a portion of the sole covering the bulb cut away. The sole beneath is extremely soft and vulnerable to damage; therefore, the animal should be confined to a well-strawed stall until the new horn has hardened, after which more of the sole may be removed.

Sudden changes in the quality of the forage should be avoided.

FOREIGN BODY IN SOLE

A stone or fragment of glass or metal penetrating almost through the sole will cause pain due to pressure on the corium and, if not removed, will lead to infective coriitis.

If the foreign body penetrates through to the corium, infection is introduced to the dermal level, and an abscess develops. The rapidity of onset and severity of the lameness depends to some extent on the location of the sole penetration. In the apical and subapical region, the lesion is located between the distal phalanx and the nonresilient sole. As the abscess develops, interangular pressure increases rapidly. Thus, the onset of lameness is rapid, and pain is severe. Acute lameness may cause the animal to stand with the foot off the ground or with the toe lightly touching. A differential diagnosis is fracture of the distal phalanx.

In the sub-bulbar region, the corium is located between the digital cushion (a flexible structure) and the soft, resilient horn of the bulb. The onset of lameness is relatively slow, and the pain is significant but not severe. The pus in the abscess tends to spread over a wide area through the fascial plane and to cause separation of the skin-horn junction at the heel. A moist discharge from this area may be the first indication of the lesion. This is referred to as "underrunning of the heel," a

condition that can be confused with double sole (see above).

Treatment: The foreign body should be removed and the track cored out to the corium with a fine-pointed hoof knife. Creating a large hole is inappropriate. Pus is often released under considerable pressure. Antibiotic should be squeezed into the cavity, which closes rapidly. The opening should not be plugged but covered with elastic waterproof material to prevent blockage with mud or manure.

Treatment consists of removing the foreign body if still present. The detached horn should not be stripped off in its entirety. Part of the detached horn may be removed, but the abaxial wall must be left intact to bear weight and spare the exposed, newly forming sole. Bandaging may not be required, but the animal should be housed in a well-strawed area for a few days.

VERTICAL FISSURES

(Sandcrack)

Sandcracks are vertical fissures or cracks in the wall of the claw. They account for ~0.2% of lesions of the claws of dairy cows. In western Canada, the average incidence in mature beef cows is ~20%. In individual herds, the incidence can be as high as 60%. No breed differences have been recorded. The lesion is extremely unsightly, which can be a considerable drawback for beef cattle producers who wish to sell their animals.

Clinical Findings: Vertical fissures occur almost exclusively in the lateral fore claw. In dairy cows, fissures are usually small and confined to the proximity of the coronary band. In beef cattle, they are more extensive, mostly starting at the coronary band and/or running part or all of the way to the bearing surface. In herds with the highest incidence of this disorder, lesions are also observed to start from a horizontal groove in the middle of the claw.

Etiology: The etiology remains uncertain. The incidence is highest in mature, heavy cows. Bending or buckling of the claw around one or several horizontal grooves probably creates mechanical stresses that cause rupture of the claw wall.

In beef cattle in the prairies, it is theorized that the most probable cause is a rapid change from a winter diet low in protein and high in fiber to one high in protein and low in fiber.

Treatment: Most sandcracks are not painful and require no treatment. However, if the origin of the lameness can be traced to a claw in which a sandcrack is present, routine treatment of the crack is appropriate.

A crack at the coronary band can split open, allowing infectious organisms to enter. The protrusion of granulation tissue through such a lesion can be quite troublesome. The dorsal pouch of the distal interphalangeal joint is extremely superficial at this point. The joint is very vulnerable, and lesions at this location should never be ignored. Superficial horn should be pared away and an astringent dressing applied (50% mixture of a sulfa powder and anhydrous copper sulfate). Pressure should be applied using cotton batten held tightly in place by a narrow, adhesive elastic bandage encircling the entire coronary band.

The fissures often have ragged edges that may be twisted and gape open. Sometimes, the edges move and pick up a foreign body. Cosmetic treatment may be requested in the case of show animals. The axial wall at the tip of the claw should be cut back so that the weight is borne only by the abaxial portion of the wall. The ragged edges of the fissure should be trimmed, ideally with the cutting disk of a grinding tool. In selected cases, a fissure can be immobilized with an application of methyl methacrylate after the two edges of the fissure have been laced together with steel wire.

HORIZONTAL FISSURES

Horizontal fissures result from disruption of horn production at the dermis beneath the coronary band, leading to a defect in the integrity of the wall. These fissures run parallel to the coronary band. The defect varies in severity from a shallow groove (hardship groove) to a complete fracture (fissure) of the wall. A comparable anomaly is seen as a band of horn differing in appearance from the remainder of the claw. One form of the band is seen in animals stressed after weaning (weaning groove) or during a period of nutritional deprivation. The fissure moves distally as the claw grows, and the distal portion becomes progressively more mobile (thimble) until it fractures, leaving a "broken toe." A series of grooves can destabilize the vertical strength of the dorsal wall, causing it to bend (buckled toe).

Etiology: Fissures are believed to be caused by a wide variety of stressors, including a difficult calving, an acute febrile

disease, or a sudden, relatively short-term but significant change in nutrition. A ridge may indicate an event such as compensatory growth.

Clinical Findings: The horizontal groove or fissure is an important indicator of metabolic disturbance. The date on which the causal insult occurred can be calculated by measuring the distance from the hair line to the fissure and dividing that number by the growth rate of the claw. In mature dairy cows, the rate of growth of the wall measured along the dorsal flexure of the claw is ~0.5 cm/mo. Growth rates are more rapid in young animals, in animals on intensive feed, and during the summer months.

Treatment: No treatment is possible except when very deep fissures form a thimble, which is extremely painful. In these cases, the loose horn should be removed with pincers; regional anesthesia may be needed.

CORKSCREW CLAW

A corkscrew claw is twisted throughout its length in a configuration that displaces the abaxial wall by up to 360°. One or both lateral hind claws may be affected in cows >4 yr old. Although corkscrew claws are rarely seen in bulls, many believe there is a heritable component.

Pathogenesis: Bone molding is seen in the distal phalanx, but it is not known whether this is a matter of cause or effect. Periarticular exostoses develop around the distal interphalangeal joint, possibly resulting

Corkscrew claw. Courtesy of Dr. Paul Greenough.

from strain of the distal abaxial collateral ligament. Pressure from the exostosis on the dermis of the wall probably accounts for the excessive growth of the abaxial wall.

Treatment: Correctly trimming a corkscrew claw requires much skill. The horn formation is extremely hard and difficult to cut. The abnormally narrow shape of the distal phalanx makes it difficult to pare the claw without causing bleeding at the toe. The strategy is to shorten the claw as much as possible without causing bleeding. Next, the horn wall that is displaced beneath the claw is cut away. Then, so far as is possible, the horn is shaped to approximate normal. Trimming helps the animal get around for a while but does not "cure" the condition. Affected animals should ultimately be culled.

SLIPPER FOOT

A slipper foot is named for its alleged likeness to a Persian slipper. The claw is flat and curled upward to form a square end. The horn is heavily ridged and has lost its shine, and the coronary band is rougher and darker than normal. Although there is no objective evidence to support the theory, the slipper foot is probably synonymous with chronic laminitis and may be a sequela of either acute or subclinical laminitis. Treatment is always disappointing. The claw can be shaped to approximate normal, but invariably it collapses and serious sequelae follow. Animals with slipper foot should be culled as soon as economically appropriate.

DISORDERS OF THE BONES AND JOINTS

ANKYLOSING SPONDYLOSIS

In ankylosing spondylosis, exostoses develop on the ligament of the ventral aspect of the lumbar vertebrae, primarily in older bulls. Fracture of the exostosis and associated vertebrae causes pressure on the spinal cord, which results in severe ataxia or paralysis. There is no treatment.

DEGENERATIVE ARTHROPATHY

This nonspecific condition affecting mainly the hip and stifle is characterized by degeneration of articular cartilage and eburnation of subchondral bone, joint effusion, and fibrosis with calcification of the joint capsule.

Etiology: Many causes and predisposing factors influence the development of degenerative joint lesions. There is almost certainly an inherited predisposition to the condition. Certain conformations, eg, straight hocks in beef bulls, are also incriminated. Joint instability after trauma is a common cause. Nutritional factors involved in some cases, such as rations high in phosphorus and low in calcium, influence the strength of subchondral bone. Copper deficiency or fluoride poisoning also may act similarly. Forced traction of a calf in breech presentation can impede the blood supply to the hip joint, and arthritis may result. The role of infection is unclear. Infectious arthritis in calves usually produces severe changes in the hock, but degenerative arthropathy rarely involves this joint.

Bulls fed high-grain diets for show may become lame when as young as 6–12 mo, but most cases are first noticed at 1–2 yr.

Clinical Findings: Onset is gradual (later in bulls), and both hip joints are usually affected; stifle involvement is rare. Lameness to the point of incapacitation, with crepitation of degenerate joints, may develop in a few months; however, correlation between pathologic changes and clinical signs is poor. The earliest changes occur in the acetabulum and on the dorsomedial surface of the femoral head.

In the stifle, the medial condyle of the femur shows the earliest changes. Because degenerative arthropathy may result from any of several initiating factors, a specific diagnosis may be difficult.

Radiographic, cytologic, and microbiologic evaluation of the synovial fluid are useful diagnostic aids. Arthroscopy of articular surfaces and ligaments may help attain a definitive diagnosis and prognosis.

Treatment: Changes in the joints are usually irreversible by the time of diagnosis. Palliative treatment of valuable breeding animals should be undertaken with the knowledge that the condition or predisposing factors may be inherited. The diet should be carefully analyzed and, if necessary, corrected. This is especially important in fast-growing animals, in which adequate exercise is indicated and overfinishing should be avoided.

COXOFEMORAL LUXATION

Luxation of the coxofemoral joint is usually upward. It is seen in cows riding each other. The affected limb appears shorter than the contralateral limb. The hock is turned inward

and, when trying to walk, the animal appears to be dragging one foot behind the other.

Treatment: Resolution is possible, provided that the head of the femur or the rim of the acetabulum has not been fractured. The animal should be deeply sedated to the level of recumbency. A rope should be looped around the groin of the affected limb, which should be uppermost. The free ends of the rope should be tied around a tree or some other fixed object, and traction should be applied to forcibly extend the limb. Downward pressure should then be applied to the hock, which should be strongly rotated outward (upward) until the head of the femur slips back into the acetabulum. Traction should be applied at several angles until the head of the femur clicks back into the acetabulum. If the head of the femur or the rim of the acetabulum is fractured, there will be considerable crepitation, and the head of the great trochanter will displace as soon as traction is stopped.

PATELLAR LUXATION

Intermittent fixation of the patella on the upper part of the femoral trochlea results in a characteristic jerky action of one or both hindlimbs. The limb remains in caudal extension for a longer period than normal and may even be dragged for a few steps before clicking forward to a normal posture. In young animals, the condition may resolve spontaneously. For luxations that do not resolve, medial patellar desmotomy should be performed.

FETLOCK DISLOCATION

Fetlock dislocation is seen in young cattle when they cross cattle guards (grillwork laid over a pit as a gate substitute). Tranquilization or light anesthesia facilitates replacement of dislocated structures. A padded, fiberglass cast maintained in place for 3 wk usually promotes a satisfactory recovery.

HIP DYSPLASIA

Hip dysplasia, a bilateral malformation of the hip joint, is often associated with secondary osteoarthritis. It may be present at birth. However, abnormal gait may develop in rapidly growing animals. Usually, it is possible to rock the hindquarter to produce a click as the head of the femur pops in or out. Radiography may confirm the diagnosis in young animals. There is no treatment.

FRACTURES

Bone fractures occur in cattle of all ages, but they are most common in those < 1 yr old. Corrective procedures may be justified economically in this age group, provided that joints are not involved. External fixation techniques or Thomas splints have been used successfully. In selected cases, percutaneous transfixation or internal fixation may be attempted.

Fractures of major long bones in adult cattle usually are not treated. The tuber coxae may fracture when cattle are hurried through narrow doorways. In these cases, spicules of bone may penetrate the skin, or unsightly distortions of the flank can result. Fractures of the proximal and intermediate phalanges may be considered for treatment in tractable, young adult cattle.

Fracture of the distal phalanx is relatively common in adult cattle. Onset of lameness is rapid, and the pain is usually severe. If the medial digit is involved, the animal may seek relief from the pain by crossing its legs. Natural recovery is prolonged, and because most such fractures extend into the distal interphalangeal joint, a debilitating arthritis may develop at the fracture site. If treatment is undertaken, the sound digit should be elevated on a wooden block and the affected digit immobilized in a flexed position to the block using methyl methacrylate adhesive.

SEPTIC ARTHRITIS OF THE DISTAL INTERPHALANGEAL JOINT

Most frequently, one of the causal lesions is present and the transition from the initial lesion to the joint infection is readily apparent. However, when a swollen foot is treated before the cause has been established, a joint infection may have been ongoing for weeks before the true nature of the condition is diagnosed. If aggressive treatment of a footrot case does not lead toward resolution within 3 days, septic arthritis should be suspected. Increased pain, together with swelling of the anterior region of the coronary band in cases of sandcrack and white line disease, is suggestive of joint infection. Using regional analgesia and strict aseptic technique, an aspirate of the joint can be collected and examined for infection. A radiograph may indicate an abnormal separation of the joint surfaces.

Etiology: Infection enters the distal interphalangeal joint via three possible main sites: 1) the dorsal commissure of the interdigital space, via penetrating trauma or complicated footrot (interdigital phleg-

mon); 2) sandcracks; or 3) white line disease or retroarticular abscess.

Treatment: Digital amputation is indicated in animals that have a limited life expectancy, eg, old or poor-producing animals. The procedure is simple, quick, can be performed in standing animals under regional analgesia, and in most cases, produces rapid relief. Amputation is performed through the skin with an embryotomy wire placed as close to the skin-horn junction as possible. Hemorrhage is arrested by means of a tight bandage.

Alternatively, in the case of valuable animals, arthrodesis to fuse the distal and middle phalanges may be attempted. General anesthesia is recommended. A 1-cm canal is drilled through the abaxial wall into the joint, and a second canal is drilled from the causal lesion into the joint. The joint cavity is enlarged by curettage, and a drainage tube drawn through. Continuous irrigation with sterile saline should be performed for 2–3 days. A wooden block is then applied to the sound claw and the affected digit immobilized by fixing it to the block with methyl methacrylate. Immobilization is further facilitated by encasing the digital region in a cast. The cast is removed after 4 wk.

SEROUS TARISITIS

(Bog spavin, Puffy hock)

Serous tarsitis is characterized by three soft, fluctuating swellings between the ligaments of the femorotarsal joint. In some instances, this condition is heritable. It does not cause pain or lameness. In later life, there may be a predisposition to arthritis. Serous tarsitis is diagnosed by depressing the swelling of the joint capsule at one location and palpating the fluctuation that is seen at another. There is no successful treatment.

NEUROLOGIC DISORDERS ASSOCIATED WITH LAMENESS OR GAIT ABNORMALITIES

SUPRASCAPULAR PARALYSIS

This rare condition results from paralysis of the supraspinatus and infraspinatus muscles caused by damage to the sixth and seventh cervical nerves. Acute trauma to the prescapular area (eg, struggling into a head gate) produces a nonspecific ataxia immediately after the injury. Several days after the injury, the muscles may show signs

of wasting, indicating the possibility of permanent damage.

Chronic injury to the nerves causes marked wasting of the muscles within weeks. A specific gait aberration develops. The stride is shorter than normal; when weight is borne on the limb, it tends to swivel. In some cases, the cause may be nerve compression in or around the vertebrae (eg, an abscess or fracture), which may be identified on radiographs.

If the trauma is complicated, primary treatment must be directed toward resolving the immediate problem. However, if the clinical presentation suggests that the injury is localized to the nerve, immediate treatment with steroids or other anti-inflammatory agents is appropriate.

RADIAL PARALYSIS

Distal radial paralysis results in an inability to extend the carpus and digit. Proximal radial paralysis prevents the animal from extending the elbow, carpus, and fetlock to bear weight.

Etiology: The proximal radial nerve may be injured by stretching close to the brachial plexus, in which case the triceps muscles as well as the extensors of the carpus and digits may be compromised. The damage is frequently associated with casting an animal with ropes or with any situation in which the forelimb is accidentally restrained and the animal struggles violently to free itself. Either distal or proximal radial paralysis can result from prolonged recumbency in very heavy animals.

The distal radial nerve is vulnerable to injury in the musculospiral groove of the humerus, either from fractures or deep, soft-tissue trauma. A lesion of the nerve proximal to the sulcus for the brachial muscle causes proximal radial paralysis.

Clinical Findings and Diagnosis: In proximal radial paralysis, the elbow drops, the carpus and fetlock are in partial flexion, and the limb is usually dragged. In distal radial paralysis, because the triceps muscles remain functional, dropping of the elbow is minimal. However, paresis affecting carpal and fetlock position is present.

Treatment: Rapid improvement can be expected in most cases. Animals should be confined in a generously bedded stall. Anti-inflammatory drugs may be helpful, particularly in the early hours after the initial trauma. If skin sensation in the forelimb has been completely lost, the

prognosis is guarded. When the condition persists for ≥ 2 wk, damage is likely permanent and the prognosis is grave.

ISCHIATIC PARALYSIS

(Sciatic paralysis)

Damage to the ischiatic and obturator nerves after intrapelvic parturient trauma may cause recumbency after calving. It may be a component of the downer cow syndrome. The tibial and peroneal nerves are branches of the ischiatic nerve that can be damaged at extrapelvic sites.

OBTURATOR PARALYSIS

Passage of a calf through the pelvis exerts pressure on the obturator nerve. The close association of the obturator nerve with the origin of the ischiatic nerve can complicate interpretation of clinical signs.

Clinical Findings: Because the adductors are innervated by the obturator nerve, an animal adopts a base-wide stance or, in recumbency, a sitting position with both hindlimbs extended forward. There is considerable risk that the adductor muscles will be damaged and that permanent recumbency will result. In addition to the base-wide stance, knuckling of the fetlock may be present. This indicates injury of the ischiatic nerve. Both conditions may contribute to downer cow syndrome (see p 1188).

Treatment: If obturator paralysis is recognized early enough, vigorous measures should be adopted to prevent complications involving the adductor muscles. The animal should be immediately transferred to a site where there is good footing (eg, a base of tenacious manure over which clean straw has been spread) to prevent slippage during attempts to rise. The hindlimbs can be tied together with a soft nylon strap fixed below the hocks. The limbs are restrained from "spreading" >3 ft (1 m) apart.

FEMORAL PARALYSIS

In femoral paralysis, paralysis of the quadriceps muscles, which extend the stifle, and partial paralysis of the psoas major muscle, which flexes the hip, are seen.

Clinical Findings and Diagnosis:

Femoral nerve paralysis is seen in large, newborn calves (eg, Charolais, Simmental) after the use of mechanical force during an assisted birth. Reduced quadriceps tonicity

reduces tension on the patella, with the result that a lateral patellar luxation may develop. Atrophy of the quadriceps soon becomes obvious and, although the patella can be replaced easily, the animal has extreme difficulty walking. The condition may affect one or both limbs. Prognosis is related to the severity of the clinical signs.

Treatment: Despite a fair or good prognosis, the animal may be unable to suckle unaided. The animal should be maintained in a well-bedded area, and colostrum given as soon as possible after birth. A radiographic study should be done to exclude fractures. The administration of anti-inflammatory drugs may be useful.

PERONEAL PARALYSIS

Peroneal paralysis results in paralysis of the muscles that flex the hock and extend the digits.

Clinical Findings: The peroneal nerve is the cranial division of the ischiatic nerve. It passes superficially over the lateral femoral condyle and the head of the fibula, which makes it vulnerable to external trauma or pressure from recumbency. An affected animal stands with the digit knuckled over onto the dorsal surface of the pastern and fetlock. The hock may appear to be overextended. In mild cases, the fetlock tends to knuckle over intermittently during ambulation; however, this may also occur if the animal is experiencing pain in the heels.

In severe cases, the dorsal surface of the hoof may be dragged along the ground, and sensation to the dorsum of the fetlock is often decreased. Testing of reflexes may demonstrate that hock flexion is absent, but stifle and hip flexion are normal. This would not be the case if the ischiatic nerve was involved.

Treatment: Most cases resolve naturally. However, if the condition is associated with long periods of recumbency, care must be taken to avoid exacerbation of the initial injury.

TIBIAL PARALYSIS

In tibial paralysis, there is paralysis of the extensors of the hock and flexors of the digits.

Etiology: The tibial nerve is the caudal branch of the ischiatic nerve, which, in its proximal course, is well protected by the gluteal muscles. Distally, it progresses

beneath the tendon of the gastrocnemius muscle and can be damaged when the tendon is traumatized.

Clinical Findings: The hock joint is overflexed (dropped hock syndrome) and the fetlock is partially flexed. The gastrocnemius appears to be longer than normal and gives the impression that it or its tendon could be ruptured. The fetlock tends to be buckled, but the animal can walk and bear weight, although its attempts to do so are awkward. Compared with that seen in peroneal nerve injury, the gait disturbance is mild, but the postural disturbance could be permanent.

Treatment: The use of anti-inflammatory drugs may be of value in the early stages. However, the primary efforts should be directed toward ensuring that the animal does not injure itself further, by maintaining it on surfaces with good footing.

SPASTIC SYNDROME

Episodic, involuntary muscle contractions or spasms involving the hindlimbs are associated with postural and locomotor disturbances as well as spasticity. The condition may progress to posterior paresis or hindlimb paralysis. It is seen most frequently in Holstein and Guernsey cattle 3–7 yr old. Spastic syndrome is regarded as a genetic disease, possibly due to an autosomal dominant gene with incomplete penetrance. The pathology and pathophysiology remain obscure.

Clinical Findings: Clinical signs may vary in severity, duration, and frequency. Usually, some stimulus provokes the onset of clinical signs, such as the effort associated with rising or any factor that induces a significant emotional reaction. Pain, particularly in the feet or joints, may precipitate an attack. During an attack, the animal may be unable to move forward, stands trembling, and characteristically extends its hindlimbs backward. Between episodes, the animal can ambulate normally.

Treatment: Spastic syndrome is progressive, and because of the possibility of genetic transmission, animals (particularly bulls used for artificial insemination) are best eliminated as soon as a positive diagnosis is made. Palliative treatment for animals in the peak of production may be helpful. Mephenesin (30–40 mg/kg, PO, for 2–3 days) may be given during an episode. Phenylbutazone may also have beneficial effects.

SPASTIC PARESIS

(Elso heel)

Spastic paresis is a progressive unilateral or bilateral hyperextension of the hindlimb(s). It is seen sporadically in most breeds of cattle. Post-legged cattle are most frequently affected. Attempts to move are believed to simultaneously trigger contractions of both extensors and flexors of the limb. Spastic paresis is currently considered to be inherited via a recessive gene(s) with incomplete penetrance.

Clinical Findings: The disease may be seen within the first 6 mo of life. As the animal ages, the gastrocnemius muscles gradually contract. The hock and stifle become increasingly extended. Over a period of months, the hindlimbs become so stiff that the animal walks with short, pendulum-like steps. If only one limb is affected, the animal stands with the affected limb camped back and the sound limb held toward the midline to maintain balance. If both hindlimbs are affected, the animal may attempt to bear more weight on the forelimbs by holding them well back and simultaneously arching its back.

The quadriceps muscle has been implicated in the pathology of this disorder and can be distinguished from the form of the disorder affecting the gastrocnemius through use of a femoral nerve block.

Treatment: There is no successful medical treatment. Because spastic paresis is heritable, affected animals (especially breeding bulls) should be eliminated from the herd. Palliative surgical treatment may be attempted, although ethical issues should be considered when breeding stock is involved. The procedures, usually performed on calves, include complete tenotomy of the gastrocnemius tendon, which results in a dropped hock; complete tibial neurectomy, which results in sufficient relief to permit a steer to be finished for slaughter; and partial tenectomy of the two insertions of the gastrocnemius muscle and the calcanean tendon sheath, which overcomes the problem of the dropped hock.

SOFT-TISSUE DISORDERS CAUSING LAMENESS

CARPAL HYGROMA

Carpal hygroma is a localized swelling of tissues, including the precarpal bursa, dorsal to the carpal joint. It results from intermit-

tent mild trauma to the precarpal area caused by lack of bedding or a poorly designed manger. *Brucella abortus* may be isolated from the false bursa of some cases in countries where this organism has not been controlled. The lesion is a firm swelling, possibly fluctuating and up to several inches in diameter, located over the dorsal aspect of the carpus. The hygroma is a lesion that is very difficult to resolve. The first step is to ascertain radiographically whether there is more than one cavity. Each cavity should be drained and infiltrated with a long-acting corticosteroid preparation. Surgical removal is messy, with little guarantee of a successful outcome. Introducing irritant materials into the cavity has had uncertain results. If the animal is milking and eating well, hygromas should be left untreated.

RUPTURE OF THE GASTROCNEMIUS MUSCLE

Rupture of the gastrocnemius muscle or tendon is relatively rare. It is most likely to be associated with deficiencies of calcium, phosphorus, and vitamin D. Prolonged recumbency, with resulting myositis and struggling to rise, occasionally precipitates rupture of these muscles. Occasionally, the condition has been associated with pyelonephritis, which presumably causes a myositis, weakening the muscle enough to permit rupture. Injections of irritating medicaments into the gastrocnemius muscle may cause necrosis and rupture.

The hock remains flexed. When the muscle is completely ruptured, the standing animal rests the hock and distal portion of the limb on the ground or walking surface, which is diagnostic, although rupture of the Achilles tendon may produce an identical gait.

Successful treatment is extremely unlikely in heavy adult animals. A leg cast or splint that maintains the hock in extension, supplying adequate vitamins and minerals, and proper nursing may be successful, but a long recovery period is required.

RUPTURE OF THE PERONEUS TERTIUS MUSCLE

The peroneus tertius muscle can be forcibly avulsed from its insertion by accidents associated with mounting or, more frequently, by the inexperienced use of ropes to restrain a hindlimb.

The hock is abnormally extended, while the stifle remains flexed. The animal cannot advance the limb normally, the calcanean tendon is flaccid, and the hooves may be

dragged. The site of avulsion may be painful to the touch. A specific diagnostic feature is that the limb can be pulled backward without any resistance from the animal.

The condition may improve slowly if the animal is confined in a stall (loose) for several months.

TARSAL CELLULITIS

(Concrete hock)

Tarsal cellulitis is characterized by a firm, subcutaneous swelling on the lateral aspect

of the hock that has little effect on joint mobility. It can include the formation of a false bursa. The condition is caused by severe abrasion of the skin and subcutaneous tissue overlying bony prominences. The skin may be excoriated by contact with concrete and particularly sharp curbs. Superficial abscesses must be drained extremely cautiously, because there is considerable danger of entering the joint. Padding and bandages should always be applied. Poultices rapidly reduce acute swelling.

LAMENESS IN GOATS

Abnormality of gait is a sign common to many diseases and conditions. A complete history is important for diagnosis and should include incidence and duration in the herd, nutrition, feed changes, method of rearing, and recent introductions to the herd. (See also HEALTH-MANAGEMENT INTERACTION: GOATS, p 2147.)

Some causes of lameness may be associated with systemic disease. Therefore, a thorough physical examination should always be performed, followed by a detailed examination of all four limbs, with a specific assessment of gait and mobility in an attempt to localize locomotor problems. In goats, as in other species, locomotor difficulties usually involve the musculoskeletal system directly, but conditions of the nervous system can mimic musculoskeletal disease and should be considered during the clinical examination.

The hoof of the affected leg(s) should be examined, and excess horn material removed to leave a level, weight-bearing surface. If the feet have not been trimmed recently, or the goats have been on soft ground or bedding, excess horn commonly overgrows from the walls, toes, and heels, and folds over the sole. With severe neglect, "sled-runner" or "Turkish slipper"-type hooves with elongated toes may cause the goat to walk on its heels. The following should be noted during foot trimming: any portion of the horn that is abnormally thickened, any underrunning of the heel or sole, any abnormal wear of one claw, or any abnormal or necrotic smell.

After trimming, the feet should be scrubbed clean and inspected for puncture

wounds, foreign bodies such as stones or clover burrs caught in the interdigital space, or pus from a discharging abscess. Inspection should include the coronary band or coronet.

The rest of the leg should be palpated carefully, including the bones, tendons, and muscles. Any muscle atrophy or restriction of movement should be noted, and contralateral limb structures should be compared for signs of asymmetry. The joints also should be checked for heat, swelling, or pain.

If the clinical examination suggests joint involvement, it may be necessary to aseptically sample fluid from an affected joint for visual examination, cytology, Gram stain, and culture and sensitivity tests. Joint fluid containing pus alone, or with Gram-stained bacteria, indicates joint-ill; fibrin and pus combined suggest *Mycoplasma* spp; clear or cloudy joint fluid with many mononuclear cells suggests caprine arthritis-encephalitis virus (CAE, see p 747).

A blood or serum sample may also be useful to establish the underlying cause of lameness. In joint-ill, the WBC count is high due to neutrophilia. Blood calcium, phosphorus, and vitamin D levels may help diagnose epiphysitis or rickets, although blood levels often return to normal before the affected goat is examined. If CAE is suspected, the presence of antibody can be checked; however, false negatives may be seen during severe stress, and positive tests may be coincidental to another cause of lameness if seroprevalence of the CAE virus is high in the herd of origin.

Radiography may be helpful. In epiphysitis, the growth plates should be checked; there is also lateral deviation of the radii and occasionally thinness of the bone. In CAE virus infection, the initial swelling of the soft tissue surrounding the affected joint may be followed by calcium deposits in the swollen periarticular tissue, joint capsule, ligaments, tendons, and tendon sheaths. Later changes may include mild periarticular osteophyte production, "joint mice," and rough extensions of the periarticular bone proximally and distally.

Some of the more important conditions that cause lameness in goats are discussed below, listed in alphabetical order. The differential diagnosis in any case of lameness is influenced by geographic location, herd history, management practices, and other relevant factors.

CAPRINE ARTHRITIS AND ENCEPHALITIS

Caprine arthritis and encephalitis (CAE) virus infection has emerged during the past 35 yr as a major cause of disease, primarily in European breeds of dairy goats under intensive management. All breeds of goats are susceptible to this retrovirus, and prevalence of infection is related to exposure to virus. Two distinct forms of locomotor problems are seen. A neurologic form of the disease is seen in young goats, usually 2–4 mo old but as old as 1 yr. It is characterized by a progressive paresis with incoordination leading to paralysis, usually involving the hindlimbs and later the forelimbs. In older, adult goats, the virus infection manifests as a chronic, progressive arthritis involving one or more joints and usually involving the carpal joints. The initial sign is usually swelling of the affected joint(s), followed by progressive degeneration of articular and periarticular tissues with calcification, leading to decreased range of motion, ankylosis, and overt loss of mobility.

For a more detailed discussion, see p 747.

CONTRACTED TENDONS IN KIDS

Contracted tendons in newborn kids are seen sporadically in goats of all breeds throughout the world, usually with unexplained causation. However, there are two specific, inherited conditions of goats that result in contracted tendons of newborns.

A usually bilateral, congenital condition that is a genetic defect is seen in Angoras in Australasia. It is due to a recessive autosomal allele that must reach a certain level before affected animals appear; the time between purchase of a carrier buck and appearance of affected kids may be 5–6 generations. Either the fore- or hindlimbs are affected. In rare cases, only one forelimb is twisted. In severe cases, the kid is either unable to stand or walks on its fetlocks. In less severe cases, the kid may move relatively easily with fetlocks that are permanently partly flexed. In mild cases, the limbs may gradually be splinted straighter and straighter until the kid is able to bear weight on its feet.

Anglo-Nubians in the USA, Canada, Australia, and New Zealand can have a rare genetic condition called β -mannosidosis. At birth, affected kids have varying degrees of fixed flexion of the forelimbs and fixed extension of the hindlimbs. They can see, bleat, and suckle if held up to the teat. Their withdrawal reflexes are normal or depressed, and there is intention tremor, especially of the head. There may be nystagmus, deafness, and facial abnormalities. At necropsy, cutting the tendons allows free movement of the limbs. Histologic examination reveals typical lesions of lysosomal storage disease characterized by cellular vacuolation. Affected kids have no plasma levels of β -mannosidase, and both parents have levels half the normal range.

COPPER DEFICIENCY

Copper deficiency may cause locomotor difficulties in goats in two distinct ways. Abnormal bone growth with increased bone fragility can predispose to fractures of long bones. Independently, a neurologic condition known as enzootic ataxia or swayback develops, in which copper deficiency of kids in utero or after birth results in permanent myelin degeneration in the spinal cord, leading to progressive incoordination and paralysis with failure of mobility. Clinically, this appears similar to the neurologic form of caprine arthritis-encephalitis virus (see p 747) infection in young kids. Copper status of the ration needs to be evaluated, and copper supplementation provided as necessary.

EPIPHYSITIS

(Bent leg, Windswept)

Epiphysitis may result from imbalance in the calcium:phosphorus ratio. It is seen

in young, rapidly growing kids (more often in males than in females) and in young does in late pregnancy or in the early stages of their first lactation. These does are young (eg, 12 mo), extremely heavy milkers, or carrying twins or triplets. Epiphysitis is sometimes compounded by rickets (see p 1051).

Clinical Findings and Diagnosis: Epiphysitis starts with lateral or medial bowing of one or both radii. Later changes may consist of lateral deviation of the digits on the fore- or hindfeet; lameness and reluctance to walk; an arched back; and soft swelling and pain in the carpal, metacarpophalangeal, tarsal, and metatarsophalangeal joints. Diagnosis of epiphysitis can be confirmed with radiography.

Conditions that have been implicated in its cause include an excess of dietary calcium with a calcium:phosphorus ratio of >1.4:1 (generally >1.8:1), excess protein intake, excess dietary iron, indoor housing of kids, or lack of vitamin D caused by prolonged overcast weather and low vitamin D levels in the feed. Carotene has an antivitamin D effect. Vitamin D has poor stability in prepared feed, especially when mixed with minerals. Alfalfa is high in calcium (1.4% calcium to 0.2% phosphorus) and protein. Owners frequently feed kids milk for prolonged periods because of a lack of commercial outlets for milk.

Treatment and Control: Once the probable cause(s) is identified, the diet should be corrected and the appropriate supplement given—usually injectable vitamin D and/or phosphorus or oral balanced calcium/phosphorus supplements.

Predisposing factors also must be corrected. The diet of growing kids should be changed to slow growth rate. The mating of young does <7 mo of age should be discouraged, and buck kids should be separated from doe kids by 3 mo of age to avoid unplanned matings. The diet for young does in milk with limb deformities should be corrected to allow for normal bone growth. Proper nutritional management stops limb deformities from worsening, and such deformities self-correct over time in most does.

FOOTROT AND FOOT SCALD

Footrot and foot scald are serious problems of sheep and can also have a major adverse impact on goats under certain management conditions (see p 2147).

JOINT-ILL

Several joints of kids can be involved in joint-ill, a nonspecific bacterial infection. Bacteria that have been incriminated are mainly gram-positive and include staphylococci, streptococci, *Corynebacterium* spp, *Actinomyces* spp, and *Erysipelothrix rhusiopathiae*, as well as gram-negative coliforms.

Environmental bacteria gain entry to the neonate's circulation, usually via the umbilical cord. Other methods of entry include contamination of breaks in the skin or via the GI or respiratory tract. Predisposing factors include lack of routine dipping of the umbilical cord; poor sanitation in the kidding pens; or does kidding in overcrowded, dirty conditions. *E. rhusiopathiae* are soil-living bacteria that may persist on farms or in pens used by sheep or pigs. *Mycoplasma* infection is also a differential diagnosis (see p 1095).

Clinical Findings: With joint-ill, more than one joint is hot, swollen, and painful. Often, the affected limb(s) cannot bear weight, and kids with more than one leg affected may be unable to stand. The more commonly affected joints include the carpus, shoulder, hock, and stifle. Generally, there is a fever but no reduction in appetite. Sometimes the navel area is inflamed, but often there is no visible abnormality. An abscess may form on the navel long after the kid has recovered. The WBC count may be increased with a left shift.

If the condition becomes chronic, the limbs are stiff, some joints may be ankylosed, and overall growth is poor. At this stage the temperature is normal.

Treatment: To be successful, treatment must be given early and, when possible, antibiotic selection should be based on culture and sensitivity testing. Frequent injections of high doses of parenteral antibiotics given for ~1 wk may effect a cure if combined with careful nursing. Joint lavage with saline and antibiotic solutions may enhance therapeutic outcome in select cases. Complications should be prevented by providing soft bedding, frequently turning any kid unable to stand, and massaging the affected joints. If ankylosis starts to develop, the kid should be supported in a sling for short periods as frequently as possible.

In large, commercial herds, treating severely affected kids may not be economically justified, and humane euthanasia

should be considered. Many that do recover remain unthrifty for the rest of their lives.

Control: Hygiene at parturition is essential. A deep bed of clean sawdust, wood shavings, or straw should be provided; it is often better to allow the doe to kid on fresh pasture if the weather is warm.

The umbilical cords of newborn kids should be dipped several times in strong, 7% tincture of iodine. Cords should be dipped each time the kid is handled in the first 24–48 hr. Owners should clean their footwear before entering kidding pens. Kids must receive adequate colostrum at birth.

LAMINITIS

(Founder)

Laminitis in goats is seen worldwide, but the incidence is lower than that in dairy cattle and horses. Predisposing causes include overeating or sudden access to concentrates, high-grain and low-roughage diets, or high-protein diets. Laminitis can also develop as a complication of acute infections such as mastitis, metritis, or pneumonia, especially after kidding.

When laminitis is severe, the affected goat is lame and reluctant to move; there is a fever, and all four feet are hot to the touch. Touching the coronary band elicits a severe pain reaction. In less severe cases, only the forefeet are affected. Laminitis can become chronic if the initial phase is not diagnosed or treated successfully. The onset is insidious, but eventually the goat is seen walking on its knees, with “sled-runner” deformities of its hooves.

In acute laminitis, the predisposing condition, if identifiable, must be corrected promptly. The laminitis is treated with analgesics such as daily parenteral flunixin meglumine, and hosing or soaking the affected feet is also useful. Although antihistamines are frequently used, their effectiveness in treatment of laminitis in goats remains unproved. Similarly, the use of corticosteroids is controversial because they may contribute to laminitis in horses, and they should not be used in pregnant does because of the risk of abortion. Chronic laminitis with deformed hooves is treated by routine, vigorous foot trimming.

MYCOPLASMOSIS

See also **CONTAGIOUS AGALACTIA**, p 1352, and **CONTAGIOUS CAPRINE PLEURO-PNEUMONIA**, p 1474. Kids infected with *Mycoplasma mycoides*

mycoides (large colony variant) or other *Mycoplasma* spp may show severe lameness with multiple hot swollen joints, weight loss, pyrexia, and poor coats. Some have diarrhea, and some have increased lung sounds and respiratory rates. Affected kids are generally 2–4 wk old. Morbidity and mortality rates of 90% and 30%, respectively, have been reported. Adult does with *Mycoplasma* infection may have mastitis and polyarthritis. Treatment is with tetracycline, tylosin, or tiamulin, but prognosis for complete recovery is guarded.

TRAUMA

Goats, in general, are agile creatures, but if frightened they may attempt impossible jumps, with resultant fractures or other injuries. Yards designed for goats that are infrequently handled should have a visual as well as physical barrier. Chain-link fences are often associated with limb fractures when used for goat enclosures. Fortunately, most fractures of the lower limbs heal rapidly with normal casting. Shearing of Angoras is a source of potential problems when the shearer's comb cuts into or through the Achilles tendon. Orthopedic procedures suitable for large dogs can be used. If goats are attacked by dogs or wild canines and survive, they often have multiple traumatic injuries that can include fractures.

Some IM injections can cause problems. For example, mixed clostridial vaccines can cause severe soft-tissue swelling and lameness for ≥48 hr. Irritant drugs can damage nearby nerves and cause lameness, particularly when thin or young goats are injected in the thigh muscles and the sciatic nerve is affected. In some cases of severe mastitis, especially gangrenous, there is a hindlimb lameness on the affected side as the doe changes her gait because of swelling and pain in the udder.

WHITE MUSCLE DISEASE

See also **NUTRITIONAL MYODEGENERATION**, p 1172. Most kids affected by white muscle disease have been in good condition and are 2–3 mo old (range, 1 wk to 4 mo). Commonly, sudden death is associated with cardiac muscle damage. Other kids are depressed, reluctant to move, and appear stiff, with a “sawhorse” stance, or become recumbent. Muscles, especially of the hindlimbs, are firm and painful to the touch. Treatment is with selenium and vitamin E injection in acute cases.

LAMENESS IN HORSES

Lameness is defined as an abnormal stance or gait caused by either a structural or a functional disorder of the locomotor system. The horse is either unwilling or unable to stand or move normally. Lameness is the most common cause of loss of use in horses. It can be caused by trauma, congenital or acquired disorders, infection, metabolic disorders, or nervous and circulatory system disease.

Lameness is not a disease per se but a clinical sign. It is a manifestation of pain, mechanical restrictions causing alteration of stance or gait, or neuromuscular disease. Pain is the most common cause of lameness in all horses. Mechanical lameness is best typified by complete upward fixation of the patella with its characteristic gait abnormality but can also be the result of fibrotic myopathy of the semitendinosus muscle or of restrictions caused by annular ligaments, adhesions, or severe fibrosis.

It is critical to correctly determine the cause of the lameness, because treatment varies greatly depending on the cause. For example, the mechanical lameness of complete upward fixation of the patella will not respond to analgesics, whereas lameness caused by pain often responds to systemic or local analgesics and anti-inflammatory drugs. Some causes of lameness produce very characteristic and classically described gaits. In fibrotic myopathy, a mechanical lameness, the affected limb is pulled back and down quickly before the end of the protraction phase, giving the impression that the foot "slaps down" on the ground. The signs are most obvious at the walk. In stringhalt, a neuromuscular disorder, the affected limb is hyperflexed during the cranial or swing phase, while the stepwise caudal jerking movement before foot contact does not occur. Unfortunately, many causes of lameness do not produce a characteristic gait abnormality, making diagnosis a challenge.

Pain-related lameness can be classified as weight bearing (supporting leg) or nonweight bearing (swinging leg) lameness. Although lameness is most often observed as a weight-bearing deficit, it may be composed of both. A supporting leg lameness is seen when the horse reduces the amount of time or reduces the amount of force applied to the weight-bearing limb. The most consistent and easily recognized

clinical signs of lameness are the head nod associated with forelimb lameness and the sacral rise, also called a pelvic rise or hip hike, associated with hindlimb lameness. Hindlimb lameness should be assessed from the side as well as from behind, because this provides an opportunity to assess arc of foot flight, duration of protraction and retraction phases, length of weight-bearing phase, and the presence or absence of a sacral rise. Forelimb lameness should be observed from the front and side. Hindlimb and forelimb lameness in many horses will be accentuated when the horse is worked in a circle with the affected limb on the inside.

Factors that predispose horses to lameness include physical immaturity, which may occur in premature or dysmature foals, and training older foals before maturity. Other factors include preexisting developmental orthopedic disease (eg, osteochondrosis, flexural limb and angular limb deformities); poor conformation; improper hoof balance or shoeing; failure to adequately condition performance horses; monotonous repetitive stresses on bones, tendons, ligaments, and joints in performance horses; hard, slippery, or rocky surfaces upon which horses work; and extremely athletic activities. Inciting factors in lameness include direct or indirect trauma, fatigue resulting in incoordination of muscles (which often occurs in racehorses at the end of races), inflammation, infection, and failure to recognize early disease before it creates significant pain.

Lameness in one part of a limb often results in secondary soreness in another area of the same limb and may result in lameness of the contralateral forelimb or hindlimb from overuse due to compensation. The entire horse should be evaluated for secondary lameness even when the cause of the primary problem is obvious. Secondary lamenesses are very common in performance horses but may occur in all types of horses. A dramatic example of a secondary lameness occurs when biomechanical laminitis develops in the normal contralateral limb of a horse with limited weight bearing from a severe orthopedic problem causing shifting of weight from the injured limb to the normal limb.

THE LAMENESS EXAMINATION

A systematic investigation of a lame horse may be time consuming when the cause is not obvious. The examination benefits from standardized facilities such as a level, firm, nonslip surface to walk and trot the horse and a soft support area to lunge and ride the horse. The examiner must be knowledgeable in equine anatomy, normal conformation and gaits, regional anesthesia, and imaging techniques and be able to recognize forelimb and hindlimb lameness.

The examination begins with a comprehensive medical history; type, age, and training regimen may give important clues to the lameness, as will the time since onset of lameness, interim management, and any suggestions that the lameness may improve with either rest or exercise. The interval since the last shoeing should also be noted. Response to anti-inflammatory or analgesic medications may provide useful information. Results of hematologic and biochemical analyses may shed light on other problems that influence overall performance.

Although valuable, modern diagnostic imaging techniques are no substitute for detailed visual inspection and thorough manual palpation of the limbs in weightbearing and nonweightbearing positions. Conformation should be evaluated and the horse visually checked for symmetry, swellings, muscle loss, abnormal stance, and obvious injuries. The trunk and limbs should be palpated for heat, pain, swellings, and joint effusion. The high degree of variation between horses should be remembered, and comparison with the contralateral limb should always be done, although the latter may not necessarily be a useful control. The reaction of the horse to palpation and the range of flexion and extension of all joints should be noted. The feet should be thoroughly examined, including compression of the walls and sole with hoof testers. Wear patterns of shoes and feet should be noted. A number of abnormalities such as broken toe/pastern axis; mismatched hoof angles; under-run, contracted, and sheared heels; and disproportionate hoof size are seen more frequently in lame than in sound horses. Shoes should be left on during the initial stages of the examination, because removing them might make the horse footsore and preclude further examination with the horse being trotted or ridden. Shoes should be removed for complete and thorough examination of the foot when the lameness has been localized to the foot and

any exercise needed for diagnosis has been completed.

The back and neck should be thoroughly examined with the horse restrained and standing square on a level surface. Flexibility and extensibility of the back can be checked by alternately pinching the midline in the midthoracic and sacrococcygeal regions, whereas lateral flexion can be checked by turning the horse short around its own axis.

Examination during exercise is often required to localize the lameness to a specific limb or site and to evaluate the response to diagnostic regional anesthesia. If lameness is major and acute and a fracture is suspected, exercise should not be undertaken or a catastrophic breakdown may result. Similarly, diagnostic regional anesthesia should not be performed when a fracture is suspected. It is important to determine whether the horse may have been given analgesic medication before the lameness examination.

Recognition of lameness is a key skill to successful diagnosis. The most consistent sign of a unilateral forelimb lameness is the head nod. The head and neck of the horse rise when the lame forelimb strikes the ground and is weightbearing, and fall when the sound limb strikes the ground. The sacral (pelvic) rise is the most consistent and easily observed sign of hindlimb lameness. The entire pelvis and sacrum rise when the lame limb strikes the ground and is weight bearing, and fall when the sound limb strikes the ground. Both head nod and sacral rise serve to reduce concussion on the lame limb. A computerized, handheld gait analysis system that objectively measures the head nod and sacral rise is available to detect lameness and is being used by some veterinarians.

The horse should initially be examined by walking and jogging in hand with a loose line to the halter so that the movement of the horse is not restricted. A firm, nonslippery surface (eg, hardpack fine gravel) is ideal to trot on a straight line and to lunge on a firm surface. It also provides an opportunity to listen to the footfall and consider this information along with the visual appraisal. However, feet of different sizes and shapes and different shoes make slightly different impact sounds, often rendering these sounds of little diagnostic value. Frequently, lameness is more pronounced when the horse is worked in a circle. Circling can be done on a lunge line, free exercise in a large round pen, in hand, or under saddle. Lunging on asphalt or concrete predisposes the horse to slipping and

injury but may be done in selected cases to accentuate a very subtle hoof or lower limb lameness. Both forelimb and hindlimb lameness may become worse when the horse is circled; most of the time, the lameness is accentuated when the affected limb is on the inside of the circle.

Flexion tests are useful diagnostic tools. The range of movement and response to passive flexion, along with any suggestion of increased lameness or onset of lameness after flexion, should be observed. The distal phalanges in both forelimbs and hindlimbs should be flexed independently of the carpus and hock to obtain maximal information. Bending pressure should be firm but not excessive, which can create false-positive responses. All tests should be done on both sound and lame limbs for comparison. Consistency should always be applied, and individual experience used. A single positive flexion test without associated lameness may not be of significance.

To establish consistency, the entire examination should involve the same handler, the same biting when the horse is under saddle, and the same surfaces under foot. The horse should be controlled so that it is trotting at a useful, repeatable pace to evaluate the lameness. Very slight sedation of nervous or fractious horses with 3 mg romifidine or 100 mg xylazine may result in a horse with a more relaxed outline and allow a better assessment without seemingly influencing the degree of lameness. Slowing down the pace at the trot often illustrates a subtle lameness better, because the horse loses its momentum and struggles with suspension in the affected limb(s).

A ridden assessment of the horse may be necessary, particularly with a subtle lameness that can only be observed under saddle. A multiple-limb lameness without an obvious single-limb lameness may also be detected. The clinical signs may be minor (eg, the horse refusing certain movements or activities, slight head tilts, or tail swishing). However, a good rider can, often inadvertently, hide a problem by his or her inherent expertise and ability to "correct" difficulties.

Occasionally, a horse appears to be sound when lunged and ridden, but the rider feels that the performance is impaired. In such cases, it may be worth working the horse on concomitant analgesic or anti-inflammatory medication at therapeutic levels for an adequate period (eg, phenylbutazone 2–3 g/day, PO, for 7–14 days) to assess whether improvement occurs. Some clinical signs purported to be caused by lameness

are training problems. If improvement on medication occurs, the medication should be withdrawn and diagnostic anesthesia used beginning in an arbitrary limb, most often a forelimb. In this way, multiple-limb lamenesses (as many as four), often mimicking the clinical picture associated with back pain, can be evaluated and treated.

Diagnostic regional anesthesia (see p 1101) should be used to determine the area of pain in all lame horses in which the lameness can be localized to a specific limb but not to a specific site on the limb. A consistently observable lameness must be present for the clinician to evaluate response to anesthesia.

Because lameness may be caused by neuromuscular disorders, a complete neurologic examination should be part of the lameness examination whenever an obvious painful or mechanical cause has not been found. The examination should include evaluation of cranial nerve and upper and lower motor neuron function.

Observing the horse execute movements such as turning short, backing, "hopping" on one forelimb (with the other forelimb held up), negotiating a curb, turning in tight circles, and walking uphill and downhill should be done. These tests help determine whether reduced proprioception, weakness, or spasticity may be the cause of the gait abnormality.

IMAGING TECHNIQUES

Imaging techniques provide important pathologic and physiologic information necessary to treat specific conditions. Imaging can be divided into anatomic and physiologic methods. Anatomic imaging methods include radiology, ultrasonography, CT, and MRI. Physiologic imaging methods include scintigraphy and thermography. When diagnostic analgesia has failed to eliminate the lameness, the lameness is too subtle for localization by diagnostic analgesia, or the horse is not amenable to handling or injection, physiologic imaging techniques may help narrow the problem to a specific region. Anatomic imaging methods can then be used to evaluate those areas. Imaging may also help prevent injury. This requires early detection of the physiologic changes associated with injury. Although frequent use of an anatomic imaging method can detect change in one region, physiologic imaging allows assessment of the entire horse on a routine basis.

Anatomic Imaging Techniques

Radiologic techniques are the methods most commonly used to evaluate lameness in horses. Plain film radiography used to be the standard, but it has been replaced by computed radiography in equine practice. Computed radiography can be divided into indirect and direct. Indirect uses a special plate instead of film. The plate stores energy that is then read by a computer to produce the image. Direct digital radiography also uses a special plate, but the radiation is converted to a digital signal and sent directly to a computer. Direct digital radiography produces images faster, but both share the advantages of fewer retakes, a lower radiation requirement, and post processing techniques that eliminate contrast problems. Radiography requires multiple projections to evaluate any area. It allows assessment of bony tissues and reflects both acute and chronic changes. Occasionally, radiographic techniques that provide more information are needed. Contrast radiography provides information about articular cartilage and surfaces and is of particular value in determining whether subchondral cysts communicate with the joint and in delineating subcutaneous tracts. More recently, these techniques have been used to delineate changes in the navicular bursa and have produced 60% more information than plain radiography. Pathologic diagnoses are usually made by radiography in conjunction with clinical examination.

The goal of radiology, regardless of system used, is to examine the region sufficiently to fully evaluate the anatomic structure. Diagnostic films require preparation, positioning, and production. Preparation involves readying the object to be radiographed. In most cases, this requires the object to be clean and all foreign materials removed (eg, any iodine-based products on the limb will cause artifacts on the radiograph). For radiographs of the hoof, the shoe may need to be removed and the sulci packed, in addition to cleaning.

Positioning is critical; the object must be evaluated from a sufficient number of angles to ensure adequate evaluation. Minimally, this means two radiographs 90° apart. Many of the limbs require more views for adequate evaluation. Examination of those projections may necessitate further views to better assess any areas of interest. For instance, the equine foot, fetlock, and carpus require five projections, whereas the pastern and hock require four. The upper

limbs of the horse require fewer projections. This is not because these are less complex areas; rather, the size of the horse makes it difficult to get more projections. Two views can usually be made of the elbow and the stifle. For the shoulder joint, usually only one view is possible. For the hip, anesthesia is usually required. However, digital radiography has made it possible to take standing hip projections on young horses and those with smaller muscle mass.

Production of good radiographs requires the correct exposure of the film. Proper kVp and mA settings, as well as proper focal film distance, are critical. Unfortunately, these factors vary and depend on the particular x-ray machine and the film or electronic system used. For ambulatory equine practitioners, another factor that must be considered is the electricity output in the barn where the images are taken—older barns may not have sufficient electrical output for the x-ray generator to make the desired exposure. New computed radiography systems that are battery operated can avoid these types of electrical problems.

Ultrasonographic examination can be used to assess any soft tissues. Like radiography, the area to be examined should be evaluated in two planes 90° apart. Selection of a probe should take into account the depth, contour, and location of the tissue to be examined. The deeper the tissue to be evaluated, the lower the wavelength of the probe used. The higher the wavelength, the greater the detail that can be achieved. For examination of superficial and deep flexor tendons or the suspensory ligament, a 7.5–10 MHz linear probe is best. Examination of complex anatomic areas such as the foot or pelvic region requires a convex linear probe. Examination of the pelvic region internally requires a rectal linear probe.

Ultrasonography is most useful in the evaluation of tendons and ligaments but can also be used to evaluate muscle and cartilage. In all cases, tissue fiber alignment and echogenicity are the factors used to determine anatomic disruption. Generally speaking, loss of fiber alignment and decreased echogenicity are signs of acute injury; increased echogenicity is generally thought to indicate chronic conditions. However, if any questions arise during the examination, the opposite limb or area can be examined to compare changes. For the novice ultrasonographer, it is a good idea to compare the right and left sides before making an ultrasonographic diagnosis.

Assessment of anatomic changes serves as the basis for any pathologic diagnosis, as well as being important in determining prognosis. For these purposes, radiography and ultrasonography are complementary. Radiography provides information regarding bony tissues, whereas ultrasonography provides information about the soft tissues that connect bone or provide support.

MRI and CT are high-detail anatomic imaging tools. Their use is becoming more common in equine lameness evaluations. MRI in particular has become quite popular. Two types of MRI are available: low-field and high-field magnets. High-field scanners produce a stronger signal and higher resolution pictures in a shorter time than low-field scanners. However, some low-field scanners can be used to examine the standing, sedated horse, whereas high-field scanners require the horse to be anesthetized. The standing units can only be used to evaluate from the carpus and hock distally. Because of the slower image acquisition with the low-field scanners, motion can be a problem. MRI provides sliced images of the anatomic region of interest. The slices are usually in three different planes: axial (transverse), sagittal (longitudinal), and dorsal. MRI of orthopedic disease is performed in several acquisition sequences. Each sequence displays different anatomic, physiologic, and pathologic information. The most common sequences are the proton density and the T1-weighted and T2-weighted images. Proton density provides the most anatomic detail. T1-weighted images highlight the structural characteristics of bone and soft tissues, whereas T2-weighted images emphasize the fluid characteristics of tissues and are sensitive for detecting synovial effusions, cysts, and edema. Special sequences can further clarify or highlight a lesion. For instance, fat-suppressed sequences are used to evaluate edema in high-fat signal areas such as the bone marrow.

CT is a technology that uses very small x-ray beams from many different angles around the body (called a slice) that are reconstructed by computer to produce an image. Because the images are in slices, there is less interference from surrounding anatomy. Therefore, the CT scanner provides the clearest images possible of the limbs, joints, nasal passages, skull, sinus cavities, and neck. These images improve the clinician's ability to accurately define and identify the extent of abnormalities of these regions.

Physiologic Imaging Techniques

These techniques provide images that reflect physiologic processes. Unlike anatomic imaging, which reflects structure, physiologic imaging techniques assess metabolism or circulation. Thermography and scintigraphy allow examination of the entire horse. When combined with a thorough clinical examination, these methods help identify injuries that may otherwise go undetected.

Thermography is the pictorial representation of the surface temperature of an object. It is a noninvasive technique that measures emitted heat in the form of infrared radiation and helps detect inflammatory changes that may contribute to lameness. Relative blood flow dictates the thermal pattern; normal thermal patterns can be predicted based on vascularity and surface contour. Skin overlying muscle is also subject to temperature increase during muscle activity. Circulation is invariably altered in injured or diseased tissues. Thermographically, the "hot spot" associated with the localized inflammation generally is seen in the skin directly overlying the injury. However, diseased tissues may have a reduced blood supply due to swelling, vessel thrombosis, or tissue infarction. With such lesions, the area of decreased heat is usually surrounded by increased thermal emissions, probably due to shunting of blood. The American Academy of Thermology has published guidelines for the use of infrared thermography in veterinary medicine. The purpose of the guidelines is to provide criteria for the production of reliable and repeatable thermal images.

During scintigraphy, polyphosphonate radiopharmaceuticals are given IV. Their distribution is then measured by a gamma camera, which measures the radiation emitted from the radiopharmaceutical after it is distributed through the body. The polyphosphonates bind rapidly to exposed hydroxyapatite crystal, generally in areas where bone is actively remodelling. Because inflammation causes an increase in blood flow, capillary permeability, and extracellular fluid volume, inflamed tissues accumulate high levels of radiopharmaceutical during the soft-tissue phase of scintigraphy, allowing evaluation of soft-tissue injuries. During the bone phase, the radiopharmaceutical accumulates in areas of increased remodelling or vascularity. Because injured bone is remodelled more rapidly, scintigraphy helps detect lesions in bone and ligaments, particularly to identify enthesopathy (damage to the insertions of tendons and ligaments on bone).

ARTHROSCOPY

(Tenoscopy, Bursoscopy)

Arthroscopy is the accepted way to perform joint surgery in horses and is a valuable tool in the diagnosis of joint disease. Arthroscopic surgery can be used to remove bone and cartilage fragments, debride damaged ligaments and menisci, assist the repair of articular fractures with internal fixation, debride or inject subchondral bone cysts, repair cartilage, and debride and flush contaminated or septic synovial cavities. Arthroscopy is a valuable method to evaluate intrasynovial structures and is particularly useful to evaluate soft-tissue structures such as ligaments, cartilage, menisci, and synovial membranes. It should be used in concert with other diagnostic methods, including high-quality radiographs, ultrasonography, and CT and MRI when available. Diagnostic arthroscopy is the most sensitive and specific tool for intra-articular evaluation in horses.

Arthroscopes of 2.5–5 mm diameter can be placed in all joints of the equine limbs; however, not all areas of every joint can be examined. The arthroscope has also been used to examine, diagnose, and perform surgery on structures within the digital, carpal, and tarsal tendon sheaths (tenoscopy) and in the navicular, calcaneal, and bicipital bursas (bursoscopy).

Advantages of arthroscopy compared with standard surgical procedures include the use of small stab incisions for placement of the arthroscope and instruments, the ability to view numerous areas of the joint, easy operations on more than one joint during the same surgical procedure, less trauma to periarticular soft tissues, less pain, reduced convalescent times, and reduced complications.

Diagnostic and surgical arthroscopy is technically demanding, and extensive experience is necessary to become proficient. Good knowledge of joint anatomy and good hand-eye coordination and spatial awareness are essential characteristics of successful surgeons.

Most arthroscopic procedures are performed with the horse under general anesthesia. Many surgeons prefer dorsal recumbency to allow surgical access to all sides of the joint, to allow surgery on multiple joints and limbs, and to control hemorrhage. Routine aseptic surgical preparation and draping is necessary. Basic equipment required for arthroscopy includes an arthroscope and insertion sleeve, light source and cable, fluid pump for joint distention, egress cannula, and an assort-

ment of hand instruments for intra-articular procedures. A video camera and video screen are highly recommended to decrease the risk of contamination, to improve visualization and depth perception, and to allow capture of images and videos. Triangulation techniques are used to optimize manipulation of intra-articular instruments.

Arthroscopy, bursoscopy, and tenoscopy are often used to evaluate and treat contaminated synovial cavities. The techniques facilitate wound debridement, removal of fibrin and foreign debris, and copious flushing of the cavities without inducing more trauma from a major incision. The normal intrasynovial environment can recover quickly. Bursoscopy of the navicular bursa has greatly reduced the need for the streetnail procedure to treat punctures of the navicular bursa and has reduced the morbidity of calcaneal infections after injury to the hock. Tenoscopy has improved the recovery rate of septic tenosynovitis in horses.

REGIONAL ANESTHESIA

Regional anesthesia is a valuable diagnostic aid used to localize lameness when, after a thorough clinical examination, the site of pain remains uncertain. Localizing pain allows other diagnostic procedures, such as anesthesia of a joint, radiography, ultrasonography, CT, scintigraphy, or MRI to be used more effectively and economically to identify the cause of lameness. Additionally, use of regional anesthesia allows some surgical procedures to be performed without the need for general anesthesia, and it can be used to provide temporary, humane relief of pain.

Lidocaine HCl (2%) and mepivacaine HCl (2%) are the local anesthetic agents most commonly used to induce regional anesthesia during the lameness examination. Mepivacaine HCl is preferred by most clinicians, because it causes less tissue reaction than lidocaine HCl. Bupivacaine HCl is used to induce regional anesthesia for humane relief of pain, because it provides anesthesia that lasts 4–6 hr.

The choice of anesthetic agent may depend on its duration of action. The anesthetic effect of mepivacaine HCl, which lasts 90–120 min, makes this agent valuable for examining a horse with lameness in multiple limbs or if multiple sites of pain on a limb are suspected. Lidocaine HCl, which has an anesthetic effect of only 30–45 min, might be the preferred local anesthetic agent when different techniques of diagnostic analgesia are likely to be used during the lameness examination.

Most nerves below the carpus or hock are anesthetized using a 25-gauge, 5/8-in. (1.59-cm) needle. A 1½-in. (3.8-cm), larger-gauge needle (eg, 22- or 20-gauge) is used to anesthetize nerves located more proximally on the limb. If a relatively large-gauge needle is to be used, SC deposition of a small amount of local anesthetic solution, using a 25-gauge needle, may avoid resentment by the horse when the larger-gauge needle is inserted.

To avoid broken or bent needles during perineural administration of local anesthetic solution, the needle should always be inserted detached from the syringe. Spinal needles are flexible and more likely to bend than break and, thus, safer to use if there is a possibility the horse may move the limb. Using a flexible needle is especially important when the difference in range of movement between skin and deeper tissues is large, in case the horse moves during injection. Luer-lock syringes should not be used because they are difficult to attach to the needle after it is inserted, and this type of syringe cannot be detached quickly from the needle to prevent the needle from being pulled out, bent, or broken if the horse moves during the procedure. The needle should be directed distally during insertion when anesthetizing nerves in the distal portion of the limb. Directing the needle

proximally may result in proximal migration of anesthetic solution and unintended anesthesia of more proximal branches of the nerve, thus confusing the results of the examination.

When the goal of regional anesthesia is to identify a site of pain below the carpus or hock, only the smallest effective volume of anesthetic solution should be administered to avoid inadvertent anesthesia of adjacent nerves. When the nerve can be palpated subcutaneously, a very small volume of local analgesic solution can be used because the solution can be placed more accurately into the fascia surrounding the nerve.

Before regional anesthesia is performed, the horse should be consistently and sufficiently lame so that any improvement in gait can be detected. Lungeing or riding the horse may exacerbate a subtle lameness. The lameness of some horses improves or resolves during exercise; for these horses, a false-positive response to regional anesthesia may result if the horse has not been sufficiently exercised before it is examined. If a horse is subtly lame, using a wireless, inertial sensor-based system designed to evaluate lameness allows objective interpretation of results of diagnostic analgesia.

Relief of pain and resolution of lameness after local anesthetic solution is

Arthroscopy and arthrocentesis joint entry sites in the digit, lateral aspect, horse. Illustration by Dr. Gheorghe Constantinescu.

administered into the fascia surrounding a nerve in the distal portion of the limb usually occurs within 5 min, but anesthesia of larger nerves in the proximal portion of the limb may take 20–40 min. Results of a regional nerve block can be misinterpreted if the horse's gait is assessed before the onset of pain relief. When assessing the effects of anesthesia of nerves in the distal portion of the limb, the clinician should keep in mind that anesthetic solution might migrate up the nerve to anesthetize more proximal structures, thus confusing the results of the examination. To avoid this complication, the gait should be evaluated within 15 min after administering a regional nerve block in the distal portion of the limb. When a regional nerve block is administered in the proximal portion of the limb, the horse may develop a gait abnormality or stumble because of altered proprioception. When nerves above the hock or carpus are anesthetized, it may be prudent to assess the horse's gait on a soft surface or after bandaging the distal portion of the limb so that abrasion to skin over the dorsum of the fetlock is avoided if the horse stumbles.

If the gait is unchanged after regional anesthesia, the effectiveness of the nerve block should be determined by checking for skin sensation within the dermatome expected to be desensitized. Skin sensation is assessed by pressing the tip of a ballpoint pen, key, or similar instrument over the skin covering the region intended to be desensitized. For a fractious horse, skin sensation is more safely checked with the limb held or from a distance using a blunt instrument taped to a 3-ft pole. A well-behaved, stoic horse may not react to stimulation of skin even though regional anesthesia was ineffective. For such a horse, reaction to cutaneous stimulation should be assessed before regional anesthesia is performed, or reaction to cutaneous stimulation of the same dermatome on the contralateral limb should be assessed.

When performing regional anesthesia, especially in the distal portion of the limb, local anesthetic solution can be administered inadvertently into a blood vessel, joint, tendon sheath, or bursa. Aspiration before injection may indicate that the needle has been placed within a blood vessel. Administering the anesthetic solution as the needle is withdrawn decreases the likelihood of depositing the solution in an unintended structure and results in deposition of the solution in more than one tissue plane, which increases the likelihood of the solution contacting the nerve.

Opinions vary concerning the amount of skin preparation necessary before administering regional anesthesia. For short-haired horses, the site of injection is often prepared by wiping the site with cotton pledgets or gauze sponges soaked in 70% isopropyl alcohol until a pledget or sponge appears clean. If the site of injection is particularly dirty, it should be scrubbed with antiseptic soap. The consequences of a nonsterile, SC injection are usually minimal, but inadvertent, nonsterile injection of a tendon sheath or joint could result in septic synovitis.

Regional anesthesia of the distal portion of the limb can be accomplished in most horses using minimal restraint, but for fractious horses or for horses previously subjected to regional anesthesia, using a lip twitch or lip chain is prudent. The twitch works best when applied immediately before placing the needle. If this does not provide sufficient restraint, xylazine (0.2 mg/kg) or detomidine (10 mcg/kg) can be given IV. Acepromazine has no analgesic effect and, therefore, is less likely to ameliorate lameness than is a sedative, such as xylazine or detomidine, which provides some analgesia. In fact, some clinicians claim that acepromazine accentuates subtle lameness, possibly by making the horse less aware of its environment and, therefore, more aware of pain in the lame limb. The degree to which sedation or tranquilization interferes with assessment of gait depends on the severity of lameness and the skill of the clinician performing the examination.

Restraining the horse in stocks to administer regional anesthesia of the distal portion of the limb increases the likelihood of injury to the clinician. Regional anesthesia of the distal portion of the limb usually requires multiple injections, which is most safely accomplished with the limb held. When a nerve block is performed with the horse's limb on the ground, the contralateral limb can be lifted off the ground to enhance the safety of the procedure for the clinician.

When anesthetizing the foot of a forelimb, most clinicians prefer to hold the limb while facing in the opposite direction as the horse; however, some clinicians prefer to anesthetize the foot while facing the same direction as the horse. When facing the same direction as the horse, the foot can be held between the clinician's knees to free both hands for the procedure, but the clinician is at risk of injury if the horse swings its limb caudally. When the clinician faces the opposite direction as the horse, the procedure is performed using one hand because the other hand must hold the limb.

Nerve blocks performed distal to the fetlock of the pelvic limb are most safely performed with the pelvic limb stretched caudally and held on the thigh of the clinician performing the block.

Complications of regional nerve blocks are rare but include a broken needle shaft, SC infection, and infection of a synovial structure adjacent to the nerve anesthetized. Local anesthetic solution is detectable systemically, which could create a problem for a horse participating in a competition if the horse's serum is examined for the presence of drugs.

Regional Anesthesia of the Forelimb

Because perineural analgesia should start distally and progress proximally, the **palmar digital nerve (PDN) block** is the most commonly performed regional nerve block of the forelimb. The PDN block is performed with the limb held. The needle is inserted directly over the palpable neurovascular bundle ~1 cm proximal to the cartilage of the foot. The needle is directed distally, and 1.5 mL of local anesthetic solution is deposited near the junction of the nerve and the cartilage of the foot. The PDN block is sometimes called a "heel block," but this terminology is erroneous because the block anesthetizes the entire foot, including the distal interphalangeal (coffin) joint. For a few horses, the PDN block may also cause at least partial anesthesia of the proximal interphalangeal (pastern) joint, especially if a large volume of local anesthetic solution (eg, >3 mL) is injected.

If the horse's gait does not improve after a PDN block, some clinicians next administer a **semi-ring block at the pastern** to anesthetize the dorsal branches of the digital nerve that supply the foot. Because the dorsal branches of the digital nerve contribute little to sensation within the foot, a semi-ring block at the pastern is unlikely to improve the gait if a PDN block failed to improve it.

Most clinicians proceed to a **basisesamoid nerve block** if the horse's lameness is not reduced with a PDN block. With this regional nerve block, the palmar nerves are anesthetized at the level of the base of the proximal sesamoid bones, before the nerve branches into the dorsal and palmar digital nerves. When performing an abaxial sesamoid nerve block, 2.5–3 mL of local anesthetic solution is deposited at the base of the proximal sesamoid bones over the neurovascular bundle, which is easily palpated at this location. More proximal deposition of local anesthetic solution may

anesthetize a portion of the fetlock joint. Positive response to a basisesamoid nerve block, performed after a PDN block has failed to ameliorate lameness, localizes the site of pain causing lameness to the pastern.

The low **palmar nerve block**, or **low 4-point block**, is performed after a negative response to the abaxial sesamoid nerve block. This nerve block is usually performed with the horse bearing weight on the limb, but it can also be performed with the limb held. The medial and lateral palmar nerves are anesthetized, using a 25-gauge, 5/8-in. needle, by depositing 2 mL of local anesthetic solution over each palmar nerve where it lies subcutaneously at the dorsal border of the deep digital flexor tendon. The palmar nerves should be blocked at the level of the metacarpus to avoid the possibility of misdirecting a needle into the digital flexor sheath, which often extends proximally to the level of the end of the splint bones. When the palmar nerves are blocked at the level of the middle of the metacarpus, the communicating branch that connects them, the ramus communicans, should also be blocked with 1 mL of local anesthetic solution. Blocking one palmar nerve proximal to the ramus communicans and the other distal to it allows sensory impulses to propagate through the ramus from the side blocked proximal to the ramus and then proximally through the palmar nerve blocked distal to the ramus. Though easily palpated on the forelimb, the ramus communicans is often nonexistent or impossible to palpate on the pelvic limb. To complete the 4-point block, 1–2 mL of local anesthetic solution is deposited SC at the distal end of each splint bone, where the palmar metacarpal nerve lies next to the periosteum of the third metacarpal bone. A positive response to a low 4-point block, performed after a negative response to an abaxial sesamoid nerve block, localizes the site of pain causing lameness to the fetlock.

The **high palmar nerve block**, or **high 4-point block**, can be performed when the low 4-point block fails to improve lameness. With the limb bearing weight, the medial and lateral palmar and palmar metacarpal nerves are anesthetized slightly distal to the level of the carpometacarpal joint. To anesthetize a palmar nerve, a 25-gauge, 5/8-in. needle is inserted through fascia to where the nerve lies near the dorsal border of the deep digital flexor tendon, and 3–5 mL of anesthetic solution is deposited over the nerve.

Anesthetizing the medial and lateral palmar nerves alone desensitizes the flexor tendons and inferior check ligament. With the limb held or bearing weight, the palmar metacarpal nerves are anesthetized slightly

distal to the level of the carpometacarpal joint by inserting a 20- to 22-gauge, 1 ½-in. needle into the angle formed by the junction of the third metacarpal bone and the second or fourth metacarpal bone. Anesthetizing the medial and lateral palmar metacarpal nerves alone desensitizes the splint bones and their interosseous ligaments and the proximal aspect of the suspensory ligament.

An easier alternative to the high palmar nerve block, when the site of pain causing lameness is suspected to be in the proximal portion of suspensory ligament, is the **lateral palmar nerve block**, which is performed, with the limb bearing weight, by inserting a 25-gauge, 5/8-in. needle over the lateral palmar nerve where it courses over the medial aspect of the accessory carpal bone. The needle is inserted in a medial to lateral direction at the distal third of a palpable groove, and 2 mL of local anesthetic solution is deposited. Because the medial and lateral palmar metacarpal nerves arise from the deep branch of the

lateral palmar nerve distal to this site, the structures they innervate, such as the proximal aspect of the suspensory ligament, are desensitized.

If the site of pain causing lameness cannot be localized by performing the previously discussed nerve blocks, most clinicians perform joint blocks of the carpus, elbow, or shoulder. The order in which these synovial structures are desensitized is not important. The median and ulnar nerves are sometimes anesthetized simultaneously as part of a lameness evaluation to exclude pain below the elbow as the cause of lameness, but more commonly, they are anesthetized along with the medial cutaneous antebrachial nerve to allow surgery of the limb without the need for general anesthesia.

Regional Anesthesia of the Pelvic Limb

Techniques to administer regional anesthesia of the distal portion of the pelvic limb are

Landmarks for nerve block of the horse pelvic limb. Illustration by Dr. Gheorghe Constantinescu.

slightly different than the techniques to administer regional anesthesia of the forelimb, because branches of the deep peroneal (fibular) nerve of the pelvic limb supply additional innervation to this region. These branches, the medial and lateral dorsal metatarsal nerves, course adjacent to the extensor tendon and innervate the dorsal aspect of the laminar corium. After depositing local anesthetic solution for a low 4-point nerve block at the level of the distal aspect of the splint bones, the needle is redirected dorsolaterally or dorsomedially, parallel to the bearing surface of the foot, and an additional 2 mL of local anesthetic solution is deposited SC to anesthetize the medial or lateral dorsal metatarsal nerves. Most lamenesses of the pelvic limb, however, can be evaluated accurately without anesthetizing the dorsal metatarsal nerves.

The **high plantar nerve block** is administered, using techniques similar to those used to administer the high palmar nerve block, ~1 cm distal to the tarsometatarsal joint. When the proximal aspect of the suspensory ligament is suspected to be the site of pain causing lameness, 3–4 mL of local anesthetic solution can be deposited

through a 20- to 23-gauge, 1-in. needle, axial to the lateral splint bone and ~1 cm distal to the tarsometatarsal joint, between the tendon of the deep digital flexor muscle and the suspensory ligament. The solution diffuses to anesthetize the deep branch of the lateral plantar nerve, which branches into the medial and lateral plantar metatarsal nerves that supply the proximal aspect of the suspensory ligament.

Depending on results of flexion tests or causes of lameness typical for the particular athletic function of the horse, the clinician may proceed to joint blocks or to more proximal regional nerve blocks. The peroneal and tibial nerves can be blocked simultaneously to exclude pain in the hock or regions distal to the hock as a cause of lameness, or the blocks can be performed separately to gain added insight as to the possible site of pain. If lameness is ameliorated after a tibial nerve block, but not after a low 4- or 6-point block, the suspensory ligament is a likely source of pain. If lameness is ameliorated after a peroneal (fibular) nerve block, but not after a low 4- or 6-point block, one or more of the tarsal joints are the likely source of pain.

The **tibial nerve** is blocked ~10 cm above the point of the hock on the medial aspect of the limb, where it lies in fascia on caudal surface of the deep flexor muscle, cranial to the Achilles tendon. Twenty mL of mepivacaine HCl is deposited through a 20-gauge, 1½-in. (3.8-cm) needle at this site, in at least several planes in the fascia surrounding the nerve. The deep peroneal nerve can be blocked on the lateral aspect of the limb ~4 in. above the point of the hock in the groove formed by the lateral and long digital extensor muscles. A 20-gauge, 1½-in. needle is directed slightly caudally until it contacts the caudal edge of the tibia, and 20 mL of mepivacaine HCl is deposited.

DISORDERS OF THE FOOT

OSSEOUS CYST-LIKE LESIONS IN THE DISTAL PHALANX

Osseous cyst-like lesions in the distal phalanx can result in a lameness that varies from mild to severe and may be unresponsive to anti-inflammatory medication. There is no apparent breed or sex predisposition. The cysts are commonly first diagnosed in young horses (1–3 yr old) but may be diagnosed in older horses. It is unknown whether the cysts have a developmental or traumatic origin. They are most commonly located in the subchondral bone either in the extensor process or along the joint surface close to the midline; the cysts may communicate with the distal interphalangeal joint. The lameness may be exacerbated with distal limb flexion, and it usually responds to intra-articular anesthesia of the distal interphalangeal joint if the cysts communicate with the joint. The lameness may respond to palmar digital nerve anesthesia but more commonly requires a more proximal nerve block (eg, abaxial sesamoid) for resolution of the lameness. Diagnosis is confirmed by radiography and/or CT. Differential diagnoses include keratoma, navicular disease, and primary degenerative joint disease of the distal interphalangeal joint. Surgical treatment includes arthroscopic debridement; extracapsular (through the hoof wall) approaches to the cysts have been used in less accessible lesions. Secondary fracture of the extensor process has been reported to occur due to a cyst in that region. Some horses return to performance status, whereas others are used for alternative purposes such as breeding.

BRUISED SOLE AND CORNS

Bruising on the solar surface of the foot usually is caused by direct injury from stones, irregular ground, or a poorly fitting

shoe. Horses with flat feet or either thin or dropped soles are predisposed to bruising, usually at the toe or around the periphery of the sole. Bruising in the caudal sole at the buttress (the angle between the wall and the bar) is termed a **corn**. Bruising commonly occurs with no abnormalities present on the keratinized sole, although solar changes may be present ranging from some red staining of the inner solar epidermis (due to minor hemorrhage) to the palpable presence of serum either under the solar epidermis or seeping through it. If untreated, the affected area can become infected (ie, a subsolar abscess). Persistent, nonresponsive bruised sole dorsal to the apex of the frog suggests possible distal displacement of the distal phalanx secondary to laminitis.

A “corn” is most common in the forefeet on the inner buttress and can be caused by 1) the heel of a shoe improperly placed (heel of branch bent excessively toward frog); 2) a shoe left on too long, causing pressure on the buttress; or 3) shoes fitted too closely at the quarters or too small for the foot. Corns are described as dry (only mild bruising), moist (serous exudate present), or suppurative (infected or abscessed). Bruising may be associated with lameness, depending on the severity. When the foot is raised and the solar surface freed of dirt and loose horn, a discoloration, either red or reddish yellow, may be noted. Pressure on the affected area with hoof testers usually causes varying degrees of discomfort, again depending on the severity of the lesion.

Treatment of sole bruising is intended to remove pressure and protect the bruised area. In horses predisposed to corns, proper shoeing with branches that fit well on the hoof wall at the quarters and heels (and extend to the caudal aspect of the buttress) will decrease the incidence of lesions. In horses predisposed to bruising due to dropped soles, application of a wide-webbed shoe beveled on the solar surface (made concave relative to the solar surface) to avoid solar pressure will help protect the sole. Additionally, a pad can be placed on the foot to protect the sole. In horses with painful corns, the affected heel can be unweighted by trimming the wall and insensitive sole to minimize contact with the shoe until healed; a bar shoe can also help disperse pressure away from the trimmed area.

If the bruise/corn is suppurative, ventral solar drainage, usually established with a hoof knife, is usually adequate to allow healing. If the affected subsolar area is large, the abscess can usually be addressed by establishing small areas of drainage (~1 cm in diameter) at opposite sides of the affected area (established by probing),

followed by lavage with saturated Epsom salt solution via either a 14-gauge catheter or teat cannula attached to a 60-mL syringe, repeated daily or every other day until healed. This is usually more effective than foot baths or application of poultices. The sole should be covered until the solar surface is covered by tough epithelium (horn). Parenteral antibacterial therapy is of questionable value unless cellulitis is present proximal to the coronary band.

CANKER

Canker is a chronic hypertrophy and apparent suppurative of the horn-producing tissues of the foot, involving the frog and the sole. The cause is unknown. Although frequently described as a disease seen in animals kept in moist or unsanitary environments, it is also encountered in well-cared-for animals. The disease can be observed in both front- and hindfeet. It most commonly starts in the caudal frog, where the affected area consists of an inflamed granulation tissue with proliferative epithelium, often appearing as fronds. The affected tissue is commonly covered by caseous exudate, which may be foul smelling. The surface of the lesion is irregular, with a characteristic, cauliflower-like vegetative growth. The disease process may extend to the sole and even to the wall, showing no tendency to heal.

Treatment requires sharp debridement down to normal tissue, attempting to maintain any normal epithelium. All loose horn and affected tissue should be removed. After debridement, an antiseptic or antibiotic dressing should be applied daily; good results have been reported using a solution of 10% benzoyl peroxide dissolved in acetone. Metronidazole is commonly applied topically with the benzoyl peroxide/acetone treatment. A clean, dry wound environment must be maintained to allow healing, which may take weeks or months. Close attention is required over the healing period; if any questionable areas appear, they must be aggressively addressed.

FRACTURE OF NAVICULAR BONE

Navicular bone fractures are usually a result of trauma or excessive concussion to the foot, but the cause is not always known. It is much less common than distal phalanx fracture and is more commonly seen in the forelimb. Although pain is variable, hoof testers usually induce a painful response over the frog. Lameness is severe with acute fractures, but it may be less in a chronic fracture in which a fibrous union has presumably failed. The lameness usually is

markedly improved by palmar digital nerve block (which blocks both the navicular region and the coffin joint). Radiography confirms the diagnosis, in which a sagittal fracture is usually found medial or lateral to the midline; care must be taken to pack the sulci of the frog to avoid artifacts that appear as navicular bone fractures.

Conservative treatment is prolonged rest with corrective shoeing to apply a dramatically raised heel (up to 12°); however, a bony union at the fracture site is seldom satisfactory, and the prognosis is guarded to poor. Surgical repair by lag screw has been described to have a better prognosis.

FRACTURE OF DISTAL PHALANX

(Fracture of third phalanx, os pedis, or coffin bone)

Fracture of the distal phalanx is a fairly common injury that occurs most commonly at high speed (ie, during a race) or less commonly from kicking a firm object (eg, a stall wall). The fracture is caused by concussion and produces a sudden onset of lameness. The lameness is severe if the fracture is intra-articular but may be less severe if only a wing (or solar margin of the distal phalanx) is fractured with no articular component. Distal phalangeal fractures occur more frequently in the forelimb but are also common in the hindlimb. Intra-articular fractures may be easily isolated to the foot; lameness is commonly associated with joint effusion. Nonarticular fractures may require compression of the foot with hoof testers and possibly unilateral palmar digital nerve anesthesia for localization. Lameness is exacerbated by turning the horse or making it pivot on the affected leg. If the fracture does not extend into the joint, the lameness may improve considerably after 48 hr of stall rest.

The clinical signs may be suggestive, but the diagnosis is confirmed by palmar digital nerve block and radiographic imaging. Radiographic confirmation may be difficult immediately after the injury, because the fracture is only a hairline at this stage. Often, more than two views are required before the fracture line is evident. Repeating the radiography several days or weeks later (to allow bone resorption) and using oblique views may be necessary to confirm the presence and exact site of the fracture. Additionally, if the suspected fracture is in a wing of the distal phalanx, unilateral palmar digital nerve anesthesia may be performed to localize the lameness to that side. Determining whether the fracture extends into the distal phalangeal joint is important. Scintigraphy and MRI are other imaging

options if a definitive diagnosis is not possible by radiographs.

Conservative treatment of 6–9 mo rest is usually all that is required for fractures not involving the joint. Fractures often heal with a fibrous union, so that, even though the horse returns to soundness, radiographic evidence of the fracture remains. A straight bar shoe with a clip well back on each quarter can be applied to limit expansion and contraction of the heels. In young horses (<3 yr old), fractures into the joint may heal satisfactorily, provided a 12-mo rest period is given. Older horses (>3 yr old) have a much less favorable prognosis, and insertion of a cortical bone screw using interfragmentary compression across the fracture site is indicated; however, infection is a frequent complication, because an extracapsular approach is required. Many fractures heal in the presence of infection, but the screw must be removed at a second surgery to restore the horse to complete working soundness. Unilateral palmar digital neurectomy of racehorses with nonarticular wing fractures has been used to allow return to competition without the delay for complete healing.

KERATOMA

(Keraphyllocele)

A keratoma is a benign mass made up of keratin that is situated between the hoof wall and distal phalanx. The cause is unknown. Although keratomas originate at the level of the coronary band, the condition may be difficult to detect until the growth is well advanced and located in the wall far distal to the coronary band. There is commonly bulging of either the coronary band or the hoof wall over the keratoma, depending on its position within the foot. Pressure from the keratoma causes well-demarcated bone resorption of the distal phalanx (usually appears that a “bite” has been taken out of the solar margin in most cases), which can usually be visualized best via the 65° dorsopalmar radiographic view of the distal phalanx. Surgical removal of the mass is indicated. Once localized, it is best to resect the mass through an approach through the hoof wall versus from a solar approach.

LAMINITIS

(Founder)

Equine laminitis is a crippling disease in which there is a failure of attachment of the epidermal laminae connected to the hoof wall from the dermal laminae attached to

the distal phalanx. Because the laminae are responsible for suspending the distal phalanx within the hoof wall, laminar failure in combination with the downward forces of the weight of the horse and distracting forces such as the tension from the deep digital flexor tendon commonly results in a catastrophic displacement of the distal phalanx, resulting in severe lameness. Laminitis affects all breeds of horses.

Etiology and Pathogenesis: Three main disease states are thought to be associated with laminitis: 1) diseases associated with sepsis or endotoxemia, 2) endocrinopathic laminitis encompassing both equine metabolic syndrome (including pasture-associated laminitis, *see p 1006* and pituitary adenoma), and 3) supporting limb laminitis. The pathogenesis of laminitis remains controversial and most likely varies widely between these three primary causes. A fourth, less common cause is ingestion of shavings (sometimes inadvertently used for bedding) from black walnut heartwood; the pathophysiology of this type of laminitis appears similar to that of sepsis-related laminitis. The diseases causing systemic sepsis in sepsis-related laminitis are diseases commonly associated with gram-negative bacterial (or polymicrobial) sepsis and include ingestion of excess carbohydrate (grain overload), acute postparturient metritis (retained fetal membranes), colic (anterior enteritis, large colon volvulus), and enterocolitis. Laminitis secondary to equine metabolic syndrome most commonly occurs in overweight horses and ponies and is commonly exacerbated when grazing lush pastures. It is possible that laminitis occurring from an acute intake of lush pasture may be a combination of sepsis-related laminitis (similar to grain overload) and metabolic syndrome. Supporting limb laminitis can occur any time the horse places excessive weight on one limb for an extended period because of inability to use the other limb (eg, post-operative orthopedic procedures, radial nerve paralysis, or a septic joint or tendon sheath).

The basic cause of laminar failure in laminitis is a failure of attachment of the laminar basal epithelial cells (LBECS) of the epidermal laminae to the underlying dermal laminae. Although this failure was thought to be primarily due to breakdown of the matrix molecules in the basement membrane and dermis (to which the LBECS attach) by matrix metalloproteases, studies have questioned the importance of matrix metalloproteases. It appears that the LBECS

may primarily be losing attachment to the underlying dermal laminae due to dysregulation of the hemidesmosomes (the adhesion complexes on the basal side of the LBECs that attach the cells to the underlying matrix molecules of the basement membrane) and possibly the associated cytoskeleton. Inflammatory mediators and enzymes (eg, proinflammatory cytokines, cyclooxygenase-2) are markedly increased in the laminae in the early stages of sepsis-related laminitis and may injure the LBECs or cause cellular dysregulation, leading to loss of attachment. Hypoxia and ischemia due to aberrant vascular flow is also likely to play a role in LBEC dysfunction in sepsis-related laminitis but appears to occur later in the disease process.

The pathophysiology behind laminitis associated with equine metabolic syndrome is not as well researched as sepsis-related laminitis, but work indicates that inflammatory signaling does not play a major role and that dysregulation of the LBECs is likely to result from insulin-related signaling, possibly through growth factor receptors such as IGF-1 receptor. The pathogenesis of supporting limb laminitis is only now being intensively investigated. These studies indicate that the central pathophysiologic factor in supporting limb laminitis is decreased laminar blood flow due to a lack of movement of the supporting limb because of pain in the opposite limb.

After loss of integrity of the laminar attachments, the distal phalanx can undergo three types of displacement depending on the forces placed on the foot and the pattern of laminar injury. Symmetrical distal displacement of the entire phalanx (usually termed "sinking") occurs when there is circumferential loss of laminar attachments, most commonly seen in severe cases of sepsis but also seen in equine metabolic syndrome. Palmar rotation of the distal margin of the distal phalanx (usually termed "rotation") is the most common displacement seen, and most likely occurs due to a combination of loss of the dorsal laminar attachments (while maintaining some laminar integrity in the quarters and heels) and tension on the deep digital flexor tendon. Rarely, uniaxial/unilateral distal displacement of the distal phalanx occurs, most commonly to the medial side in the forelimb; this displacement can only be visualized on an anterior-posterior radiograph of the foot. In laminitis related to sepsis and equine metabolic syndrome, the forelimbs are most commonly affected, although the hindlimbs can also be affected in severe cases. In supporting limb laminitis, either a front or rear foot is affected

depending on which opposite limb has the weight-bearing problem.

Clinical Findings: Classically, laminitis is considered acute, subacute, or chronic. Acute laminitis is classically defined as the initial few days of clinical signs of laminitis (usually <3 days) in a horse in which the distal phalanx has not undergone displacement. Subacute laminitis is commonly used to define laminitis in which clinical signs have continued >3 days, but the horse still has no distal phalangeal displacement. Chronic laminitis is classically defined as the case in which distal phalanx displacement has occurred regardless of the duration of the disease. Early in laminitis, the horse is depressed and anorectic and stands reluctantly. Resistance to any exercise is marked, and the normal stance is altered in attempts to relieve the weight borne by the affected feet. If only the forelimbs are affected, the horse will stand with the forelimbs placed far forward (to decrease the weight on the front digits); the hindlimbs also are placed more forward to support more of the weight of the horse. If forced to walk, the horse shows a slow, crouching, short-striding gait. If all four limbs are affected, the animal will appear "camped out," with the forelimbs placed more forward than usual and the hindlimbs placed more caudally than usual. Each foot, once lifted, is set down as quickly as possible.

In the acute stage of laminitis, the entire hoof wall may be warm. An exaggerated and bounding pulse can be palpated and may be visible in the digital arteries. Pain can cause muscular trembling, and a fairly uniform tenderness can be detected when pressure is applied to the sole (most commonly in the toe region). The pulse rate (60–120/min) and respiratory rate (80–100/min) are commonly increased, primarily because of pain. Lameness is usually moderate to severe at this time. In exceptionally severe cases, for which the prognosis is unfavorable, a blood-stained exudate may seep from the coronary bands. These clinical signs do not always occur in endocrinopathic laminitis because of the insidious nature of the disease process, which can occur over months or years; the first clinical sign in many of these horses is toe bruising due to solar compression by the slowly displacing distal phalanx. Radiographic evidence of displacement of the distal phalanx can be present as early as the third day after the onset of disease in horses with sepsis/endotoxemia. However, an MRI study has shown that, in the acute case, the horse may have normal-appearing distal phalanx on radiographs, despite

destruction of the entire dorsal laminar attachment that is visible on MRI.

Subacute cases may exhibit any or all of the above clinical signs but to a lesser degree. Often, there is only a mild change in stance, with reluctance to walk and some increased sensitivity to concussion on the soles of the affected feet. There may be no demonstrable heat in the coronary band or increase in digital pulse. The acute and subacute forms of laminitis tend to recur at varying intervals and may develop into the chronic form.

During and immediately after displacement of the distal phalanx (classically termed chronic laminitis once displacement occurs, regardless of the temporal aspect of the disease course), the horse is usually extremely lame and may spend a great deal of time recumbent. In severe cases, the foot may prolapse through the sole cranial to the frog, or the coronary band may separate; both occurrences gravely affect the prognosis. Long-term cases of chronic laminitis are characterized by changes in the shape of the hoof and usually follow one or more attacks of the acute form. Especially with cases of rotation of the distal phalanx, bands of irregular horn growth (laminar rings) may be seen in the hoof, close at the toe and diverging at the heel (due to minimal hoof growth from the dorsal coronary band). The hoof itself becomes narrow and elongated, with "dishing" of the dorsal surface of the hoof wall with a steep angle to the hoof wall proximally and a much more horizontally oriented wall distally.

As the displacement of the distal phalanx progresses in long-term cases, the sole becomes flattened or somewhat convex in outline on the ground surface immediately cranial to the apex of the frog. The gait is similar to that already described, and when standing, the body weight is continually shifted from one foot to the other. Radiography commonly reveals rotation and some bony resorption of the dorsal solar margin of the distal phalanx in longer term cases.

Diagnosis: In acute laminitis, diagnosis is usually straightforward and is based on the history (eg, grain overload) and posture of the horse, increased temperature of the hooves, a hard pulse in the digital arteries, and reluctance to move. Abaxial sesamoid nerve blocks of the forelimb digits in the very lame horse allow assessment of possible involvement of the hindfeet (by walking the animal a few steps) and enable full assessment of the soles of both feet (for solar prolapse, etc). These nerve blocks also make it possible to obtain good quality lateral and anterior-posterior radiographs of

the foot without severe duress to the horse. Lidocaine should be used for the nerve block, because it will last only a short time (ie, not long enough for the animal to move excessively and further damage the laminae); applying a temporary pad to the foot not being radiographed (to protect that foot) is also recommended. Gross observation and distinct measurements of the hoof wall and sole thicknesses from the radiographs allow determination of whether distal displacement, rotation, both distal displacement and rotation, or unilateral sinking has occurred. Depending on the radiographic diagnosis of the type of phalangeal displacement present, there is usually time while the nerve block is still effective to apply a temporary type of pad or shoe.

Treatment: Acute laminitis constitutes a medical emergency, because phalangeal displacement can occur rapidly. Despite prompt therapy, the prognosis is guarded until recovery is complete and it is evident that the hoof architecture is not altered. Most animals should be administered NSAIDs, with flunixin meglumine being the drug of choice if the horse is still systemically ill (ie, enterocolitis). Phenylbutazone is usually used in the early chronic stage when the horse is lame but does not have signs of systemic disease such as sepsis/endotoxemia. Close attention to the potential toxicities of NSAID therapy, particularly with phenylbutazone, is required. Because phenylbutazone accumulates in the tissue (unlike flunixin or most other NSAIDs), it is best to skip a day every 5–7 days to "clear the system" (flunixin can be administered that day). NSAIDs should be used according to label instructions and, if used in combination, the dosage of each drug should be reduced accordingly. Another option for treatment of chronic laminitis in horses at risk of renal or GI complications is the COX-2-selective NSAID firocoxib. Other options for analgesia include detomidine, butorphanol, morphine, or a constant-rate infusion of a "cocktail" of sedatives and analgesics.

For treatment of possible ongoing ischemia, acepromazine is the only drug found to effectively increase digital blood flow in some studies; however, this has been questioned again by a study using laminar microdialysis catheters in which urea clearance (an indicator of blood flow) was not changed in horses administered acepromazine. In a horse at risk of or in the early stages of sepsis-related laminitis, digital hypothermia (cooling of the foot by placing it directly in ice water) has been popularized again by several experimental studies consistently

demonstrating efficacy in protection of the structural integrity of the lamellar tissue; in one clinical study of enterocolitis cases in two hospitals, risk of developing laminitis was decreased 10-fold in septic/endotoxemic horses in which continuous digital hypothermia was performed.

During the first 2–3 wk, it is important to remove standard shoes, because shoes place the majority of stress on the hoof wall and therefore the laminae. The feet should be padded with a soft, resilient substance such as a 1- to 2-in. thick piece of closed-cell foam cut to the diameter of the foot. Pads to provide sole support can also be made from different putties available to farriers. Decreasing padding (or beveling the pad) in the region dorsal to the apex of the frog decreases the stress on the dorsal laminae. Styrofoam insulation (2 in. thick) can be used in small equids but usually provides minimal support in larger animals. Other temporary shoes (eg, Redden Ultimate and wooden or EVA clog) that can be applied without severe concussion can provide different physical properties depending on the type of displacement (and veterinarian/farrier preference) in the first few weeks.

Shoeing laminitic horses with metal shoes is usually not a good option until ~3–4 wk after the onset of laminitis, when the laminar structure may be stabilizing. The type of shoeing depends on the type of displacement. In a horse with distal phalangeal rotation, an attempt is made to begin realigning the palmar surface of the distal phalanx to the sole, while not allowing excessive forces on the laminae. The breakover of the shoe is moved as far caudally as possible, and some of the caudal hoof (from the frog apex caudally) is removed to allow realignment to the sole. This may have to be performed in combination with raising of the heel (with wedge pads, etc), which still allows alignment of the distal phalanx to the solar surface while avoiding excessive changes in relation to the ground surface, thus preventing excessive tension on the deep digital flexor tendon and therefore the dorsal laminae. It may be appropriate to place some type of resilient putty on the solar surface to provide support to the distal phalanx in horses in which some degree of laminar instability is still suspected. Multiple types of shoes can be used, including heart bar shoes, egg bar shoes, and natural balance shoes. Steward clogs are an important option for treating horses with distal displacement of the distal phalanx; these allow the horse to maximize comfort because of being beveled in multiple directions (and therefore minimizing laminar stress). Some farriers/clinicians also use

clogs in cases of rotation of the distal phalanx.

Surgical options include deep digital flexor tenotomy, to neutralize the pull of the deep digital flexor tendon, and dorsal hoof wall resections. Deep digital flexor tenotomy is most commonly performed in cases of chronic rotation that do not respond to the above shoeing techniques; it should always be accompanied by aggressive derotation via rasping of the caudal foot. The farrier and veterinarian must address subluxation of the coffin joint subsequent to deep digital flexor tenotomy in most cases (usually by applying adequate heel wedging to neutralize the subluxation). Hoof wall resections are performed much less frequently than in the past. Generally, only a partial hoof wall resection is performed (usually on the distal hoof wall) because of the severe digital instability caused by removing the entire dorsal wall in an extensive hoof wall resection.

NAVICULAR DISEASE

(Palmar foot pain, Podotrochlosis, Podotrochlitis)

Navicular disease is one of the most common causes of chronic forelimb lameness in the athletic horse but is essentially unknown in ponies and donkeys. Navicular disease is a chronic degenerative condition of the navicular bone that involves 1) focal loss of the medullary architecture (with subsequent synovial invagination), 2) medullary sclerosis combined with damage to the fibrocartilage on the flexor surface of the bone, 3) traumatic fibrillation of the deep digital flexor tendon from contact with the damaged flexor surface of the bone with adhesion formation between the tendon and bone, and 4) enthesiophyte formation on the proximal and distal borders of the bone.

Etiology: The pathophysiology of navicular disease is unknown. The syndrome is likely due to a complex pathogenesis rather than a specific disease entity, although the greatest consensus appears to support a biomechanical component (causing increased bone medullary pressure) and possibly a vascular component. There appears to be a hereditary predisposition, indicated by the sharp decrease in incidence of the disease in Dutch Warmbloods after certification of stallions with severe navicular changes for breeding was disallowed. It is considered to be a disease of the more mature riding horse, commonly not appearing until 8–10 yr of age.

Navicular disease is overrepresented in some breeds (eg, Warmblood horses, Quarter horses, and Thoroughbreds) and rare in others (eg, Arabians, Friesians). It is usually a progressively deteriorating condition after onset. Conformation of the distal limb is likely to play a large role in the disease process and degree of lameness. Excessive pressure on the navicular bone occurs with a "broken back" hoof-pastern axis, usually accompanied by an underrun heel and excessively long toe. This conformation, leading to excessive concussion between the flexor tendon and the navicular bone, may also cause navicular bursitis, with direct damage to the fibrocartilage of the flexor surface and the collagenous surface of the flexor tendon itself.

Clinical Findings and Diagnosis: The disease is usually insidious in onset. An intermittent lameness is manifest early in the course of the disease. Because disease is bilateral, there may be no obvious head nod to the lameness when the horse is trotted in a straight line, with only a shortened stride present. Lameness is usually exacerbated by lunging the horse in a circle in both directions, with the inside foot usually exhibiting the greatest lameness. In early stages of the disease, the lameness may not be visible even at a lunge until a nerve block is performed on one of the two digits (ie, the two lame feet cancel each other out). A flexion test of the distal forelimb may produce a transient exacerbation of lameness.

Clinical diagnosis is mainly based on presentation of the horse (age, breed commonly at risk) and, importantly, on the lameness examination, including a characteristic response to palmar digital nerve anesthesia. These horses are rarely positive to hoof testers (11% positive in one study). The lameness can be eliminated by palmar digital nerve block, except in some horses with extensive secondary moderate to severe damage to the deep digital flexor tendon (pain can radiate proximal to the palmar digital nerve block with this pathology). However, because this nerve block anesthetizes the entire sole and coffin joint in addition to the heel, response to the block itself is not diagnostic. A transfer of lameness to the other forelimb, which also is eliminated by a palmar digital nerve block, is necessary for a tentative diagnosis of navicular disease. Anesthesia of the navicular bursa is much more specific but is not as commonly performed during a lameness examination because of the pain involved in performing the injection (needle passes through the deep digital flexor tendon) and the complexity of the injection (usually done

under radiographic guidance). Radiographic changes are variable and do not always correlate with the severity of lameness. Thus, they may not be as important in the diagnosis as the lameness examination (although they can be). Radiographs may demonstrate a range of degenerative changes involving the navicular bone: marginal enthesiophytes, enlarged synovial fossae (so-called vascular channels) of variable size and cysts due to loss of medullary trabecular bone, general sclerosis of the medullary cavity, and flexor surface changes (observed on "skyline" radiographic view), including erosions and loss of a defined cortex.

Treatment: Because the condition is both chronic and degenerative, it can be managed in some horses but not cured. The most common effective treatments include NSAID administration and corrective shoeing. Phenylbutazone is the most commonly used NSAID, but it must be used with caution because of adverse effects (renal and GI injury). If used daily, it may be best to take the horse off the drug one day a week to allow the body to clear some of the accumulated drug; the horse can be given flunixin for that day. Another option in horses at increased risk of NSAID complications is the COX-2-selective NSAID firocoxib, which is fairly effective for orthopedic and articular pain. With severe lameness, rest is indicated.

Foot care should include trimming and shoeing that restores normal phalangeal alignment and balance; response to corrective shoeing commonly takes ~2 wk. The principal object of shoeing is to decrease the pressure on the navicular bone. The shoeing technique that most effectively decreases pressure on the navicular area is raising the heel (usually performed with wedge pads or a wedged shoe). Rolling the toe of the shoe further relieves the pressure on the navicular bone. The egg bar shoe does not decrease navicular pressure in sound horses on a hard surface but has been reported to effectively decrease forces on the navicular bone in some horses with navicular disease or collapsed heels. Additionally, egg bar shoes are likely to more effectively decrease forces on the navicular area on soft surfaces (that horses are normally worked on); they are purported to work somewhat like a snowshoe by not allowing the heel to sink as deeply into a soft surface as a foot with a standard shoe would. Natural balance shoes are ineffective at decreasing navicular pressure.

Injection of the coffin joint with corticosteroids will markedly improve soundness in ~1/3 of horses (for an average of 2 mo),

whereas injection of corticosteroid into the navicular bursa is reported to resolve the lameness for an average of 4 mo in 80% of horses that do not respond to standard treatments (phenylbutazone, shoeing, and coffin joint injection). Increased incidence of rupture of the deep digital flexor tendon has been reported with multiple intrabursal injections. Isoxsuprine hydrochloride is ineffective as a vasodilator when administered orally and has little therapeutic value.

Palmar digital neurectomy may provide pain relief and prolong the usefulness of the horse, but no neurectomy should be considered curative. Digital neurectomy has a high incidence of severe complications such as painful neuroma formation and rupture of the deep digital flexor tendon. Catastrophic injury to the distal limb in horses brought back to a high level of athletics after neurectomy has resulted in death of the rider. Othersurgical procedures for navicular disease are unproved.

Although the prognosis is guarded to poor, a carefully designed therapeutic regimen, including corrective shoeing, NSAID therapy, and navicular bursa injections (and/or possibly coffin joint injections), can prolong the usefulness of most horses and the competitive status of many. Over months or years, most affected horses reach a point of nonresponsiveness to treatment.

PEDAL OSTEITIS

Pedal osteitis is a radiographic finding of demineralization of the solar margin of the distal phalanx, commonly associated with widening of vascular channels near the solar margin, which is best observed on a 65° proximal-distal dorsopalmar radiographic view. Although the term is usually used to describe changes in the dorsal distal (toe) solar margin, it can be used to describe bone resorption of any aspect of the solar margin of the distal phalanx. The bony resorption usually occurs due to chronic or repeated pressure and/or inflammation of the affected region. The resorption can be focal due to a focal lesion such as a keratoma, or it can be more diffuse in states such as chronic toe bruising, in which the entire distal margin of the toe may appear "moth-eaten" due to extensive bone resorption at the solar margin. Resorption in the toe region commonly occurs in chronic laminitis cases in which displacement of the distal phalanx results in inadequate sole depth between the ground surface and solar margin of the distal phalanx, resulting in chronic trauma and inflammation of that region of the phalanx and surrounding soft tissue (ie, sole bruising or chronic

subsolar sepsis). Because the bone resorption is usually permanent, the radiographic finding does not indicate current pathology and may be due to a pathologic state that occurred years ago. Therefore, it is essential that a thorough examination be performed, including application of hoof testers to the entire solar margin of the foot and a lameness examination with nerve blocks if lameness exists. (The entire solar surface, including the toe, will be anesthetized with a palmar digital nerve block.)

Navicular disease is an important differential diagnosis to pedal osteitis—associated toe bruising, because toe bruising is also commonly bilateral and both conditions respond to a palmar digital nerve block. Radiography is helpful in diagnosis and in differentiation from navicular disease. Pedal osteitis associated with chronic subsolar abscess is usually aseptic, with the sepsis isolated to the soft tissue. Radiographic signs of sequestration or severe focal lucency in the same region as the subsolar sepsis may indicate septic pedal osteitis, but lucency can also be an artifact caused by subsolar gas once an abscess is drained (an unopened abscess usually has a tissue density). Curettage of the affected distal phalanx should be avoided unless it is documented to be septic.

Local treatment (ie, curettage of the affected area) is necessary only if there is an active septic process associated with the radiographic changes of pedal osteitis. General treatment of nonseptic cases should be directed at the primary disease that caused the resorption (eg, corrective shoeing for chronic laminitis cases with distal phalanx displacement that predisposes to solar margin bruising).

PUNCTURE WOUNDS OF THE FOOT

(Subsolar abscess, Septic navicular bursitis)

Puncture wounds are common in horses and are the most common cause of subsolar sepsis. Most puncture wounds result only in sepsis of the subsolar soft tissue (ie, subsolar abscess) but can be catastrophic when the puncture is in the frog and travels deep enough to enter synovial structures such as the navicular bursa, the distal interphalangeal joint, or possibly the deep digital flexor tendon sheath.

Puncture of the sole by a foreign body is associated with introduction of pathogenic microorganisms that lead to subsolar abscess formation. Lameness is usually severe; the degree of lameness may be

similar to that of a fracture. The horse may stand pointing the affected foot. There is commonly a prominent digital pulse in the affected limb. If allowed to progress, the abscess may travel proximally to rupture at the coronary band; there will usually be edematous swelling proximal to the coronary band before rupture. Diagnosis is made by confirming the site of pain by pulling the shoe, using hoof testers, and picking or paring the suspect area to locate the foreign body or its dark tract. If a foreign body is found in the frog, it may be best to obtain a lateral radiograph of the foot to assess the structures penetrated before removing the offending object. If a tract is found in the frog, it should be probed and a radiograph taken with the probe in place. Because puncture wounds in or near the frog commonly enter a synovial structure, they constitute a serious problem requiring rapid, aggressive diagnosis and therapy. If a synovial structure is entered, the horse should be placed on broad-spectrum antibiotics and transported to a facility capable of advanced surgical and medical techniques; the affected synovial structure should be lavaged with sterile polyionic solution as soon as possible (within hours).

If a puncture wound is noted in the solar area, ensuring adequate drainage from the site helps prevent abscess formation. If there is a suspected abscess but no tract is found, the foot can be poulticed in an attempt to promote organization of the abscess for localization. If a tract is found that leads to a subsolar abscess, adequate drainage should be established with a hoof knife; the drainage hole should be kept as small as possible (~0.5–1 cm diameter) to avoid a prolapse of sensitive corium. Some farriers and veterinarians prefer to drain the abscess through the hoof wall (instead of the sole) if possible. Once the abscess has been entered, it should be probed to determine its extent; a palmar digital nerve block will usually be necessary before probing and lavage of the area. If the abscess underruns a large area of the foot, another small ingress/egress hole can be made at the farthest extent of the abscess from the original entry point, and lavage can be performed by placing a 14-gauge catheter or teat cannula into the affected subsolar space and flushing with saturated Epsom salt solution (made by adding Epsom salts to boiling water or saline until some salt crystals sit on the bottom of the container and will not go into solution). If a chronic subsolar abscess has developed, this treatment may have to be repeated daily to every other day for several treatments. The foot should be protected until there is

full healing/epithelialization of the solar region entered; healing appears to be much more rapid and is easier to treat if the abscess is entered through the wall instead of the sole. All horses with puncture wounds should be immunized against tetanus. Local and systemic antibiotic therapy are not necessary for a sole abscess but should be considered with swelling above the coronary band (indicating septic cellulitis) and must be used aggressively if sepsis of a synovial structure is present.

PYRAMIDAL DISEASE

(Extensor process fracture, Buttress foot)

Fragmentation of the extensor process of the distal phalanx is thought to occur due to trauma, osteochondrosis, or presence of separate centers of ossification. Forelimbs are more commonly affected than hindlimbs. The fracture fragments are usually intra-articular but are commonly nondisplaced; they may be adhered to the extensor tendon. The fragments may be incidental findings, but they may also cause lameness. The close association of the extensor process with the distal interphalangeal joint can result in secondary arthritis if the fragments are not removed. Fractures can be removed either via arthroscopy or arthrotomy; arthroscopic removal of small fragments carries a good prognosis. With large, untreated fractures, an enlargement of the toe region just above the coronary band is usually present, which results in the "buttress foot" or pyramidal appearance to the foot. Systemic anti-inflammatory medication may be beneficial.

QUITTOR

(Coronary sinus)

Quittor is a chronic, septic condition of one of the collateral cartilages of the distal phalanx characterized by necrosis of the cartilage and one or more sinus tracts extending from the diseased cartilage through the skin in the coronary band region. It is seldom encountered today but was common in working draft horses in the past. Quittor usually follows injury to the limb on the medial or lateral aspect of the lower pastern (immediately proximal to the coronary band, over the proximal extent of the cartilage), by means of which infection is introduced into the traumatized collateral cartilage. This leads to localized sepsis or abscessation of the cartilage. The cartilage may also become infected through a quarter crack (*see below*). The first sign is an

inflammatory swelling over the region of the collateral cartilage, which is followed by sinus formation and intermittent drainage. During the acute stage, lameness occurs.

Surgery to remove the diseased tissue is required, but care must be taken not to enter the distal interphalangeal joint. Local or parenteral antibiotic therapy (or both) without surgery is likely to fail. In the absence of any therapy, poor drainage, cartilage necrosis, and recurrent abscessation lead to chronic lameness and extension to deep structures. The prognosis is unfavorable if the disease progresses to involve the distal interphalangeal joint.

QUARTER CRACK

(Sandcrack)

Cracks in the hoof wall are thought to occur primarily because of excessive forces placed on the hoof wall and the germinal tissue of the coronary band. It is proposed that shoeing does not allow the hoof wall to expand normally with weight bearing and that quarter cracks commonly form at the placement of the caudal nail, because the hoof wall will deform caudal to the nail but not cranial to it. This would place abnormal forces on the laminar tissue and the germinal tissue of the coronary band at that point, resulting in a defect in horn growth that appears as a crack. The same excessive force on a quarter can occur with a shoe in which the branch is too short (either due to placement of a shoe that is too small or to an inappropriate interval between resetting the shoe), resulting in excessive pressure and wall stress at the point where the shoe ends on the quarter. Toe cracks are also thought to occur in shod horses due to the fact that the toe expands abnormally between the cranial-most medial and lateral nails, leading to disruption of tubule formation at the coronary band.

A crack in the horn emanating distally from the coronary band is the most obvious sign. Lameness may be present, depending on the degree of wall instability or the presence of submural sepsis. If infection is established, there may be a purulent discharge and signs of inflammation and lameness.

Therapy first involves proper trimming of the foot to remove abnormal forces on the coronary band and wall. Once the farrier and veterinarian are satisfied that the foot is responding to the corrective trimming and shoeing (including the application of a bar shoe), the crack should be debrided (usually with a rotary tool), and any moisture or sepsis treated with appropriate antiseptic and/or astringent agents (eg, 2% iodine) until the

crack is dry. Multiple wires are then applied across the crack to stabilize it. The wires can be placed either around sheet metal screws placed in the hoof wall on either side of the crack or through small holes drilled through the horn of the hoof wall on each side and exiting through the crack. The crack can be filled with either a resilient acrylic or putty, but it is critical that there be no moisture or sepsis present. Fenestrated tubing can be placed between the deepest aspect of the crack and the acrylic to allow for drainage. The hoof is then bandaged until new horn formation is evident.

SCRATCHES

(Greasy heel, Dermatitis verrucosa)

Scratches is a chronic, seborrheic dermatitis characterized by hypertrophy and exudation on the caudal surface of the pastern and fetlock. It often is associated with poor stable hygiene, but no specific cause is known. Heavy horses (eg, draft horses) are particularly susceptible, and the hindlimbs are affected more commonly. Standardbreds can be affected in the spring when tracks are wet.

Scratches may go unnoticed if hidden by the "feather" at the back of the pastern. The skin is itchy, sensitive, and swollen during the acute stages; later, it becomes thickened and most of the hair is lost. Only the shorter hairs remain, and these stand erect. The surface of the skin is soft, and the grayish exudate commonly has a fetid odor. The condition can become chronic, with vegetative granulomas. Lameness may or may not be present; it can be severe and associated with generalized cellulitis of the limb. As the condition progresses, there is thickening and hardening of the skin of the affected regions, with rapid hypertrophy of subcutaneous fibrous tissue.

Persistent and aggressive treatment is usually successful. This consists of removing the hair, regular washing and cleansing with warm water and soap to remove all soft exudate, drying, and applying an astringent dressing. If granulomas appear, they can be cauterized. Cellulitis requires systemic antibiotic therapy and tetanus prophylaxis.

WHITE LINE DISEASE

(Hollow wall, Seedy toe, Onychomycosis)

In white line disease, the hoof wall separates from the underlying laminae (stratum internum) at the level of the stratum medium (tubular horn). The separation likely starts as a result of abnormal wall stress due to poor

foot conformation or trimming (eg, long toe, underrun heels) and can start at the toes, quarters, or heel. Opportunistic bacteria and fungi may be present in the fissures in the hoof wall. The outer surface of the wall may appear sound, but on dressing the foot from the solar surface, there is commonly a separation of the hoof wall from the underlying laminae. Tapping on the outside of the wall at the toe elicits a hollow sound over the affected portion. Lameness may be present in severe cases, in which loss of support of the distal phalanx results in displacement similar to that seen in laminitis.

The diagnostic evaluation includes a thorough physical examination and lateral and dorsopalmar radiographs to assess the extent of separation of the hoof wall and any displacement of the distal phalanx. For treatment, corrective trimming is critical to remove abnormal stresses on the hoof wall, followed by removal of the entire extent of the separated hoof wall to the point that firm, healthy adhesion of the hoof wall to the underlying stratum internum can be seen. This hoof wall debridement is performed with a combination of hoof nippers, hoof knives, and possibly a rotary tool. With proper debridement, there may be no need for antiseptic or astringent treatment. However, topical treatment with tincture of iodine is commonly performed daily for at least a week. Additionally, commercial equine foot formulations that produce chlorine dioxide can also be used. Corrective shoeing is critical to provide adequate support to the remaining foot, while removing stress from the affected regions; a heart bar or egg bar shoe in combination with a resilient putty in the caudal two-thirds of the sole (to provide distal phalanx support) may be necessary if displacement of the distal phalanx is a concern.

SHEARED HEELS

In sheared heels, there is severe acquired imbalance of the foot with asymmetry of the heels. When viewing the caudal aspect of the foot, one heel is higher than the other side; the higher side commonly has a more vertical hoof wall. When viewed from the side, the coronary band does not gradually angle toward the ground surface in a cranial-to-caudal direction (the normal appearance) on the higher side. Some horses with sheared heels are lame. Hoof cracks, deep fissuring between the bulbs of the heel, and thrush frequently accompany the problem. Sheared heels are most likely caused by abnormal forces being placed on one side of the foot and are seen frequently

in horses with abnormal limb or foot conformation on the affected foot or feet.

Corrective trimming and shoeing, in an attempt to restore proper heel alignment and foot balance, are required and entail floating the heel on the higher heel. A full bar shoe to increase ground surface area while protecting the affected quarter and heel is used. Several shoe resettings may be required before improvement is evident. The prognosis is good in uncomplicated cases if the corrective measures are consistently applied until new hoof growth occurs.

SIDEBONE

(Ossification of the collateral cartilages)

Sidebone is ossification of the collateral cartilages of the distal phalanx; it occurs most often in the lateral cartilage. It is most common in the forefeet of heavy horses working on hard surfaces. Repeated concussion to the quarters of the feet is purported to be the cause. Some cases arise from direct trauma. Sidebone is usually an incidental radiographic finding and rarely causes lameness. If sidebone is a cause of lameness, the lameness should entirely subside with a unilateral palmar digital nerve block on the affected side.

When lameness is present, corrective shoeing to promote expansion of the quarters and to protect the foot from concussion may be of value. Grooving the hoof wall on the affected side has been reported to help reduce lameness. If sidebone is documented as a cause of lameness, unilateral palmar digital neurectomy may be indicated if the horse does not respond to corrective shoeing and trimming.

THRUSH

Thrush is a degeneration of the frog with secondary anaerobic bacterial infection that begins in the central and collateral sulci. The central sulcus is more commonly involved if the horse has sheared heels; the lateral sulci are primarily involved in most cases of thrush (without sheared heels). The affected sulci are moist and contain a black, thick discharge with a characteristic foul odor; the borders of the frog are commonly necrotic. These signs alone are sufficient to make the diagnosis. Although many describe the primary etiology as a moist environment with poor hygiene, it is more likely caused by poor foot conformation or trimming and lack of exercise (thought to help "clean out" the sulci when the weight of the horse pushes down on the frog and surrounding

structures) than from lack of hygiene in the stall. However, a moist environment should be avoided in animals with thrush.

Treatment should begin by providing dry, clean flooring and thorough debridement of the frog and sulci. Additionally, the foot needs to be balanced, and affected horses placed on a regular exercise schedule in a dry area. An astringent solution (eg, copper sulfate solution) may be applied with daily hoof cleaning. Commercial equine foot formulations that produce chlorine dioxide can also be used. If granulation tissue or sensitive tissue is exposed, astringent solutions should be avoided; a paste made of metronidazole tablets can be applied instead to the affected areas in combination with foot bandaging. The prognosis is usually favorable with appropriate changes in shoeing and exercise.

DISORDERS OF THE PASTERNS AND FETLOCK

FRACTURES OF THE FIRST AND SECOND PHALANX

Fractures of the first/proximal phalanx (P1) may occur in any type of horse used for performance. They may be small osteochondral “chip” fractures along the dorsal margin of the proximal joint surface, sagittal (complete or incomplete), or comminuted. Another category involves fragments of the palmar or plantar proximal aspect of P1, which may be associated with osteochondrosis.

“Chip” fractures of the dorsoproximal aspect of P1 typically involve the medial aspect of the joint and occur in horses that exercise at speed. These fractures are normally traumatic in origin and result from hyperextension of the fetlock joint. Acute lameness and increased effusion in the fetlock joint along with sensitivity to firm flexion of the fetlock are clinical signs that a fracture may be present and radiographic examination indicated. In nonracing breeds, a chip fracture may be present on radiographs, but its clinical significance should be determined with diagnostic analgesia before being implicated as a source of lameness.

The cause of proximopalmar and proximoplantar osteochondral fractures is questionable; one thought is that they are from osteochondrosis, the other is that they are fractures. Axial fractures are classified as type I fractures and are generally articular. Type II fractures are located abaxially and typically have minimal articular cartilage present. Type I fractures

are generally associated with lameness at speed with clinical signs similar to those of dorsoproximal P1 fractures. These fractures are more common in the hindlimb, and intra-articular diagnostic analgesia is often needed to implicate these fractures as a cause of lameness.

Diagnosis is confirmed by radiography. A number of oblique radiographic views may be necessary to ensure visibility of the fractures. For palmar or plantar osteochondral fractures, oblique radiographic views with the beam raised ~20° from horizontal may be more helpful for identification. The diagnosis of sagittal or comminuted fractures of P1 is typically straightforward, with marked lameness and swelling. Incomplete, short sagittal fractures can be more difficult to diagnose and may require special radiographic views off of dorso-palmar/plantar and/or nuclear scintigraphy in the initial stages, because the fracture line may be difficult to detect radiographically.

Osteochondral “chip” fractures can be removed arthroscopically with an excellent prognosis if no other abnormalities within the joint exist. Routine, nondisplaced sagittal P1 fractures can be repaired by internal fixation using screws placed in lag fashion via stab incisions. More complex P1 fractures typically require open reduction and repair via lag screws to allow accurate realignment of the articular surface of the fetlock to limit postoperative arthritis. Careful attention should be paid to the fracture configuration to ensure that all components are incorporated in the repair. In some circumstances, CT may aid an

Comminuted fracture of the second phalanx in a horse. Courtesy of Dr. Matthew T. Brokken.

accurate diagnosis and reconstruction of the fracture. Conservative treatment of severely comminuted fractures involves immobilization with a plaster or fiberglass cast for up to 12 wk, with or without the use of transfixation pins through the third metacarpal/tarsal bone. Complications of P1 fracture repair include implant failure, poor alignment at the fracture site leading to secondary arthritis, and contralateral limb laminitis.

Fractures of the second/middle phalanx (P2) are most common in Quarter horses and typically affect the hindlimbs. Whereas osteochondral "chip" fractures are common off of proximal P1, osteochondral fractures are relatively uncommon off of P2. The most common fractures of P2 are either palmar/plantar eminence fractures of proximal P2 or comminuted fractures. Treatment of most P2 fractures is either with internal fixation with a combination of plate(s) and screws and/or a transfixation pin cast. Residual lameness typically is present and depends on the degree of osteoarthritis that develops in the distal interphalangeal joint and, to a lesser extent, the proximal interphalangeal joint (if not arthrodesed in the fracture repair). Prognosis depends on how comfortable the horse will be after fracture stabilization to limit the risk of contralateral limb laminitis.

FRACTURES OF THE PROXIMAL SESAMOID BONES

Fractures of the proximal sesamoid bones are classified according to their location in the bone. The most common sesamoid fractures in Standardbreds and Thoroughbreds are apical. They are caused by over extension and often are associated with suspensory ligament damage. The lateral proximal sesamoid in the hindlimb of Standardbreds may be fractured as a result of torque forces induced by shoeing with a trailer-type shoe. Other fractures include mid-body, basilar, abaxial, axial, or comminuted, and they may involve one or both sesamoids. Most, apart from some abaxial and base fractures, are articular. Clinical signs include heat, pain, and acute lameness, which is exacerbated by flexion of the fetlock. There is often hemarthrosis and synovial effusion of the metacarpal/tarsophalangeal joint. Diagnosis is confirmed radiographically. Of Thoroughbred racehorses ≥ 2 yr old, 82% of horses with apical sesamoid fractures removed arthroscopically ran at the same or at an improved level. Horses with apical fractures of the forelimb medial proximal sesamoid are less likely to race after fragment

removal. The presence of suspensory desmitis (see p 1122) in the affected limb also decreases the prognosis after surgery. Horses with apical sesamoid fractures in the forelimbs are less likely to race than those with fractures in the hindlimbs (55% vs 86%). Size and shape of apical sesamoid fractures does not appear to affect racing performance. Mid-body fractures typically require reduction using lag screw(s) fixation with a prognosis of 75% (44% in another study) to return to racing. The prognosis for basilar fractures involving a portion of the sesamoid is fair compared with that for fracture of most of the base or in horses with associated articular disease (poor prognosis). Complete disruption of the suspensory apparatus, including fractures of both sesamoid bones, is a catastrophic injury that may be accompanied by vascular compromise; however, some horses can be salvaged for breeding by surgical arthrodesis of the fetlock joint.

OSTEOARTHRITIS OF THE PROXIMAL INTERPHALANGEAL JOINT

Osteoarthritis of the proximal interphalangeal joint (high ringbone) is a common cause of lameness in many types of horses used for a variety of disciplines. The osteoarthritic process can start as a single traumatic episode or as a result of "wear and tear," or overuse. Other causes of osteoarthritis of this joint are infection and developmental orthopedic disease. The proximal interphalangeal joint is a lower motion joint that is somewhat unforgiving to high loads placed upon it. Osteoarthritis is characterized by cartilage loss and periarticular new bone formation. In the chronic, progressive osteoarthritic pastern, lameness is typically subtle at first and becomes more noticeable as the disease progresses. Radiographic findings may include periarticular new bone formation, subchondral lysis and/or sclerosis, and loss of joint space (typically the medial aspect of the joint). In the early stages of disease, diagnostic analgesia is typically required to localize the lameness. In addition, a positive response may be seen on lower limb flexion. Oral or intra-articular anti-inflammatory medication may relieve the signs of lameness temporarily. The use of intra-articular ethanol injection into the proximal interphalangeal joint has been described. If surgical fusion is not an option, multiple injections were successful in some horses for facilitated ankyloses. Surgical arthrodesis of the pastern joint is frequently required to successfully restore

performance. Typically, this involves a combination of plate(s) and screw(s). In a retrospective study of 53 horses that had a proximal interphalangeal joint arthrodesis using a combination plate-screw technique (81% forelimb, 95% hindlimb), 87% of horses with follow-up were used as intended. Deterioration of articular cartilage within the metacarpal/tarsophalangeal joint is a common injury in racehorses and can lead to development of periarticular osteophytes, enthesophytes, and joint space collapse. In young, training horses, periosteal bone can form on the dorsal aspect of the distal metacarpus and the proximal aspect of the proximal phalanx, often involving the joint capsule (osselets). Osteoarthritis is often secondary to a primary abnormality such as a chip fracture or osteochondrosis (*see* p 1140). Treatment typically has two goals: reducing pain and minimizing further joint deterioration. The judicious use of anti-inflammatories (eg, NSAIDs, corticosteroids) can provide pain relief. Newer biologic therapies (platelet-rich plasma, stem-cell therapy, interleukin-1 receptor antagonist protein) may help slow down or arrest the progression of osteoarthritis. In severe, advanced cases, arthrodesis of the joint is necessary to provide pain relief.

PALMAR/PLANTAR METACARPAL/METATARSAL NONADAPTIVE BONE REMODELING

This condition affects the subchondral bone of the palmar/plantar aspects of the distal metacarpal/metatarsal condyles and is a common cause of performance-limiting lameness in Standardbred and Thoroughbred racehorses. It is thought to be a stress remodeling response to high-level activity in young racehorses and is associated with lameness referable to the fetlock region. Typically, the lameness improves with a block of the palmar/plantar metacarpal/metatarsal nerves proximal to the fetlock. Intra-articular analgesia of the fetlock joint can have varying results and is less reliable to improve lameness. Radiographic signs may be minimal, and the changes are identified earliest using nuclear scintigraphy, CT, or MRI. Treatment consists of controlled exercise.

SESAMOIDITIS

The sesamoid bones are maintained in position by the branches of the suspensory ligament proximally and by a number of sesamoidean ligaments distally. Because of the great stress placed on the fetlock during

fast exercise, the abaxial portion of the proximal sesamoid bones is susceptible to stress-related injury. Sesamoiditis is a clinically distinctive condition; however, it is poorly characterized pathologically.

The clinical signs are similar to, but less severe than, those resulting from sesamoid fracture. Depending on the extent of the damage, there are varying degrees of lameness and swelling. Pain and heat are evident on palpation and flexion of the fetlock joint. Radiographic evidence of sesamoiditis involves periarticular osteophytes, enthesophytes, focal osteolysis, and enlarged vascular channels (or linear defects in the abaxial margin of the proximal sesamoid bones). Grading scales for sesamoiditis exist and particularly note the vascular channels on radiographs. Severity of sesamoiditis on radiographs has been linked to a decrease in racing performance in one study. In another study, when radiographic signs of significant sesamoiditis were present, horses had a 5 times greater risk of developing clinical signs of suspensory ligament branch injury with onset of training.

The recommended treatment is enforced rest and symptomatic treatment to combat inflammation and soreness. The insertion of the suspensory ligaments should also be carefully evaluated by ultrasonography for concurrent lesions.

CHRONIC PROLIFERATIVE SYNOVITIS

(Villonodular synovitis)

Proliferative synovitis is the enlargement of the fibrocartilaginous pad on the dorsoproximal aspect of the joint capsule attachment of the fetlock joint. The cause of this inflammation is thought to be from repetitive trauma from exercise. Typically, this condition is found most frequently in racing Thoroughbreds, but it may also develop in Standardbreds and nonracing breeds. Clinical signs include fetlock joint effusion, firm swelling over the dorsoproximal aspect of the fetlock joint, lameness, and decreased range of motion and a positive response to firm flexion of the fetlock.

Diagnosis can be suspected by palpation. Radiography can be used to identify associated osteolysis at the proximal aspect of the dorsal mid-sagittal ridge of the distal third metacarpal bone on the lateromedial projection. The radiolucency is a result of the damage to the cortical bone from the overlying fibrous mass. Ultrasound examination can also be performed, and the synovial pad is considered abnormal if it is >4 mm thick, has rounded distal margins, or

if hyperechoic regions are found within the pad. Treatment is surgical excision via arthroscopy.

DIGITAL SHEATH TENOSYNOVITIS

Tenosynovitis of the digital flexor tendon sheath is common in all types of working horses. Chronic digital sheath tenosynovitis may be bilaterally symmetric in the hindlimbs in horses with minimal clinical significance ("windpuffs"). The digital sheath encompasses the superficial and deep digital flexor tendons and extends from the distal one-third of the metacarpus/metatarsus distally to just proximal to the navicular bursa. Asymmetric tendon sheath effusion typically indicates a problem. Lameness degree is variable, depending on the structure(s) involved, and may increase with exercise. Horses are typically sore on firm flexion of the distal limb. Although some cases of tenosynovitis are primary and respond to conservative therapy with or without treatment of the sheath with corticosteroids and/or hyaluronic acid, others are secondary to lesions of structures contained within the sheath. Ultrasonographic examination of the entire digital flexor tendon sheath, including the intersesamoidean ligament and distal sesamoidean ligaments, is recommended and typically leads to a diagnosis. However, marginal tears of the deep digital flexor tendon (typically dorsolateral in the pastern) and tears of the manica flexoria can be difficult to diagnose via ultrasound but are confirmed through tenoscopic examination of the sheath. Verification of site of lameness should be confirmed via intrathecal injection of analgesia.

Palmar/plantar annular ligament constriction can be primary due to desmitis of the ligament or secondary to longstanding tenosynovitis or enlargement of the flexor tendons contained within the fetlock canal. Clinical signs are similar to those of other causes of tenosynovitis and include pain on palpation, swelling, and lameness, especially after forced flexion of the distal limb. Careful ultrasonographic examination is recommended to assess accompanying pathology. Treatment can be either conservative (ie, steroids) or surgical (palmar/plantar annular ligament desmotomy). Surgery is best performed tenoscopically, which allows visualization of the remainder of the sheath for primary pathology and assessment of the degree of constriction.

Other common causes of tendon or ligament pathology distal to the fetlock include desmitis of the distal sesamoidean ligaments (oblique and straight), deep

digital flexor tendon, superficial digital flexor tendon, and the distal digital annular ligament. Any of these conditions can result in tenosynovitis of the digital sheath and can typically be diagnosed using ultrasonography or MRI.

DISORDERS OF THE METACARPUS

TENDINITIS

(Bowed tendon)

Inflammation of a tendon can be acute or chronic, with varying degrees of tendon fibril disruption. Tendinitis is most common in horses used at fast work, particularly racehorses. The problem is seen in the digital flexor tendons and is more common in the forelimb than in the hindlimb. In racehorses, the superficial digital flexor is involved most frequently. The primary lesion is a central rupture of tendon fibers with associated hemorrhage and edema.

Etiology: Tendinitis usually appears after fast exercise and is associated with overextension and poor conditioning, fatigue, poor racetrack conditions, and persistent training when inflammatory problems in the tendon already exist. Improper shoeing may also predispose to tendinitis. Poor conformation and poor training also have been implicated.

Clinical Findings and Diagnosis: During the acute stage, the horse is severely lame and the involved structures are hot, painful, and swollen. In chronic cases, there is fibrosis with thickening and adhesions in the peritendinous area. The horse with chronic tendinitis may go sound while walking or trotting, but lameness may recur under hard work. Ultrasonography delineates the cross-sectional and longitudinal extent of the tendinitis.

Treatment: Tendinitis is best treated in the early, acute stage. The horse should be stall-rested, and the swelling and inflammation treated aggressively with cold packs and systemic anti-inflammatory agents. Some degree of support or immobilization should be used, depending on the amount of damage to the tendon. Intratendinous corticosteroid injections are contraindicated. When a distinct hypoechoic or anechoic core lesion is present on ultrasound examination, tendon splitting has been recommended (the rationale is to decrease intratendinous pressure due to

serum or hemorrhage). Cases also have been treated with shock wave therapy, intralesional injection of fat-derived stromal cells or cultured bone marrow-derived mesenchymal stem cells, or platelet-rich plasma products. The levels of evidence for these modalities are variable. The horse should be rehabilitated using a regimen of increasing exercise. Superior check ligament desmotomy has been used as an adjunctive treatment to minimize recurrence of the problem before the horse is returned to training.

Other treatments for chronic tendinitis have included superficial point firing (of questionable benefit) and percutaneous tendon splitting. Annular ligament desmotomy is also used when tendinitis occurs within the confines of the digital tendon sheath.

The prognosis for a flat-racing Thoroughbred racehorse to return to racing after a bowed tendon is guarded, regardless of treatment. However, increasing success is seen with eventers, show jumpers and show hunters, and dressage horses, respectively.

SUSPENSORY DESMITIS

Injuries of the suspensory ligament (interosseous muscle) are common in forelimbs and hindlimbs of horses. Lesions are typically classified as affecting the proximal, body, or branches of the suspensory ligament.

Proximal Suspensory Desmitis: The term proximal suspensory desmitis (PSD) is restricted to lesions confined to the proximal one-third of the metacarpus. PSD can occur unilaterally or bilaterally and is a common injury in all types of athletic horses. Injury to the proximal suspensory ligament and/or its attachment to the proximal palmar aspect of the third metacarpal bone typically results in sudden onset lameness that seems to improve within a few days. Lameness varies from mild to moderate and is typically not severe unless there is substantial involvement of the ligament and its attachment (avulsion of the palmar cortex). If the horse has bilateral PSD, there may be less overt lameness but more loss of action of the horse. Lameness is typically more noticeable on soft ground and with the affected leg on the outside of the circle. Response to distal limb and/or carpal flexion tests is variable. Pressure applied to the proximal palmar metacarpal region may elicit pain; however, this response/reaction should be compared with that of the other limb to determine significance.

Diagnosis of PSD usually requires localization with diagnostic analgesia, because typically horses do not have clinical signs (eg, heat, pain, swelling) that allow

lameness to be localized to this region. There are multiple techniques to desensitize the proximal aspect of the palmar metacarpus. However, there is confusion interpreting the results of subcarpal analgesia because of the lack of specificity of local analgesic techniques. After lameness has been localized, radiographs as well as ultrasonographic examination of the region should be performed. Ultrasound of the proximal suspensory should be critically compared with that of the other limb, remembering that bilateral lesions do exist. Nuclear scintigraphy can help detect osseous injury at the proximal suspensory attachment, but negative scintigraphic images do not exclude the presence of PSD. MRI is also extremely useful to detect subtle changes in the proximal suspensory ligament that may not be visible or conclusive with ultrasonography. In addition, MRI allows accurate examination of the osseous structures adjacent to the suspensory ligament (metacarpal bones and distal carpal bones).

In contrast to hindlimb PSD, most horses with acute forelimb PSD respond well to rest and a controlled exercise program for 3–6 mo (~90% return to function). Premature return to work typically results in recurrence/persistence of lameness. Horses with chronic PSD may require a longer rehabilitation program or adjunct therapy (NSAIDs, shockwave, regenerative therapies) to return to consistent work.

Desmitis of the Body of the Suspensory Ligament: This is principally an injury of racehorses. Injuries usually affect the forelimbs of Thoroughbreds and the forelimbs and hindlimbs in Standardbreds. Soreness on palpation of the forelimb suspensory ligament is quite common in horses with lameness associated with a more distal limb problem; however, structural abnormality of the ligaments is only rarely identifiable ultrasonographically. Clinical signs vary and involve enlargement of the ligament, local heat, swelling, and pain. Diagnosis is usually based on clinical signs and can be confirmed ultrasonographically. Treatment is aimed at reducing inflammation by systemic NSAIDs, hydrotherapy, and controlled exercise. Shockwave therapy, platelet-rich plasma, and stem-cell therapy have also been used for suspensory body lesions.

Desmitis of the Branches of the Suspensory Ligament: This relatively common injury is seen in all types of horses in forelimbs and hindlimbs. Usually only a single branch in a single limb is affected, although both branches may be affected,

especially in hindlimbs. Foot imbalance is often recognized in affected horses, and this may be a predisposing factor.

Clinical signs depend on the degree of damage and the chronicity of the lesion(s) and include localized heat and swelling. Swelling is often due to local edema of the affected branch. Effusion can be present in the adjacent palmar/plantar fetlock joint and/or the digital flexor tendon sheath. Pain is usually elicited either by direct pressure applied to the injured branch or by flexion of the fetlock. Lameness is variable and may be absent.

Diagnosis is based on clinical signs and ultrasonographic examination. Radiographic examination should also be performed to evaluate the attachment of the suspensory branch on the proximal sesamoid bones. Low 4-point diagnostic analgesia as well as intra-articular analgesia of the fetlock joint (varying degrees based on the location of the branch injury) improves lameness. Ultrasonography can detect a range of abnormalities, including enlargement, alteration of shape, and alterations in echodensity.

Management depends on the severity of the signs and on the breed and use of the horse. Shockwave therapy, local anti-inflammatories, ligament splitting, and regenerative therapy have all been used with varying results. Strict attention to foot balance is also critical in management of these lesions. Clinical signs may take ≥ 6 mo to improve, and the condition may recur. Prognosis for reinjury or persistence of lameness is worse in horses that are hyperextended in their fetlocks at rest or in horses with marked periligamentous fibrosis around the branch on ultrasound.

INFERIOR CHECK DESMITIS

The accessory ligament of the deep digital flexor tendon (inferior check ligament [ICL]) is a strong fibrous band that is the direct continuation of the common palmar ligament of the carpus. Desmitis of the ICL may be seen alone or develop secondarily to injury to the superficial digital flexor tendon. In horses with severe ICL damage, the deep flexor tendon may also be affected. Injury to the ICL appears to be more common in adult or aged horses, affirming that degenerative aging changes may predispose the ligament to injury. Injury is relatively uncommon in racehorses and is common in ponies and Warmbloods (show jumpers and dressage). Injury of the ICL is usually unilateral. Diagnosis is typically from clinical examination, with swelling in the proximal

one-third of the metacarpus dorsal to the superficial digital flexor tendon. Ultrasonographic examination is typically confirmatory, with areas of enlargement, fiber pattern disruption, and loss of the normal border of the ligament. Injury to the ICL is usually treated with rest and controlled exercise, along with possible shockwave and/or intralesional injection of platelet-rich plasma or stem cells. Desmotomy of the ICL has also been performed in horses that have not responded to conservative therapy.

BUCKED SHINS

"Bucked shins" are part of the disease complex known as dorsal metacarpal disease. Bucked shins is a painful, acute periostitis on the dorsal surface of the third metacarpal bone. It is seen most often in the forelimbs of young Thoroughbreds (2-yr-olds) in training and racing, and less commonly in Standardbreds and Quarter horses. This injury can occur bilaterally and usually occurs sequentially, with the left leg being affected first because horses are trained and raced in North America in a counterclockwise direction. Bucked shins may be the result of high-strain cyclic fatigue caused by excessive compression on a bone that has not remodeled enough to tolerate the stress placed on it. Stressed bone forms a new layer of bone at the point of stress. This new bone is weaker and, in the process of rapid bone formation, the periosteum becomes elevated and inflamed.

Diagnosis is typically by clinical examination and history (soreness over the dorsal aspect of the cannon bone, soreness after high-speed work or the first race, or soreness the day after). Radiography is beneficial to determine the amount of periosteal reaction and if actual stress fracture(s) are present in the dorsal cortex. Treatment typically consists of altering the training schedule to short bursts of speed work 2–3 times a week. Rest from training is also important until the soreness and inflammation resolve. The acute inflammation may be relieved by anti-inflammatory analgesics and application of cold packs. Screw fixation with or without osteostixis is the method of choice to treat radiographically demonstrated stress fractures.

EXOSTOSES OF THE SECOND AND FOURTH METACARPAL BONES

(Splints)

Splints primarily involve the interosseous ligament between the large (third) and small

(second) metacarpal (less frequently the metatarsal) bones. The reaction is a periostitis with production of new bone (exostoses) along the involved splint bone. Possible contributory factors include trauma from concussion or injury, strain from excess training (especially in the immature horse), faulty conformation, imbalanced or overnutrition, or improper shoeing.

Splints most commonly involve the second metacarpal bone. Lameness is seen only when splints are forming and is seen most frequently in young horses. Lameness is more pronounced after the horse has been worked. In the early stages, there is no visible enlargement, but deep palpation may reveal local, painful, subperiosteal swelling. In the later stages, a calcified growth appears. After ossification, lameness disappears, except in rare cases in which the growth encroaches on the suspensory ligament or carpometacarpal articulation. Radiography is necessary to differentiate splints from fractured splint bones.

Complete rest and anti-inflammatory therapy is indicated. Intralesional corticosteroids may reduce inflammation and prevent excessive bone growth. Their use should be accompanied by counterpressure bandaging. If the exostoses impinge against the suspensory ligament, surgical removal may be necessary.

FRACTURES OF THE SMALL METACARPAL (SPLINT) BONES

Fractures of the second and fourth metacarpal (splint) bones are not uncommon. The cause may be from direct trauma, such as interference by the contralateral leg or a kick, but often accompany or follow suspensory desmitis and the resulting fibrous tissue buildup and encapsulation of the distal, free end of the bone. The usual site of these fractures is through the distal end, ~2 in. (5 cm) from the tip. Immediately after the fracture occurs, acute inflammation is present, usually involving the suspensory ligament. Lameness is typically noted (may be severe initially), which may recede after several days rest and recur only after work.

Diagnosis is confirmed by radiography. Ultrasound examination of the suspensory ligament may also be beneficial to determine a more accurate prognosis as well as guide a rehabilitation program. Surgical removal of the fractured tip and callus is the treatment of choice. Fractures involving the proximal one-third of the bone may require surgical stabilization of the bone to prevent carpal instability, particularly if the fracture involves the second metacarpal bone. Prognosis is based on severity of the

Lateral condylar fracture of the distal third metacarpal bone (arrow) in a horse. Courtesy of Dr. Matthew T. Brokken.

associated suspensory desmitis, which has a greater bearing on future performance than the splint fracture itself.

FRACTURE OF THE THIRD METACARPAL (CANNON) BONE

The most common site of major fracture of the third metacarpal bone is in the distal articulation (condylar fractures). Vertical fractures in the sagittal plane of the distal cannon bone (condylar fractures) occur predominately in young racehorses. Most condylar fractures are in the lateral condyle. In Thoroughbreds, condylar fractures of the third metacarpus are at least twice as common as third metatarsal fractures, but in Standardbreds, the ratio of metacarpal to metatarsal fractures is nearly equal. Nearly all lateral condylar fractures originate from the mid to midaxial portion of the lateral condyle and traverse toward the lateral cortex. In contrast to medial condylar fractures, lateral condylar fractures rarely spiral into the diaphysis of the cannon bone. Medial condylar fractures nearly always extend toward the axial aspect of the cannon bone. Clinical signs are straightforward, with acute lameness after exercise (or race) with marked effusion in the fetlock joint. Radiographic examination should include a full series of the fetlock as well as a flexed dorsopalmar view. For medial fractures, complete examination of the entire cannon bone should be performed.

Lateral condylar fractures can be treated conservatively by casting, but the treatment of choice is compression of the fracture, with screws placed in lag fashion to minimize or avoid osteoarthritis. For medial condylar fractures, in addition to lag screw fixation distally, a plate is placed up the remaining metacarpus.

The most common major long bone fracture in horses is fracture of the diaphyseal cannon bone. Typically, these fractures result from trauma incurred while the horse is pastured with other horses. Open reduction and internal fixation is the preferred treatment choice, because the lack of soft-tissue coverage over an unstable fracture typically causes these types of fractures to become open when simply cast or with a coaptation splint.

DISORDERS OF THE CARPUS

The carpus involves three articulations: the radiocarpal (antebrachicarpal), intercarpal (middle carpal), and carpometacarpal joints. Problems are localized to the carpal area based on lameness, swelling, synovial effusion and pain on palpation, and responses to flexion and diagnostic analgesia. Visualization and palpation are important to determine the site of swelling in the carpus (eg, synovial fluid in the joint or tendon sheath or swelling in the subcutaneous space). Light palpation with fingers with the horse standing and with the leg raised is beneficial in determining the specific area of fluid accumulation. Knowledge of the normal anatomic boundaries of the structures is important.

Diagnostic analgesia of the carpal joints is usually done intra-articularly. The antebrachicarpal and middle carpal joints can be injected easily. The carpometacarpal joint communicates with the middle carpal joint; therefore, local analgesia in the middle carpal joint provides analgesia of the carpometacarpal joint. There is considerable distal palmar outpouching of the carpometacarpal joint; with time, analgesia will diffuse into the area of the proximal suspensory ligament, thus leading to confusing results.

Radiography of the carpus is critical for specific diagnoses and should include flexed lateral as well as skyline views of the distal row of carpal bones (as well as proximal row/distal radius in some horses).

FRACTURE OF THE CARPAL BONES

Osteochondral fractures (carpal chip fractures) of the carpal bones are a common

Flexed lateral radiograph of a horse with a slab fracture of the third carpal bone (arrow).
Courtesy of Dr. Matthew T. Brokken.

cause of lameness in racehorses. The primary etiologic factor is trauma, usually associated with fast exercise. Chips typically occur on the dorsal aspect of the joint. In the middle carpal joint, the most frequent sites are the distal radial carpal bone, proximal third carpal bone, and the distal intermediate carpal bone. In the radiocarpal joint, the most common locations are the proximal intermediate carpal bone, distal lateral radius, proximal radial carpal bone, and the distal medial radius. Diagnosis is based on clinical signs of synovitis and capsulitis and radiographic demonstration of osteochondral chip fragment(s). Arthroscopic surgery is the treatment of choice. The overall prognosis is highly dependent on the degree of articular cartilage damage within the joint identified on arthroscopy.

Carpal Slab Fractures

Slab fractures extend from one articular surface to another articular surface. In the carpus, slab fractures occur in both frontal and sagittal planes. The most common fracture is a frontal slab fracture of the radial facet of the third carpal bone, followed by fractures of the intermediate facet and both facets of this bone. The treatment of choice is lag screw fixation for fractures >10 mm or removal of the fracture fragments if they are thin or not amenable to lag screw fixation.

Accessory Carpal Bone Fractures

These are less common than other fractures in the carpus. Lameness is typically acute

and severe, and there may be synovial effusion in the carpal sheath and, less commonly, the radiocarpal joint. Radiographs confirm the diagnosis. These fractures are typically treated conservatively; however, if the fracture is articular and fragmented, surgical removal of the fragments has been performed. Fibrous union may enable a horse to return to athletic activity.

SUBCHONDRAL BONE DISEASE OF THE THIRD CARPAL BONE

Degeneration and necrosis of the subchondral bone is common in racehorses and may precede slab fractures of the third carpal bone. The condition was initially identified in the proximal articular surface of the third carpal bone and is considered to be a consequence of cyclic trauma. Clinical signs include lameness, reduced performance, and effusion of the middle carpal joint. Horses typically improve with intra-articular analgesia of the middle carpal joint. A skyline view radiograph is critical for diagnosis and typically shows lysis and sclerosis in the third carpal bone (typically radial facet). Arthroscopic examination is the treatment of choice, with removal of the abnormal cartilage and subchondral bone.

TEARING OF THE MEDIAL PALMAR INTERCARPAL LIGAMENT

This injury, first described in 1990, most commonly involves the medial palmar intercarpal ligament but may involve the lateral palmar intercarpal ligament. A typical presentation is synovitis and capsulitis unresponsive to therapy or the presence of carpal chip fragments with an untoward amount of lameness. Diagnosis is made arthroscopically, and treatment is arthroscopic debridement of the torn fibers. Prognosis depends on the degree of tearing, as well as lack or presence of concurrent subchondral bone damage.

OSTEOARTHRITIS OF THE CARPUS

Radiocarpal and/or middle carpal osteoarthritis typically appears with chronic thickening of the joint capsule and usually associated decreased range of motion. Radiographic changes develop slowly, and usually the degree of articular cartilage compromise is severe. Cases that can possibly lead to osteoarthritis should be treated aggressively and correctly. Treatment

Marked new bone proliferation (arrow) in a horse with osteoarthritis of the carpometacarpal joint. Courtesy of Dr. Matthew T. Brokken.

of severe osteoarthritis is largely palliative. Osteoarthritis of the carpometacarpal joint has been described mainly in Arabian and Quarter horses. This condition typically affects the medial aspect of the joint and is characterized by lameness (minimal at first), firm swelling over the medial aspect of the distal carpus, and response to intra-articular analgesia of the middle carpal joint. Radiographs typically show periarticular new bone proliferation (sometimes marked) over the proximal second and/or third metacarpal bone, lysis and/or sclerosis of the bones surrounding the medial carpometacarpal joint, and possible loss of the medial joint space. Treatment consists of conservative therapy (systemic and/or intra-articular anti-inflammatories) and possible facilitated arthrodesis with use of passage of drill bits across the joint. (See also OSTEOARTHRITIS, p 1063.)

DISTAL RADIAL EXOSTOSIS AND OSTEOCHONDROMA OF THE DISTAL RADIUS

Exostosis of the caudal aspect of the distal radial physis can cause tenosynovitis of the carpal sheath and damage to the deep digital flexor tendon. Exostosis is differentiated

from an osteochondroma based on its location and histologic appearance. Osteochondromas are present on the caudal aspect of the distal radius metaphysis normally 2–4 cm proximal to the distal radial physis. Osteochondromas also have hyaline cartilage remnants present on histologic examination (exostosis do not have hyaline cartilage). Irrespective of origin, these two conditions can cause lameness (swinging leg) and carpal sheath tenosynovitis.

Diagnosis is generally made by radiography, but ultrasonic examination may be helpful to define the presence of soft-tissue injury. The condition can be treated successfully via tenoscopy of the carpal sheath with removal of the protruding mass and identification and debridement of any concomitant damage to the deep flexor tendon. The prognosis is good and depends on the degree of soft-tissue damage.

CARPAL HYGROMA

A carpal hygroma is a subcutaneous swelling over the cranial/dorsal aspect of the carpus. Typically, a history of trauma to the carpus is noted. The swelling is typically aseptic, but risk of infection can develop after drainage or injection. Typically, a hygroma is a cosmetic blemish, and lameness is not usually present. The diagnosis is made by palpation and visualization. Injection of contrast material into the hygroma and subsequent radiographic examination outlines the extent of the hygroma. Communication between joint and hygroma is confirmed or excluded through fluid injection into the carpal joints. Hygromas can be treated in the early stage with drainage, steroid injections, and bandaging. When infection is present, surgical resection of the infected tissue is recommended.

RUPTURE OF THE COMMON DIGITAL EXTENSOR TENDON

This condition occurs in foals and may be present when the foal is born or develop in the first weeks of life. It can be primary or secondary to carpal or fetlock flexural deformities (see p 1150). Affected foals have a characteristic soft/fluid swelling over the dorsolateral aspect of the carpus and distal radius. Ultrasound examination is confirmatory. Management involves stall rest and preventing secondary tendon contracture with the use of bandaging with or without PVC splints to prevent knuckling, if appropriate. Prognosis is excellent in foals without concurrent flexural deformities or cuboidal bone abnormalities.

DISORDERS OF THE SHOULDER

Shoulder lameness in horses is less common than many owners expect. Although cases are often described as having a typical gait (reduced protraction/cranial phase, wearing of the toe, a swinging lameness), they are still difficult to diagnose simply from analysis of the animal's walk or trot. However, almost all cases have atrophy of the proximal limb muscles (especially supraspinatus, infraspinatus, the cranial shoulder muscles, and muscles of the cranial antebrachium) beyond that which would normally be expected for lameness caused by distal limb disease. This is associated not with shoulder pathology per se, but is a general feature of proximal limb lameness. Intra-articular anesthesia, medication, and centesis can be accomplished by passing a 90-mm spinal needle between the cranial and caudal parts of the lateral tuberosity of the humerus, angling caudodistally, from above; an ultrasound-guided technique is also described. Radiography is limited to the mediolateral projection, with the limb extended, and in some cases oblique projections (usually caudolateral-cranio-medial or proximocranial-proximodistal). Ultrasonography is essential for full assessment of the shoulder region, particularly the soft tissues.

DEVELOPMENTAL DISEASES

Developmental orthopedic disease manifests in the scapulohumeral (shoulder) joint principally as subchondral cyst-like lesions (bone cysts) affecting the glenoid of the scapula or as osteochondritis dissecans of the humeral head. Also, a condition almost exclusive to miniature ponies, caused by dysplasia of the joint and attributable to hypoplasia of the joint surfaces, results in instability and secondary arthritis.

Subchondral Cyst-like Lesions: Bone cysts may develop in the glenoid, or socket, of the shoulder joint. They may or may not communicate with the shoulder joint and respond variably to intra-articular anesthesia. Although part of the developmental orthopedic disease complex, signs may not be apparent until the animal is mature. In common with other manifestations of this syndrome, lameness may not become a feature until the animal begins work (typically breaking in or early ridden exercise). Occasionally, bone cysts may be a cause of lameness in an older horse, having remained quiescent for most of the animal's life; the reason for these later onset cases is not clear.

Diagnosis is made by localization with intra-articular anesthesia, by exclusion of lower limb disease, or occasionally by gamma scintigraphy. Radiographs should document the lesion, although some cysts are too small to be seen.

Treatment in young horses consists of rest in the hope the cyst will remodel to become nonpainful; however, this happens only rarely. Intra-articular medication can provide relief from lameness but usually only transiently. Some disease-modifying preparations show promise (eg, autologous conditioned serum), and some clinicians favor the use of systemic glycosaminoglycans. Surgical debridement is difficult in most cases, because the cyst location and articular cartilage damage that causes secondary osteoarthritis may limit its effectiveness; however, it can be very successful. Injection of corticosteroids directly into the cyst via an extra-articular approach could be appropriate, but the lack of 3-dimensional imaging of this region in horses makes the approach hard to plan.

Osteochondritis Dissecans: Derangement of cartilage and bone development on the humeral head can result in weakness within the articular cartilage that may lead to erosion or formation of a free flap of cartilage. Typically, the caudal part of the head is affected, or at least it is the part most evident on radiographs. In other joints, osteochondritis dissecans often can be treated successfully with arthroscopic debridement. Unfortunately, access to the shoulder joint is severely restricted, and in most cases the full extent of the lesion cannot be seen or treated. Clinical resolution in all but the mildest cases in young horses is rare. Rest and various medications have been tried, with little documented success.

Scapulohumeral Dysplasia: Seemingly unique to the miniature breeds, this condition arises from a mismatch between the size of the glenoid and humeral head. This causes instability of the joint and secondary arthritis. Although undoubtedly a developmental problem, probably with a significant degree of heritability, many cases do not present until the animal is an adult, and the history is often of sudden onset lameness. On physical examination, proximal limb muscle atrophy is often profound and lameness considerable. These factors, along with the breed disposition and the often-present sign of resentment of proximal limb manipulation, make localization straightforward. Radiographs reveal the presence of osteoarthritis and variable subluxation of

the scapulohumeral articulation. Oblique views may demonstrate deep erosion of the humeral head in severe cases. The generalized destruction of the joint produces a "hot spot" on a bone scan, if performed. There is no simple treatment. Most cases present at such an advanced stage that even palliative care is impossible; euthanasia on humane grounds should be considered in such situations. Surgical arthrodesis has been described but is rarely performed.

FRACTURES

Serious trauma can result in fracture to any part of the shoulder region. However, the main sites affected are the supraglenoid tuberosity of the scapula (which serves as the origin of the biceps brachii muscle), the mid to distal scapula, and the proximal humeral metaphysis.

Supraglenoid tuberosity fractures, if complete, invariably displace in a craniodistal direction, because of the pull of the biceps. Large fractures can be surgically repaired. However, this is not easy, because the fragments are often difficult to reduce and the implants are both difficult to place and prone to failure during recovery from anesthesia or during convalescence. Smaller fragments can be removed, but the involvement of the biceps tendon of origin has to be resected. Very large fragments can involve the joint surface. Cases usually present with severe lameness and a history of trauma (eg, a fall during jumping or collision with a fixed object). On manipulation, there is often a sense of disarticulation between the lower limb and shoulder as the biceps is disrupted. Crepitus may be felt. In most cases, because the inciting cause is significant trauma, other signs such as soft-tissue abrasions or swelling will pinpoint the shoulder as the site of pain. Radiographs will reveal the fracture, and ultrasonography can be very useful to assess the biceps tendon. Management varies and depends on intended use, age, size of fragment, size of horse, etc. The prognosis for restoration of normal function is guarded. The size of the fragment, degree of displacement, presence/absence of articular involvement, degree of biceps disruption, and intended use of the horse are probably the most important prognostic factors.

Mid to distal scapula fractures occur through trauma or, in racehorses, as stress fractures associated with cumulative cyclical fatigue. Trauma can result in complete or (presumably because of the flexibility of the bone, especially in foals) incomplete fractures. Radiographs rarely help, because of the difficulty in obtaining diagnostic

images of the area. Ultrasonography can accurately assess the integrity of the bone surface and is the technique of choice. Scintigraphy can also detect the injuries. Comminuted fractures can occur, and the prognosis worsens with increased complexity of the fracture. Simple, nondisplaced, or minimally displaced fractures usually heal well with rest alone.

Ultrasonography can be used to monitor healing. Stress fractures are almost always incomplete and heal very well, carrying an excellent prognosis for return to training. Very rarely, scapula fractures manifest as severe, unstable, comminuted injuries necessitating euthanasia on humane grounds. The clinical appearance is key to making a decision in these circumstances; although painful, scapula fractures with a good prognosis cause no observable limb instability.

Deltoid tuberosity fractures are seen infrequently. They are usually the result of trauma, often a kick from another horse, and may involve a wound and variable amounts of infection within the injury. Lesion-oriented oblique radiographs and ultrasonography define these injuries, and affected horses usually recover fully with rest alone, although surgical debridement of infected bone may be required in rare cases.

Stress fractures affect the proximal humerus also, almost exclusively in the caudal metaphyseal region. They are an uncommon but important cause of lameness in racehorses (the craniodistal metaphysis of the humerus is also affected, *see* p 1051). The typical history is one of sudden onset, often moderate to marked lameness closely associated with recent exercise, in an animal usually but not always in faster work. Lameness is usually transient, and the horse generally becomes sound within a short time (days to a week). If exercise resumes, lameness recurs. Localization is difficult; many are detected after the lower limb has been eliminated as the source of pain, or with scintigraphy. Radiographs can identify periosteal and endosteal new bone at the site of injury. Recovery is usually uncomplicated and complete with a few weeks' rest. Prolonged confinement may be counterproductive, and light exercise (walking only) may be introduced surprisingly quickly once the initial painful period has subsided. The injury remains evident on radiographs long after the bone is strong enough to withstand exercise, but a gradual smoothing and resolution of the callus will be seen as remodelling proceeds. Undetected humeral stress fractures can result in failure of the bone during exercise and complete breakdown, necessitating euthanasia.

BICIPITAL BURSITIS

The biceps brachii tendon runs over the cranioproximal humerus, protected by a synovial bursa. Inflammation of this structure can cause lameness and is usually secondary to a more serious inciting cause. Trauma to the proximal humerus, cystic lesions in the underlying bone, and injury to the tendon itself will cause secondary bursitis; it is important to recognize the primary lesion and treat appropriately.

Occasionally, idiopathic primary bursitis arises and responds very well to medication of the bursa with corticosteroids. Bacterial contamination and, rarely, fungal infections can cause bicipital bursitis. In most cases, a wound in the vicinity of the bursa alerts the clinician to this possibility but, very rarely, closed sepsis can occur. Treatment for septic bursitis follows the same pattern as for other synovial structures. Radiography and ultrasonography complement each other in the diagnosis and management of primary and secondary bursitis. Repeat examinations may be necessary if a primary lesion cannot be detected, because it may become obvious with time. Scintigraphy is useful in cases in which the primary lesion remains elusive, because small areas of bone damage or cavitation can go undetected radiographically.

INFECTION

Sepsis of the shoulder joint occurs most commonly as a result of penetrating injury. Diagnosis and treatment proceed as for other joints. In foals (and rarely, weanlings or yearlings) infection can spread hematogenously and become established in the growth plates or ends of the bones (physal or epiphyseal infection). These infections, provided they are not associated with contamination of the synovial structures, can be treated with high levels of antimicrobials systemically before resorting to surgical intervention. Methods to provide high quantities of antimicrobials at the site of infection exist (eg, intraosseous perfusion).

SUPRASCAPULAR NEUROPATHY

(Sweeney)

This syndrome describes the physical appearance of the horse's shoulder. It is not a diagnosis in itself, because there are a number of potential causes. The most common cause is injury to the suprascapular nerve.

All cases have atrophy of the supraspinatus and infraspinatus muscles that cover the scapula. This results in the scapular spine

becoming prominent; in severe cases, the muscles virtually disappear. The atrophy is unusual in that it is often profound and very localized, which are hallmarks of an injury to a single lower motor nerve. The nerve involved is the suprascapular. Although the site of damage is rarely documented clinically, most cases involve trauma to the cranial shoulder at the point where the nerve is exposed to potential compression as it courses over the cranial aspect of the scapula. The severity of damage determines the degree of atrophy and the chances of recovery. If nerve function is severely compromised, the shoulder joint becomes unstable (it is a synarthrosis with no true collateral ligaments, relying on the surrounding muscles to support it) and the joint "pops out" sideways as the horse bears weight. This subluxation does not appear overtly painful to the horse, but if the joint cannot be stabilized, it may have significant implications for the longterm health of the joint and the horse's athletic career.

Therapy is aimed at maintaining muscle health during the period of nerve recovery and maximizing neurogenesis. Horses should be restricted to stable rest or a very small paddock. Complete immobilization may negatively impact the nerve and muscles, but activity probably hastens joint degeneration. A surgical procedure to remove part of the scapula over which the nerve courses has been described, aiming to provide optimal conditions for nerve recovery. This should be considered, but its usefulness is open to debate. Muscle stimulation, under the guidance of a trained physiotherapist, will help to limit muscle fibrosis and may encourage nerve regeneration. The vast majority of cases seem to be a result of neuropraxia or axonotmesis (based on clinical observations and rates of recovery), and function is recovered with time. However, this process can take many months, and frequently some loss of muscle bulk will remain. The prognosis seems most affected by duration of injury before diagnosis, degree of atrophy at diagnosis, and willingness of the owner to perform time-consuming physical treatments for many months.

Other causes of sweeney include disuse atrophy (which does not appear focal and is rarely severe), brachial plexus injury (which usually disrupts a number of nerves; atrophy is not focal but observable in a number of muscle groups), and caudal cervical disease resulting in spinal nerve radiculopathy (in which a number of motor nerves are also affected so that other muscles atrophy). Careful assessment of the muscles involved and radiography of the neck and shoulder will aid differentiation. Scintigraphy is useful

for rapid screening of the proximal limb and cervical and thoracic vertebra for damage that may have an adverse effect on prognosis.

OSTEOARTHRITIS OF THE SHOULDER

Degenerative joint disease affecting the shoulder joint poses the same problems here as it does elsewhere. If no primary cause is identified that is amenable to correction and if radiographic signs (periarticular osteophytes, etc) are established, it is safe to assume that cartilage destruction is well underway. Signs can be ameliorated, but not cured, with use of anti-inflammatory, analgesic, and disease-modifying therapies.

DISORDERS OF THE ELBOW

Elbow lameness is rare but should always be considered if the source of pain cannot be isolated to the distal limb. Synoviocentesis is achieved via lateral approaches either close to the collateral ligament or into the caudal pouch. Radiography is limited to mediolateral (limb extended) and craniocaudal projections (weightbearing). Ultrasonography allows inspection of the lateral joint margins and collateral ligament as well as the medial collateral ligament (limb flexed and abducted). Lameness originating from the elbow is not generally considered to produce characteristic gait changes, but disuse muscle atrophy may be more evident than expected with lower limb lesions. Occasionally, loss of definition or discomfort may be appreciable during careful palpation.

DEVELOPMENTAL ORTHOPEDIC DISEASE

Cyst-like lesions occur in the proximal radius (usually medial) and less commonly the distal humerus. They are most commonly seen in young animals, similar to cysts in other locations, and the usual treatment regimens of rest, intra-articular medication, and controlled exercise are used. As with the shoulder, access arthroscopically is limited. Extra-articular approaches to the proximal radius have been tried but have the same limitations as the shoulder, although in practice, when orthogonal radiographic projections can be obtained, there is more chance of building a three-dimensional impression of their size and location. Treatment options are limited.

Other types of developmental orthopedic disease in the elbow joint, seen commonly in other species, are rare or unrecognized in horses.

FRACTURES

Significant trauma can result in breakage of any type, but the most commonly encountered fracture of the equine elbow affects the olecranon of the ulna. Stress fractures affect the craniodistal metaphysis of the humerus in racehorses.

Olecranon fractures in mature horses occur as a result of external trauma and may be incomplete (rare), complete but non- or minimally displaced, or complete and significantly displaced. A number of fractures are also open, as a result of the trauma that caused them. In cases of incomplete or nondisplaced fractures, conservative therapy can be rewarding, although some will displace during convalescence. Most authorities recommend cross-tying the horse to prevent it from getting up and down during the first 6–8 wk of box stall rest. The use of splints and Robert Jones bandages is more controversial—a “pendulum effect” can result from increased weight on the lower limb, possibly doing more harm than good. Many olecranon fractures displace under the influence of the triceps muscle and require internal fixation to repair. The use of a tension band plate is most common, with reported success rates for return to athletic function of ~75%.

Fractures of the ulna in foals are less liable to displace and may therefore be treated more commonly with rest alone. If such fractures are displaced, tension band plates can be applied, but their use must be monitored carefully because they will interfere with growth of the limb (the proximal radial physis fuses at 11–24 mo of age) and must be removed as soon as satisfactory healing has been achieved. An unusual but potentially difficult injury to diagnose and treat occurs when the proximal ulnar epiphysis is avulsed due to Salter Harris type 1 or 2 injury of the physis, which fuses at 24–36 mo of age. In some cases, the epiphysis is retracted so far proximally that it does not appear on the standard mediolateral radiograph and can be missed. Less dramatic injuries of this type can be managed conservatively, but significant displacement requires surgical intervention.

Treatment and prognosis may be influenced by whether the fracture enters the elbow joint or not. To determine this, careful assessment of high-quality radiographs is needed.

Stress fractures at the craniodistal metaphysis of the humerus, just above the elbow, occur in racehorses. The history is often similar to that for fractures of the proximal humerus and other stress fractures. Mediolateral radiographs will often detect

periosteal and endosteal reaction at the predilection site. This can also be documented ultrasonographically. Scintigraphy is a sensitive method to detect fractures that cannot be seen on radiographs. Management is tailored to the comfort of the horse and severity of the initial injury but proceeds as for other injuries of this type with a careful return to exercise, balancing structural integrity with biomechanical requirements for healing.

OSTEOARTHRITIS

Degenerative joint disease of the elbow joint, in the absence of an inciting primary lesion, is managed as described for the shoulder and other joints (*see p 1051*). Some horses present with lameness localized to the elbow joint by diagnostic anesthesia with little or inconclusive abnormalities evident with imaging. It has been reasonably proposed that these horses may be suffering from subchondral bone damage.

COLLATERAL LIGAMENT INJURY

Most commonly detected laterally, probably for biomechanical and imaging reasons, these injuries can be detected with ultrasonography. Medial collateral ligaments are more difficult to image but can be assessed. Radiographs may document new bone (enthesiophytes) associated with injury. A number are found by scintigraphy, associated with a “hot spot” even in the absence of radiographic changes. Prognosis depends on the severity of the injury. At this time, no proven therapies exist to augment ligament healing. A number of treatments have been tried, including intra-articular medication, periligamentous injection of biologics (eg, platelet-rich plasma), systemic disease-modifying drugs, and extracorporeal shockwave therapy.

DISORDERS OF THE METATARSUS

BUCKED SHINS/DORSAL CORTICAL FRACTURES OF THE THIRD METATARSAL BONE

Modelling and stress remodelling of the dorsal cortex of the third metatarsal bone occur in young racehorses but, unlike in the third metacarpal bone, it is rarely associated with clinical signs of lameness. Dorsal cortical fractures of the third metatarsal bone are rare but may occur in Thoroughbred or Standardbred racehorses.

EXOSTOSES OF THE METATARSAL BONES

Exostoses of the metatarsal bones (splints) are common and may or may not be associated with lameness. Splint exostoses may be caused by direct trauma or instability between metatarsal bones. Large exostoses on the proximal lateral aspect of the second or fourth metatarsal bones are common and usually asymptomatic. Axially located splint exostoses on the proximal end of the second or fourth exostoses may impinge on the proximal end of the suspensory ligament or on the lateral and medial plantar metatarsal nerves and be associated with lameness.

Lameness is usually mild and can be alleviated by infiltration of local anesthetic solution around the exostosis or by perineural analgesia of the lateral and medial plantar metatarsal and lateral and medial plantar nerves.

Management of horses with symptomatic splint exostoses includes local cold therapy (cold hosing, icing, etc), bandaging, and administration of NSAIDs. Infiltration of corticosteroids around the exostosis may be beneficial in some cases. Surgical excision of persistently painful exostoses by periosteotomy, osteotomy of exostosis without removing the parent splint bone, adhesiolysis, and fasciotomy can be performed successfully if exostoses involve the axial aspect and encroach on or are adhered to the suspensory ligament.

DIAPHYSEAL FRACTURE OF THE THIRD METATARSAL BONE

Diaphyseal fractures of the third metatarsal bone usually result from direct trauma (eg, kicks) or may result from propagation of medial condylar fractures. Prognosis depends on age and size of horse, configuration of fracture, integrity of the vascular supply, involvement of the metatarsophalangeal or tarsometatarsal joint, and degree of contamination. Prognosis for adult horses with open, comminuted fractures of the third metatarsal bone is poor, but in those with closed, mildly comminuted or oblique fractures, internal fixation may be possible (although often limited by financial constraints). Prognosis in foals with simple or mildly comminuted fractures of the mid diaphyseal third metatarsal bone after internal fixation with two plates is fair.

INCOMPLETE LONGITUDINAL FRACTURES OF THE PLANTAR ASPECT OF THE THIRD METATARSAL BONE

Stress reaction and incomplete longitudinal fractures of the plantar aspect of the third metatarsal bone may occur due to stress-related bone injury at the origin of the suspensory ligament. These are usually associated with increased uptake of radionuclide on bone scintigraphy and are clearly demonstrable on MRI.

FOCAL BONE REACTION AND AVULSION FRACTURES OF THE THIRD METATARSAL BONE

Focal bone reaction and avulsion fractures of the third metatarsal bone at the site of the proximal attachment of the suspensory ligament are not uncommon. They may be solitary injuries or, more frequently, are associated with proximal suspensory ligament desmitis. These injuries are frequently found in sports horses. Severity of lameness is variable, and localizing signs are usually not evident. Diagnostic analgesia is necessary to localize the pain. Some fractures may be evident radiologically, whereas in other horses scintigraphy or MRI is necessary to confirm the diagnosis. Conservative treatment with rest and a controlled ascending exercise program is usually recommended. However, recurrence of lameness is common, particularly in horses with concurrent proximal suspensory desmitis; in these horses, neurectomy of the deep branch of the lateral plantar nerve may be the only chance to resume sustained athletic performance.

FRACTURES OF THE SECOND AND FOURTH METATARSAL BONES

Fractures of the second and particularly the fourth metatarsal bones are common and usually arise from direct trauma (eg, kick from another horse). Simple, comminuted, and displaced fractures occur and are often associated with overlying wounds. Diagnosis is confirmed by radiography.

Most second and fourth metatarsal bone fractures will heal with conservative treatment despite comminution and infectious osteitis with appropriate antimicrobial therapy, wound care bandaging, and rest. Rest of 4–6 mo may be necessary in horses with open or infected

fractures. Segmental ostectomy may be indicated in horses with chronic discharging wounds and sequestrum development. Complete removal of severely comminuted fourth metatarsal bones has been reported as successful, although persistent lameness may result. Internal fixation of the fractures of the proximal end of the second metatarsal bone may be indicated in some cases with marked displacement and instability of the fracture fragments. Open fractures of the proximal end of the second and fourth metatarsal bones may result in sepsis of the tarsometatarsal joints, which requires aggressive antimicrobial therapy and appropriate treatment.

Simple fractures of the distal end of the second and fourth metatarsal bones, just above the "button of the splint bone," are usually associated with desmitis of the branches of the suspensory ligament.

ENOSTOSIS-LIKE LESIONS OF THE THIRD METATARSAL BONE

Enostosis-like lesions of the third metatarsal bone appear as intense focal areas of increased uptake of radionuclide on scintigraphic examination after injection of ^{99m}Tc -labelled methylene diphosphonate. Radiologically, they appear as round or irregularly shaped areas of increased radiopacity within the medullary cavity. They are usually asymptomatic and rarely cause lameness. Lameness, if present, usually improves with rest and administration of NSAIDs.

DISORDERS OF THE TARSUS

FAILURE OF OSSIFICATION OF THE DISTAL TARSAL BONES

Incomplete ossification of the central and third tarsal bones is most common in premature or twin foals and is characterized by a "sickle-hock" appearance. It may occur unilaterally or bilaterally. Radiologically, the partially ossified cuboidal bones appear smaller and more rounded than normal. Early recognition and treatment are important to prevent crushing of the bones and resultant progressive osteoarthritis. Cylinder tube casts can be used with good results to protect the immature bones until they have ossified.

OSTEOARTHRITIS OF THE DISTAL TARSAL JOINTS

Degenerative joint disease or osteoarthritis of the tarsometatarsal, distal intertarsal

(and less commonly the proximal intertarsal joint), colloquially known as "bone spavin," is a common cause of lameness or poor performance in horses from all disciplines. Lameness may be unilateral or bilateral, and pathology may develop in one joint only, or two or even three concurrently. Distal hock joint pain may be a sequela of incomplete ossification of the central and third tarsal bones; certain conformational abnormalities (sickle hock, cow hocked, or excessively straight hock conformation) are also believed to be predisposing. It has been proposed that degenerative joint disease of the distal tarsal joints may be caused by excessive compression and rotation of these joints as the horse jumps or stops. In Icelandic horses, bone spavin is thought to be heritable.

In most horses, few clinical signs are evident on physical examination, although in horses with more chronic distal hock pathology, the soft tissues over the medial aspect of the distal hock joints may be appreciably thickened. Lameness varies from subtle loss of performance without overt lameness to moderate or severe lameness. A characteristic gait related to lameness from the distal hock joints has been described as adduction of the hindlimb with an abrupt abduction occurring just before the limb contacting the ground; this has been referred to as a "stabbing" gait, which, although frequently evident, is not pathognomonic. Horses can exhibit this gait with lameness originating from other causes, and distal hock pain may also present with a different gait. Lameness may be exacerbated when the horse is on a circle, with some horses showing more lameness with the affected limb on the inside and some with the limb on the outside. A proximal limb flexion test will exacerbate lameness in some, but not all, horses with distal hock joint pain.

Diagnostic analgesia should be used to localize the source of pain. Most, but not all, horses with degenerative joint disease of the distal tarsal joints will improve after intra-articular analgesia of the distal tarsal joints. A negative response to intra-articular analgesia of the distal tarsal joints does not preclude distal hock joint pain. Perineural analgesia of the superficial and deep fibular and tibial nerves can be useful to confirm hock pain.

Radiography is useful to confirm the diagnosis. Radiologic changes may be evident in only one or two projections; therefore, a minimum of four standard orthogonal radiographic projections of

the hock should be taken. Radiographic changes include narrowing or loss of joint space, sclerosis of the subchondral bone, lysis of the subchondral bone, periarticular osteophyte formation, and periosteal new bone formation. The severity of lameness and degree of radiologic change are poorly correlated. In those horses in which distal hock joint pain is suspected but there is little radiologic change, scintigraphy of the tarsus may reveal an increased focal uptake of radionuclide in the distal tarsal bones.

The aim of treatment is to provide pain relief so that the horse may remain in work. It has been suggested that by maintaining the horse in work, the distal hock joints will eventually ankylose and the horse will become pain free. However, progressive radiologic ankylosis is rarely observed and has not occurred in lame horses without intervention.

Conservative treatment involves systemic NSAIDs, intra-articular medication with corticosteroids, with or without hyaluronan, remedial trimming and farriery, and adaptation of the work program. Systemic treatment with polysulfated glycosaminoglycan (PSGAG), hyaluronan, or oral nutraceuticals may be used as adjunctive therapy.

Tiludronate, a bisphosphonate compound that inhibits osteoclastic activity, has been advocated for use in horses with distal hock pain. There are few controlled studies with this medication and, in a small double-blind clinical study, only one of eight horses improved with administration of tiludronate for distal tarsal inflammation or arthritis.

Extracorporeal shockwave treatment (ESWT) has also been used in treatment of distal tarsitis. Both focused and radial portable units are available. In one retrospective study of 74 horses with osteoarthritis of the distal tarsal joints treated with ESWT, 80% of the horses showed improvement in lameness but only 18% of horses became sound.

Intra-articular injection of sodium monoiodoacetate (MIA) has been used for chemical arthrodesis of the distal intertarsal and tarsometatarsal joints. MIA inhibits chondrocyte glycolysis and causes chondrocyte death. Contrast arthrography is necessary to ensure accurate needle placement and that no communication with proximal joints is present before injection of MIA. After injection, pain control is important, because severe pain is often present for 4–18 hr. Several studies have shown that 75%–85% of horses have been free of lameness with radiographic evidence of joint fusion at ~6 mo after treatment. However, when horses were followed for

several years after treatment, the success rate decreased and a significant number of horses developed arthritis of the proximal intertarsal and tarsocrural joints. Other complications, including persistent swelling, septic arthritis, skin sloughing, and increased lameness, have been reported. Therefore, this technique is difficult to recommend because of the initial severe pain and significant possible complications. Intra-articular injection of ethyl alcohol to achieve arthrodesis has also been reported, although more longterm follow-up studies are required to evaluate its usefulness and safety.

In horses that do not respond to conservative treatment, a number of surgical techniques have been reported. These include cunean tenectomy, subchondral forage, neurectomy, and several different techniques of surgical arthrodesis.

Cunean tenectomy may result in a temporary improvement in lameness but is unlikely to restore soundness. It is believed to reduce the pressure over the medial aspect of the distal tarsus and cunean bursa and to reduce the rotational and shear stress over these joints during contraction of the tibialis cranialis muscle.

The most common surgical technique used in treatment of distal tarsal osteoarthritis is facilitation of fusion of the affected joints. Drilling across the distal intertarsal and tarsometatarsal joints is the most frequently used procedure to promote distal tarsal arthrodesis. Initial techniques described a more aggressive procedure, with 60% of the articular cartilage removed. Significant postoperative pain was associated with this procedure, and a more conservative approach using three drill tracts is currently recommended. Return to full athletic performance usually takes 10–12 mo. Retrospective studies evaluating this technique report ~60% of horses successfully return to their previous level of performance.

Both neodymium:yttrium aluminum garnet (Nd:YAG) and 980-nm diode laser have also been used to facilitate arthrodesis of the distal tarsal joints. Several studies have shown that horses treated with laser-facilitated arthrodesis are more comfortable after the procedure than when surgical drilling or MIA is used. It has been theorized that the superheating that occurs with the laser may cause thermal damage to nerve endings and diminish postoperative pain. Intra-articular drilling with diode-laser treatment has also been recommended, because the drilling should stimulate more bone production and fusion, whereas the laser reduces the postoperative pain.

Surgical stabilization in addition to intra-articular drilling of the distal tarsal joints has been proposed to have a superior clinical result versus intra-articular drilling alone. Lag screws or a screw and plate combination have been used. One study reported a success rate of 88% of horses returning to soundness versus 60% with drilling alone; however, only a small number of cases were reported.

Neurectomy of the deep fibular nerve and a partial neurectomy of the tibial nerves may be performed to relieve pain associated with the distal hock joints, with ~60% of horses undergoing surgery returning to full athletic function.

OSTEOARTHRITIS OF THE TALOCALCANEAL JOINT

Osteoarthritis of the talocalcaneal joint is rare. There are frequently no localizing signs. Lameness is usually partially improved by intra-articular analgesia of the tarsocrural joint and alleviated by perineural analgesia of the fibular and tibial nerves. Diagnosis is confirmed by radiography, with radiologic changes of subchondral sclerosis, lysis, and joint narrowing evident within the talocalcaneal joint. The prognosis for return to athletic soundness with conservative management is poor. Surgical arthrodesis has resulted in improvement in lameness but not complete resolution of signs.

OSTEOARTHRITIS OF THE TARSOCRURAL JOINT

Osteoarthritis of the tarsocrural joint may be seen as a primary disease or develop secondary to trauma, osteochondrosis, or osteoarthritis of the distal hock joints. It is usually associated with joint effusion. Lameness may vary from mild to severe and is usually improved by intra-articular analgesia of the tarsocrural joint. In horses with primary osteoarthritis of the tarsocrural joint, often no radiologic abnormalities are evident, and diagnosis is based on arthroscopic examination. Response to intra-articular medication with corticosteroids and hyaluronan is often disappointing, and prognosis for return to athletic soundness is guarded to poor.

SYNOVITIS/CAPSULITIS OF THE TARSOCRURAL JOINT

(Bog spavin)

Acute or chronic synovitis of the tarsocrural joint resulting in distention of the joint

capsule may occur due to osteochondrosis, degenerative joint disease, trauma, poor joint conformation, hemoarthrosis, or infection, or it may be idiopathic. Lameness may or may not be present, depending on the etiology. Diagnosis is based on clinical signs and a positive response to intra-articular analgesia of the tarsocrural joint if lameness is present. Radiographs should be taken to exclude OCD and other radiologically evident pathology, and ultrasonography should be done to assess the periarticular soft-tissue structures. Synoviocentesis of the tarsocrural joint should be performed if sepsis or hemoarthrosis is suspected. Idiopathic synovitis may be diagnosed in the absence of lameness or radiologic change.

Idiopathic synovitis rarely interferes with use of the horse but may be considered an unacceptable cosmetic blemish. Idiopathic synovitis may be managed by draining the synovial fluid and medicating the joint with intra-articular corticosteroids. Pressure bandages should be applied afterward to provide joint compression, and the horse stall rested for 2 wk. However, in approximately half of horses, effusion will recur and a persistent cosmetic blemish remains. Intra-articular injection of atropine (8 mg) may sometimes help.

OSTEOCHONDROSIS OF THE TARSOCRURAL JOINT

Osteochondrosis dessicans (OCD) of the tarsocrural joint is common in many breeds of horses, especially Warmbloods and Standardbreds. OCD of the tarsocrural joint may or may not be associated with lameness and is associated with variable amounts of joint effusion. Diagnosis is confirmed by intra-articular analgesia of the tarsocrural joint if lameness is present and by demonstrating radiologic changes. Few of the common OCD lesions in the hock will heal spontaneously after 5 mo of age, so arthroscopic surgical removal is usually advised. Prognosis for full return to athletic function after surgery is good. If left untreated, fragments may come loose, resulting in cartilage damage and acute signs of effusion and lameness.

OCD lesions in the tarsocrural joint are most commonly seen on the distal intermediate ridge of the tibia. Lesions at this site do not cause lameness unless significant effusion occurs or fragments become loose. Dislodged fragments may become lodged in the dorsal part of the proximal intertarsal joint. Arthroscopic removal of the fragments is usually associated with a good outcome.

OCD lesions of the distal end of the lateral trochlear ridge are most commonly seen in heavy horses and Standardbreds. Lesions can be large and, if loose, cause acute onset of severe lameness and effusion. Large or loose lesions should be removed arthroscopically, and even large lesions can be removed with a good prognosis. Prognosis is determined by the proximal and axial extent of the lesion.

Medial malleolar OCD lesions usually cause more lameness and effusion than the more common OCD lesions on the distal intermediate ridge of the tibia. They are usually seen on the axial aspect of the medial malleolus and may be overlooked on dorsoplantar radiographs. Early arthroscopic removal of fragments is recommended to prevent erosive lesions from developing on the medial trochlea of the talus. Arthroscopic surgery usually has a good prognosis for return to athletic function.

Lateral malleolar fragments are usually traumatic and are only rarely (1%) OCD lesions.

OSTEITIS OF THE CALCANEUS

Osteitis of the end of the tuber calcanei may be seen after traumatic injury and subsequent infection. This most often occurs after a kick from another horse or when the horse kicks a fixed object, such as a wall. Osteitis causes moderate to severe lameness, cellulitis, and tarsal tenosynovitis. Concurrent sepsis of the calcaneal bursa, tarsocrural joint, or tarsal sheath may occur. Diagnosis is confirmed by radiography; however, radiologic signs of focal osteolysis may take days or weeks to develop and, therefore, sequential radiographs are recommended. Treatment involves debridement of any bony lesions, endoscopic lavage of infected synovial cavities, and wound debridement combined with appropriate local and systemic antimicrobial therapy.

FRACTURES OF THE DISTAL TARSAL BONES

Fractures of the central and third tarsal bones occur most commonly in Standardbred or Thoroughbred racehorses. Fractures usually cause acute-onset severe hindlimb lameness. Lameness is exacerbated by hock flexion. Acute fractures may be associated with heat, swelling, and pain on palpation over the distal tarsal bones; there may be tarsocrural joint effusion. Diagnosis is made by radiography, but fractures may not be visible until 7–14 days

after injury when fracture line bone resorption has occurred. CT or bone scintigraphy can be useful for diagnosis if fracture is suspected but not evident radiologically. Variable fracture configurations can occur. Horses can be treated surgically with lag screw fixation or conservatively, depending on configuration of fracture. Prognosis depends on fracture configuration.

FRACTURE OF THE TALUS

Sagittal fractures of the talus are rare and have been most commonly reported in racehorses. Lameness is usually moderate to severe and associated with tarsocrural joint distention. Fractures in racehorses usually arise in the proximal aspect of the sagittal groove of the talus and are often incomplete. Fractures after trauma are usually comminuted. Prognosis depends on fracture configuration.

FRACTURE OF THE FIBULAR TARSAL BONE (CALCANEUS)

Fractures of the fibular tarsal bone are uncommon and usually the result of trauma. Small chip fractures may be successfully removed. Complete body and physeal fractures are difficult to repair, although they have been repaired with bone plates and tension band wiring. Horses with open, comminuted fractures have a grave prognosis and warrant humane euthanasia.

FRACTURE OF THE LATERAL MALLEOLUS OF THE TIBIA

Lateral malleolar fractures are usually traumatic. Small, well-rounded fragments are occasionally seen; they are considered likely to be a form of OCD and are usually asymptomatic. Small or minimally displaced fractures may be managed conservatively. Surgical removal of fragments may result in a quicker recovery. Some fragments may be removed arthroscopically, although some require an open approach through the lateral collateral ligament of the tarsocrural joint. Larger fragments may be successfully repaired by lag screw fixation.

TARSAL JOINT LUXATION

Complete luxation or subluxation of the tarsocrural, talocalcaneal-centroquartal, and tarsometatarsal joint may occur with or without concurrent tarsal bone fracture as the result of severe trauma. Horses may be salvaged for breeding or retirement to

pasture by reducing the luxation under general anesthesia and applying a full limb cast for 6–8 wk followed by a further 4–8 wk of immobilization in a heavily padded bandage. Restricted range of motion of the hock and progressive osteoarthritis means these horses are unlikely to return to athletic use.

DESMITIS OF THE COLLATERAL LIGAMENTS OF THE TARSUS

Collateral ligament injury is usually the result of trauma or a fall. Lameness varies from mild to severe, depending on the severity of injury. Flexion of the hock is usually resented and will exacerbate lameness. Effusion of the tarsocrural joint and periarticular swelling are evident. Lameness may be improved by intra-articular analgesia of the tarsocrural joint. Diagnosis is confirmed with ultrasonography. Increased uptake of radionuclide at the proximal and distal attachments of the damaged ligament may be evident on scintigraphy, and enthesiopathy may be apparent radiologically in horses with chronic injury. Conservative treatment is recommended, with physical and chemical anti-inflammatory treatments in the acute stages and then a period of stall rest (4–6 mo) followed by a controlled ascending exercise program. Prognosis depends on the severity of injury.

RUPTURE OF THE FIBULARIS (PERONEUS) TERTIUS

The fibularis (peroneus) tertius is a tendinous structure that originates from the extensor fossa of the femur and runs over the cranio-lateral aspect of the tibia to insert on the dorsoproximal aspect of the third metatarsal bone, the calcaneus, and the third and fourth tarsal bones. It is part of the reciprocal apparatus of the hindlimb, which means there is concurrent flexion and extension of the hock and stifle. Rupture of the fibularis tertius may occur as a result of hyperextension of the limb and usually occurs in the middle of the crus, or laceration may occur on the dorsal aspect of the tarsus. Avulsion of the origin on the fibularis tertius is rare in mature horses but may occur in young animals.

Clinical signs are pathognomonic, because rupture of the fibularis tertius means horses are able to extend the hock while the stifle is flexed. Horses are able to bear weight on the affected limb. At walk, the gastrocnemius and superficial digital

flexor muscles appear rather flaccid, and there is a characteristic dimple on the caudodistal aspect of the soft tissues of the crus. At trot, an obvious lameness is usually evident, with delayed protraction of the limb due to overextension of the hock.

Diagnosis is usually based on clinical signs and can be confirmed with ultrasonography.

Conservative treatment with 3–4 mo of stall rest followed by slow and careful reintroduction to exercise usually results in complete resolution of signs and return to athletic soundness.

STRINGHALT

Stringhalt is a gait abnormality characterized by exaggerated upward flexion of the hindlimb that occurs at every stride at walk. The gait abnormality usually lessens at trot and is not evident at canter. It may occur unilaterally or bilaterally. All degrees of hyperflexion are seen, from mild, spasmodic lifting and grounding of the foot, to extreme cases in which the foot is drawn sharply up until it touches the belly and is then struck violently on the ground. In severe cases, there is atrophy of the lateral thigh muscles. In Australian stringhalt and lathyrism, the condition may be progressive and the gait abnormality may become so severe that euthanasia is warranted. Mild stringhalt may be intermittent. The signs are most obvious when the horse is sharply turned or backed. In some cases, the condition is seen only on the first few steps after moving the horse. The signs are often less intense or even absent during warmer weather. Although it is regarded as unsoundness, stringhalt may not materially hinder the horse's ability to work, except in severe cases when the constant concussion gives rise to secondary complications. However, the condition may make the horse unsuitable for some equestrian disciplines (eg, dressage).

The etiology is unknown, but lesions of a peripheral neuropathy have been identified in the sciatic, peroneal, and tibial nerves. Severe forms of the condition have been attributed to lathyrism (sweet pea poisoning) in the USA and possibly to flat weed intoxication in Australia.

Diagnosis is based on clinical signs but can be confirmed by electromyography. If the diagnosis is in doubt, the horse should be observed as it is backed out of the stall after hard work for 1–2 days. False stringhalt sometimes appears as a result of some temporary irritation to the lower pastern area or even a painful lesion in the foot.

When intoxication is suspected, removal to another paddock may be all that is required. Many of these cases apparently recover spontaneously. In chronic cases, tenectomy of the lateral extensor of the digit, including removal of a portion of the muscle, has given best results. Improvement may not be evident until 2–3 wk after surgery, and not all cases respond. This is not surprising, because the condition is a distal axonopathy. Other methods of treatment include large doses of thiamine and phenytoin.

CURB

Curb is a term used to describe a number of soft-tissue injuries that cause swelling on the distal plantar aspect of the tarsus. Traditionally, the term “curb” is used to describe enlargement of the (long) plantar ligament on the plantar aspect of the calcaneus, but curb-like swelling may also be caused by peritendinous-periligamentous inflammation, superficial or deep digital flexor tendinitis, or a combination of injuries. Curb is primarily an injury of racehorses, particularly Standardbreds, and conformational abnormalities may be predisposing. Lameness varies from absent to severe, depending on the structure involved and the extent of the injury. Diagnosis of the exact nature of the injury is confirmed by ultrasonography. In most cases, treatment involves local anti-inflammatory therapy and NSAIDs in the acute phase and then rest, and a controlled exercise program thereafter.

DISORDERS OF THE TARSAI SHEATH

(Thoroughpin)

The tarsal sheath is the synovial sheath of the lateral digital flexor tendon at the level of the hock. Tenosynovitis of the tarsal sheath (colloquially called thoroughpin) is common and can be caused by a wide range of lesions.

Idiopathic thoroughpin results in mild to moderate effusion of the tarsal sheath and is most commonly seen in young horses. Effusion may arise from acute inflammation in nearby tissues or edema in the distal limb (sympathetic effusion). It is not usually associated with lameness and tends to resolve spontaneously, although it may be recurrent or persistent.

Thoroughpin may occur as a result of direct trauma (eg, kick or hitting a fence), leading to acute inflammation and

hemorrhage in the tarsal sheath. This may occur with or without concurrent damage to the lateral digital flexor tendon. Intrathecal hemorrhage results in pain and inflammation. Chronic inflammation may lead to synovial hypertrophy, fibrosis, and intrathecal adhesions between the lateral digital flexor tendon and parietal lining of the sheath. Primary sprain injuries of the lateral digital flexor tendon may also occur. Infectious tenosynovitis after a penetrating injury and resulting in synovial sepsis may also occur.

Treatment of thoroughpin depends on the underlying cause. Treatment of acute tenosynovitis, in the absence of tendinous or bony pathology, involves rest, systemic or local anti-inflammatory drugs, and cold therapy. Intrathecal medication with hyaluronan and/or corticosteroids may be useful in more severe cases. Intrathecal corticosteroids are contraindicated if there is tendon pathology. Horses with tenosynovitis associated with bony fragments, intrathecal ossicles, tearing or fraying of the lateral digital extensor tendon, or adhesions are candidates for tenoscopic surgery. Horses with infectious tenosynovitis require lavage of the tarsal sheath (best performed tenoscopically), plus appropriate systemic and local antimicrobial therapy.

FALSE THOROUGHPIN

False thoroughpin is a term used to describe a number of swellings that may develop in the distal region of the crus or tarsus and cranial to the gastrocnemius tendon. These may be seen unilaterally or bilaterally and are more common on the lateral aspect of the limb. These discrete swellings do not extend distal to the hock and cannot be balloted from lateral to medial. The swellings vary in size and may be acute or insidious in onset and may or may not be associated with lameness.

The causes of false thoroughpin vary and are not well understood. False thoroughpins are usually solitary, fluid-filled sacs; they may be multiloculated with a wall of variable thickness and may have fibrous bands traversing them. They may develop secondary to local hemorrhage or due to herniation of the tarsal sheath, gastrocnemius, or calcaneal bursae.

Ultrasonography is useful to assess the extent and nature of these swellings. Positive-contrast radiography can be used to determine whether the swellings are discrete or communicate with other structures.

In many horses, the lesions are not associated with lameness, so no treatment is required and the horses may stay in work. In some animals, low-grade lameness may occur. Intrathecal medication with corticosteroids may improve lameness in some horses, although swelling and lameness will often recur; in these cases, surgical excision may be curative.

LUXATION OF THE SUPERFICIAL DIGITAL FLEXOR TENDON FROM THE TUBER CALCANEI

Luxation or subluxation of the superficial digital flexor tendon from the point of the hock may occur after disruption to the retinaculum that attaches the tendon to the calcaneus. Luxation or subluxation more commonly occurs laterally but may occur medially. Rarely, the superficial digital flexor tendon may split sagittally, and part of the tendon luxates medially and part laterally.

Lameness is usually acute and severe in onset and associated with marked swelling over the point of the hock. Horses may become panic-stricken in the acute stages if the tendon is moving on and off the os calcis, and they may kick out frequently with the affected limb. In some horses, the tendon will resume its normal position when the horse is standing but luxate or subluxate as the horse moves; in other horses, the tendon remains permanently displaced. Diagnosis is based on careful observation and palpation and can be confirmed by ultrasonography.

In the acute stages, sedation and analgesia are important. If the tendon remains permanently displaced laterally (or medially), treatment involves prolonged stall rest (4–6 mo), possibly with the limb immobilized in a heavily padded full limb bandage or cast. Lameness usually improves, but the horse may be left with a mechanical lameness causing a jerky hindlimb action that may limit its use as a dressage horse, although horses may be able to jump or race. Horses with a persistently medially displaced tendon usually have a greater degree of mechanical lameness and a poorer prognosis for return to athletic function.

In horses in which the tendon is unstable and subluxates on and off the tuber calcanei, endoscopy of the calcaneal bursa reveals disruption of both the medial retinacular/calcaneal insertion of the superficial digital flexor tendon and its associated fibrocartilage, with disruption

of the medial wall of the bursa creating or establishing communication with an acquired subcutaneous bursa. Treatment is by radical resection of the disrupted fibrocartilage and division of remaining attachments of the fibrocartilage or retinacular insertions with the unstable main body of the superficial digital flexor tendon, thereby creating a stable lateral subluxation. Although repair or reconstruction techniques have been reported, results have been unreliable. Permanent stable subluxation eliminates anxiety and usually results in a "sound" functional horse.

GASTROCNEMIUS TENDINITIS

Tendinitis of the gastrocnemius tendon is a rare cause of hindlimb lameness in a horse. Injury usually occurs distally, although rarely at the musculotendinous junction. Lameness may be sudden or gradual in onset, and the severity of lameness varies depending on the severity of injury. Distention of the calcaneal (or intertendinous) and gastrocnemius bursa is common. Lameness is usually exacerbated by a proximal limb flexion test.

Lameness is usually improved by peripheral analgesia of the tibial nerve, and diagnosis is confirmed with ultrasonography.

Conservative treatment with stall rest and controlled exercise for 6–12 mo is usually indicated. Horses with mild to moderate lesions have a reasonable prognosis for return to athletic work, but the prognosis for horses with more severe lesions is guarded.

CALCANEAL BURSTITIS

The calcaneal (intertendinous bursa) lies between the tendons of the gastrocnemius and superficial digital flexor muscles proximal to the hock and extends on the plantar aspect of the calcaneus to the level of the distal tarsus. In most horses, there is a communication between the calcaneal and gastrocnemius bursa and, in approximately a third of horses, with the subcutaneous bursa.

Inflammation and distention of the bursa may or may not be associated with lameness. It may be idiopathic, secondary to trauma or intrathecal hemorrhage, or occur in association with gastrocnemius tendinitis. Septic bursitis may occur secondary to infectious osteitis of the calcaneus or after a penetrating injury.

Horses with septic bursitis need to be treated aggressively with surgical debride-

ment and lavage and appropriate antimicrobial therapy. Horses with aseptic bursitis may be treated with rest, drainage, and intrathecal medication with corticosteroids; results are variable.

CAPPED HOCK

Capped hock is due to distention of the subcutaneous bursa or development of an acquired bursa over the tuber calcanei. This usually results from repetitive trauma (eg, kicking or leaning on stable walls) and is not usually associated with lameness. Occasionally, a subcutaneous abscess may arise as the result of a penetrating injury and lead to painful swelling and lameness. Treatment of an abscess requires surgical excision and appropriate antimicrobial treatment.

DISORDERS OF THE STIFLE

OSTEOCHONDROSIS

Osteochondrosis (*see* p 1148) is a common cause of stifle lameness in young horses. Lesions in the stifle most commonly occur on the lateral trochlear ridge of the femur but may also occur on the medial trochlear ridge, in the intertrochlear groove, or on the patella. Lesions are often bilateral and probably develop in the first 6 mo of life. In severe cases, joint effusion and lameness may be evident in foals or yearlings. In less severe cases, clinical signs may not become evident until the horse starts athletic work. In mild cases, clinical signs may be absent. The severity of lameness varies from absent to severe and is often acute in onset. Effusion of the femoropatellar joint is common. Diagnosis may be confirmed by demonstration of radiographic or ultrasonographic changes or by arthroscopy.

Mild lesions in foals have been shown to heal with conservative treatment. More severe lesions in foals may require arthroscopic debridement, but care should be taken not to remove too much of the subchondral bone. In horses with larger defects or fragmentation, arthroscopic surgery is the treatment of choice to remove osteochondral fragments and poorly attached or loose cartilage and to debride abnormal subchondral bone.

In adult horses, the prognosis after surgery for return to athletic soundness is fair to good but depends on the severity of the lesions and the size of the defect in the subchondral bone.

SUBCHONDRAL CYSTIC LESIONS

Subchondral cystic lesions most commonly occur in the stifle in the medial femoral condyle. Osseous cyst-like lesions may also occur in the proximal tibia. The pathogenesis of these cysts is poorly understood, but they may develop after trauma to the articular surface or as a result of osteochondrosis. Lesions often present in young horses but can be seen at any age. The severity of lameness varies from mild to severe and may be acute in onset. Lameness may be intermittent, particularly in older horses. In some horses there is mild effusion of the medial femorotibial joint, but in many horses no localizing signs are evident. Intra-articular anesthesia of the femorotibial joints may produce partial improvement.

Diagnosis is usually confirmed by radiography. Medial femoral subchondral cystic lesions are most evident on caudocranial projections and may appear as a variably sized round or oval radiolucent defect in the subchondral bone. Some lesions are surrounded by an obvious sclerotic rim. In some horses, only a very small defect is evident radiographically in the medial femoral condyle; this may be a precursor to subchondral cystic lesions. Defects in the surface of the medial femoral condyle may be evident ultrasonographically in some horses. Subchondral cystic lesions in the proximal tibia are usually smaller and most evident on lateral, lateral oblique, or caudocranial radiographic projections.

Nonarticular osseous cyst-like lesions or small lesions may respond to conservative treatment, including rest, systemic NSAIDs, and intra-articular corticosteroids. If horses do not respond to conservative treatment, surgery is indicated. Some surgeons advise injection of corticosteroids into the lining of the cyst under arthroscopic or ultrasonographic guidance to decrease the shedding of inflammatory enzymes and mediators into the joint; others advise arthroscopic debridement of the cyst to remove the contents and lining.

The prognosis for return to athletic function in horses with subchondral cyst-like lesions of the medial femoral condyle after injection of the lining of the cyst under arthroscopic guidance has been reported to be fair, with 64% returning to athletic use in one study irrespective of the age of the horse. The prognosis for return to athletic function after debridement of the cyst seems to vary with the horse's age. The prognosis for athletic soundness in horses

<3 yr old was better (~64%) than in horses >3 yr old (35%) at the time of surgery in one large, multicenter retrospective study.

MENISCUS AND MENISCAL LIGAMENT INJURIES

Injuries to the menisci and the meniscal ligaments are a common cause of stifle lameness in adult horses. Lesions range from mild fibrillation of the meniscal ligaments and surface of the menisci, causing low-grade, chronic lameness, to severe tears of the meniscal ligament and menisci, causing acute and severe lameness. The medial meniscus is more commonly affected.

Effusion of the femorotibial joints is a common, associated clinical sign. In most horses, lameness is significantly improved by intra-articular anesthesia of the femorotibial joints. Subtle radiographic changes may be evident with enthesiophytes or lytic areas at the site of attachment of the meniscal ligament or dystrophic mineralization within the meniscus. Osteoarthritic changes may be evident in horses with chronic or severe injuries. Ultrasonographic examination may be useful to demonstrate meniscal injury.

Arthroscopic examination is indicated in horses that do not respond to conservative treatment (ie, rest and anti-inflammatory medication followed by controlled rehabilitation). Arthroscopy allows assessment of the extent and severity of injury, although only the cranial and caudal poles of the menisci are visible arthroscopically. Arthroscopy also allows torn or fibrillated fibers of the meniscal ligaments to be debrided and flaps of meniscus or fibrillated meniscal tissue to be removed.

The prognosis for return to athletic function depends on the severity of injury. Overall, ~50% of horses with meniscal and meniscal ligament injury return to athletic use. However, in horses with severe tears that extend beneath the femoral condyle and horses with concurrent osteoarthritis, the prognosis is considerably poorer.

CRANIAL AND CAUDAL CRUCIATE LIGAMENT INJURIES

Complete rupture of a cruciate ligament is usually a catastrophic injury resulting in severe lameness and joint instability. Strains and partial rupture of the cranial and caudal cruciate ligaments may result in variable lameness, depending on the severity of injury. Effusions of the femoropatellar or

femorotibial joints are sometimes present. Lameness is usually improved by intra-articular anesthesia of the femorotibial joints. In some horses, radiographic changes may be evident at the sites of attachment of the ligament with enthesiophyte formation or focal areas of radiolucency. Ultrasonography of the cruciate ligaments is difficult but may demonstrate some lesions. However, in many horses, diagnosis is confirmed only by arthroscopic examination.

Conservative treatment involving rest, systemic NSAIDs, and intra-articular corticosteroids is indicated in horses with acute injuries. If horses do not respond to conservative treatment, arthroscopic surgery is recommended to debride loose and torn ligament fibers.

The prognosis for return to athletic function depends on the severity of injury. Horses with complete rupture have a grave prognosis. Horses with moderate to severe injuries have a poor prognosis for return to athletic function, whereas horses with mild injuries have a fair prognosis.

COLLATERAL LIGAMENT INJURIES

Rupture or sprain of the medial or lateral collateral ligaments of the stifle is usually the result of an acute traumatic episode in which the distal limb is forced medially or laterally, thereby stressing the ligaments. Rupture or sprain is more common in the medial collateral ligament than in the lateral collateral ligament. Concurrent injury of the menisci or cruciate ligaments is common, particularly in severe injuries. Lameness depends on the severity of the injury but is usually quite severe initially. Localized edema and joint effusion is seen, particularly in the acute stages. Flexion tests of the stifle usually exacerbate lameness. Clinical signs usually improve within a few days unless there is significant joint instability. Intra-articular anesthesia of the ipsilateral femorotibial joint will not always alleviate lameness. If the ligament rupture is complete, stressed caudocranial radiographs of the stifle may demonstrate joint widening on the affected side. Enthesiophyte formation at the origin or insertion of the ligament may be evident radiographically in chronic cases. Diagnosis is usually confirmed by ultrasonographic examination.

Horses with mild sprains may be treated conservatively with stable rest and anti-inflammatory medication for 6–8 wk,

followed by a controlled, ascending exercise rehabilitation program for a further 6–8 wk. Horses with mild sprains and no joint instability have a fair prognosis for return to athletic use. The prognosis for horses with severe injury is poor.

INTERMITTENT UPWARD FIXATION OF THE PATELLA AND DELAYED PATELLA RELEASE

Intermittent upward fixation of the patella occurs when the medial patellar ligament remains hooked over the medial trochlear ridge of the femur and locks the reciprocal apparatus with the limb in extension. A horse with upward fixation of the patella stands with the hindlimb fixed in extension with the fetlock flexed. The leg will usually release with a sudden snap or jerking movement.

Some horses demonstrate a milder form of this condition. In these horses, there is delayed release of the patella during limb protraction, most commonly evident as the horse moves off or in downward transitions. This appears as a jerky movement of the patella. Horses with recurrent upward fixation or delayed release of the patella may develop chronic, low-grade lameness due to stifle soreness and may be reluctant to work on soft, deep surfaces or up or down hills.

Upward fixation or delayed release of the patella is most commonly seen in young horses and ponies, particularly if they are in poor body condition and poorly muscled. Straight hindlimb conformation may predispose to this condition. It may also be seen in older horses that have had trauma to the stifle region, particularly if the horses are stabled or have been inactive.

Diagnosis is based on recognition of typical clinical signs. In some horses, upward fixation of the patella may be induced by pushing the horse backward or manually pushing the patella proximally. Radiographs of the stifle should be taken in horses with femoropatellar joint effusion and lameness to establish concurrent or secondary pathology.

To release an upward fixated patella, the horse should be pushed backward while simultaneously pushing the patella medially and distally. Alternatively, pulling the limb forward with a rope around the pastern may unlock the patella. If upward fixation of the patella is intermittent and not causing lameness, a conditioning program should be instituted. This involves daily lunging or riding of the horse, appropriate to its age and type, as well as ensuring an adequate plane of nutrition, good dentistry, and

anthelmintic administration. Stable rest is contraindicated, and the horse should be turned out to pasture as much as possible. Remedial foot trimming to ensure the foot is well balanced and shoeing with a beveled shoe with or without a lateral heel wedge may be beneficial. A significant proportion of horses will improve with maturity and conservative treatment, although signs may recur if the horse undergoes prolonged stall rest.

Medial patellar ligament desmotomy is indicated in horses that do not respond to conservative treatment or in horses with lameness caused by upward fixation of the patella. Medial patellar ligament desmotomy is most often performed in the sedated horse under local anesthesia, although some surgeons prefer general anesthesia. After surgery, the horse should be restricted to stable or small stall rest for 2 mo to reduce the risk of complications. Fragmentation of the apex of the patella is the most common complication after surgery (*see below*); if it results in lameness, it may be treated arthroscopically with good results. Other complications include lameness, local swelling, or even patella fracture. The prognosis after medial patellar ligament desmotomy is generally considered to be good, with recurrence of the condition rare. Medial patella ligament splitting, which involves making numerous small incisions in the ligament, has also been used successfully to manage these horses.

FRAGMENTATION OF THE PATELLA

Fragmentation of the apex of the patella usually occurs secondary to medial patellar desmotomy for management of upward fixation of the patella. Lesions are believed to develop due to patellar instability as a result of the surgery. The severity of lameness varies from mild stiffness to moderate lameness. A proximal limb flexion test usually exacerbates lameness, and femoropatellar joint effusion is usually present. Lameness is localized by diagnostic anesthesia of the femoropatellar joint, and diagnosis is confirmed by radiography. Arthroscopic debridement of the apex of the patella with removal of the osteochondral fragments is the treatment of choice. Prognosis is reasonable but depends on the severity of the condition.

PATELLAR LUXATION

Lateral luxation of the patella is a rare, inherited condition in foals caused by a

recessive gene. Luxation of the patella in adult horses is unusual and likely to be traumatic in origin. Lateral luxation is more common than medial luxation and may be more likely in horses or foals with hypoplasia of the lateral trochlear ridge of the femur. The condition may be unilateral or bilateral and varies in severity from intermittent luxation that readily reduces to persistent luxation that cannot be reduced.

Severely affected foals are unable to extend the stifle and so adopt a characteristic crouching position. If the condition is less severe, foals or horses may be reluctant to flex the stifle and thus demonstrate a stiff hindlimb gait. Diagnosis can be confirmed by radiography.

Although a number of surgical treatments have been reported, the prognosis in adult horses and in horses with concurrent osteoarthritis is poor. The prognosis for athletic function in foals may be slightly better.

PATELLAR LIGAMENT INJURIES

Patellar ligament injuries are rare but may be seen in jumping horses. The middle patellar ligament is the most commonly affected. Lameness is variable but may be severe in acute cases. Clinical signs are often subtle; femoropatellar joint effusion, periligamentous thickening, and edema are inconsistent findings. In many horses, lameness is unchanged by intra-articular anesthesia of the femoropatellar joint; therefore, diagnosis is confirmed by ultrasonography. Treatment is prolonged rest (up to 6 mo). Lameness is often slow to resolve and may recur.

GONITIS AND OSTEOARTHRITIS

Mild to moderate inflammation of the femorotibial and femoropatellar joints of unknown origin is common. Severity of lameness varies. Synovitis and capsulitis may result from athletic sprain of the joints. Mild trauma to the articular cartilage, menisci, or any of the ligaments of the stifle may produce mild to moderate synovitis. Mild synovitis usually responds to rest and intra-articular and systemic anti-inflammatory drugs. If joint inflammation and lameness persist, further diagnostic investigation and arthroscopic examination are advisable to assess concurrent or causative injuries and to prevent ongoing degenerative joint disease and development of osteoarthritis.

Osteoarthritis of the femorotibial or femoropatellar joints may follow any of the

causes of stifle lameness described and usually results in persistent lameness of varying severity. Diagnosis is confirmed with intra-articular anesthesia and radiography. Radiographic changes include periarticular remodeling with osteophyte formation and remodeling of the joint margins (particularly the medial tibial plateau), changes in the subchondral bone, narrowing of the joint space, and dystrophic mineralization of the soft tissues. The prognosis for athletic soundness in horses with osteoarthritis of the stifle is poor, and treatment is usually palliative. Newer techniques for arthroscopy and regenerative therapy may offer some hope for severely affected joints.

CHONDROMALACIA OF THE FEMORAL CONDYLES

Chondromalacia of the femoral condyles is being increasingly recognized in sports horses. Horses typically present with poor performance or low grade, often bilateral, hindlimb lameness with pain referable to the stifle. Lameness or loss of performance usually becomes evident in younger horses as their work intensity increases. Frequently, there are no localizing signs, although mild effusion of the medial femorotibial and/or femoropatellar joints may be evident. Typically there are no radiologic or ultrasonographic signs evident. Arthroscopic examination of the femorotibial joints reveals abnormally soft, irregular, cracked, pitted, and poorly attached articular cartilage over all or part of the femoral condyles. Generally, the prognosis for sustained return to athletic soundness is guarded. More studies are required to determine the best form of surgical intervention in management of these horses.

FRACTURES

Fractures of the Patella

Fractures of the patella usually result from direct trauma, most commonly when a horse is kicked by another horse or hits a fixed obstacle while jumping. Prognosis depends on fracture conformation. Sagittal fractures of the medial pole of the patella are most common. These fractures are usually intra-articular and involve the attachment of the parapatellar fibrocartilage of the medial patellar ligament. Complete horizontal fractures are rare but considered serious injuries because of fragment distraction due to the massive pull of the extensor muscles. Complete sagittal

fractures may be more amenable to internal fixation, because there is less distractive force.

Fracture of the patella usually results in marked lameness initially, with swelling and edema over the patella and effusion of the femoropatellar joint. In less severe or nonarticular fractures, lameness may improve within a few days. Diagnosis is confirmed by radiography. Standard radiographic projections of the stifle, together with a cranioproximal-craniodistal oblique projection of the patella, are used to determine fracture configuration.

Management options depend on fracture configuration. Horses with small, nondisplaced, nonarticular fractures may be treated conservatively with stable rest for 6–8 wk and have a good prognosis for return to athletic function. Articular fractures of the medial pole of the patella can be removed arthroscopically or via an arthrotomy and are also considered to have a good prognosis. Larger, mid-body sagittal or horizontal fractures require repair by internal fixation. These injuries carry a risk of catastrophic breakdown during anesthetic recovery but can have a favorable outcome.

Fractures of the Tibial Tuberosity

Fractures of the tibial tuberosity are not uncommon. There is little soft tissue covering this area, and fractures usually result from direct trauma. Fracture configuration may range from small fragments off the cranial proximal part of the tuberosity to large fractures of the whole of the tuberosity extending into the femorotibial joints. Fracture of the tibial tuberosity usually results in marked lameness initially with localized swelling and edema. Lameness will often improve within a few days. Diagnosis is confirmed by radiography.

Small and nondisplaced fractures may heal with conservative treatment. Stable rest for 6–8 wk is advised. During the first 2–3 wk, the horse should be prevented from lying down by tying or the use of slings to prevent fragment displacement. Larger intra-articular fractures should be repaired by internal fixation. Fractures generally have a good prognosis for return to athletic function if appropriately managed.

Fractures of the Femoral Condyles and Femoral Trochlear Ridges

Fracture of the femoral condyles is usually the result of direct trauma. Large, intra-articular, displaced fractures in adult horses

are catastrophic and have a grave prognosis. However, traumatic fragmentation of the femoral condyles or trochlear ridges can also occur. Such injuries usually result in acute onset, moderate to severe lameness with joint effusion. Diagnosis is confirmed by radiography. Treatment involves surgical removal of the fracture fragments to prevent development of osteoarthritis. This is usually achieved arthroscopically but may require arthrotomy. The prognosis is usually considered to be good after surgery, so long as there is no significant concurrent soft-tissue damage.

DISORDERS OF THE HIP

Disorders of the coxofemoral joint are relatively rare causes of lameness in horses. Most cases are traumatic in origin, secondary to falls or being cast (within a stall) in recumbency, although septic arthropathies and developmental disorders of the joint have been occasionally reported. Regardless of the etiology of the primary disease, secondary osteoarthritis of the coxofemoral joint is a common sequela, which will frequently result in permanent lameness.

Lameness is the predominant presenting clinical sign of any coxofemoral disease. Although the lameness can be subtle, more frequently a moderate to severe lameness (non-weight-bearing) is seen at presentation. In severe cases, the horse will often stand with the limb partially flexed. With any degree of chronicity, atrophy of the muscles of the hindquarters, such as the gluteals and quadriceps, is often moderate to marked. In cases of coxofemoral subluxation, the leg will be held in a semi-flexed position with an obvious outward rotation of the stifle and toe and an inward rotation of the point of the hock. In complete coxofemoral luxations, the same rotational abnormality in limb position is observed, and additionally the leg will appear shorter, which is best identified by the point of the hock being displaced proximal to that of the contralateral limb. Most horses with coxofemoral pathology show some pain on proximal limb flexion or abduction. Rectal examination is generally unrewarding, although in some cases of acute fracture, a hematoma or alteration in the bony architecture is palpable per rectum. Intra-articular local anesthesia of the coxofemoral joint is frequently used to identify the joint as the cause of lameness, particularly in cases of chronic lameness. Although this technique can be technically challenging, ultrasonography can help guide needle placement.

Definitive diagnosis of coxofemoral pathology usually requires some form of diagnostic imaging. Bone scanning (nuclear scintigraphy) is commonly used to identify the coxofemoral joint as the site of pathology. This technique is highly sensitive for identification of the involvement of the joint but has a low specificity for identification of the pathology within the joint. Percutaneous ultrasonography can provide considerable information on the coxofemoral joint, although its use at this site is technically challenging. Radiography can be very rewarding, especially in smaller horses and ponies, although optimal views require general anesthesia. Because of the risk of using general anesthesia in horses with serious limb injuries, such imaging is only rarely performed. A number of techniques are available to radiograph the coxofemoral joint in the standing horse, using either a ventrodorsal or lateral oblique views. Arthroscopy of the coxofemoral joint is possible, although it is technically challenging in most adult horses and ponies; acceptable joint visualization can be obtained by most operators in foals.

LUXATION OF THE COXOFEMORAL JOINT

Luxation of the coxofemoral joint is relatively rare in horses because of the strong ligamentous support provided to the joint by the round ligament and the accessory femoral ligament, as well as the fibrocartilaginous lip that surrounds the acetabulum. In horses, this injury is usually secondary to trauma. Luxations are much more common in small ponies, such as Shetland ponies, in which luxation of the coxofemoral joint has been frequently described secondary to upward fixation of the patella. Fracture of the dorsal acetabular rim may accompany the dislocation. Luxations are usually accompanied by a characteristic alteration in limb appearance. Luxations of the coxofemoral joint are best managed by closed reduction under general anesthesia, although this is likely to be successful only if the reduction is performed soon after the injury. It can be difficult to maintain the reduction in place through recovery from general anesthesia, and although the use of surgical techniques or Ehmer slings has been advocated, no single technique has been shown to be successful. The prognosis for return to athletic function after coxofemoral luxation is very guarded. In small ponies, closed

reduction has allowed animals to become comfortable pasture animals.

PELVIC FRACTURE

Pelvic fractures are relatively common in horses and ponies and can occur as a consequence of trauma or stress from athletic training. Fractures involving the acetabulum almost always occur as a consequence of trauma and usually present as a severe lameness, which is frequently non-weight-bearing at the time of injury. Crepitus may be difficult to appreciate, even during passive flexion of the limb or rectal examination. Radiography can be diagnostic, but the difficulties of obtaining such images means that diagnosis is usually achieved by a combination of nuclear scintigraphy and ultrasonography. In particular, ultrasound diagnosis of pelvic fractures has advanced considerably and is now considered the first-line method to assess pelvic fractures. Fractures of the acetabulum, in contrast to other types of pelvic fractures, carry a poor prognosis for return to athletic function, because such fractures are frequently displaced and invariably lead to osteoarthritis. The only treatment is usually prolonged (6–9 mo) rest followed by symptomatic therapy for any resultant osteoarthritis.

OSTEOARTHRITIS AND OTHER COXOFEMORAL JOINT DISEASES

Osteoarthritis (OA) of the coxofemoral joint is usually secondary to major trauma such as luxation or fracture of the joint. Occasionally, idiopathic OA is diagnosed as a cause of chronic lameness. Cases of osteochondrosis or bone cyst formation within the coxofemoral joint have been reported, which can lead to secondary OA. Septic arthritis of the coxofemoral joint is seen occasionally in foals as a consequence of hematogenous spread or idiopathically in adult animals.

In cases of established OA, treatment is usually symptomatic, using NSAIDs, intra-articular corticosteroids, or other symptomatic treatments. In cases of septic arthritis, treatment should consist of surgical debridement and lavage in conjunction with local and systemic antimicrobial therapy. In cases of OA, full recovery is unusual. Successful treatment of septic arthritis is possible in foals but unlikely in adult horses unless diagnosed quickly and treated aggressively.

DISORDERS OF THE BACK AND PELVIS

Back problems are a major cause of poor performance and gait abnormalities in sport and race horses. Although it is often possible with the history and clinical (physical and dynamic) examination to suspect functional abnormalities of the vertebral column, definitive diagnosis of the cause of the pain is a challenge. There is undoubtedly a complex relationship between subtle (usually bilateral) hindlimb lameness, back pain, and poor performance. It can be challenging practically to differentiate and definitively determine the relative importance of differing orthopedic pathologies in such cases.

Once back pain is suspected or established in a horse, identification of the cause requires imaging procedures. This discipline has seen major advances, particularly relating to integrating radiographic, ultrasonographic, and nuclear scintigraphic findings. In addition, there is greater understanding of the relationships between identification of specific imaging findings and the possibly of such findings leading to pain.

SPINAL PROCESSES AND ASSOCIATED LIGAMENTS

Kissing Spines

The most common location of kissing spines is the vertebral segment between T10 and T18, although these lesions are also identified between L1 and L6. Abnormal findings can be seen in the dorsal part of the spinous processes where their identification is easy; they include kissing and overriding lesions. Different grades can be identified (grade 1: narrowing of the interspinous space; grade 2: densification of the margins; grade 3: bone lysis adjacent to the margins; grade 4: severe remodeling). Abnormal findings can also be seen in the ventral part of the spinous processes and may involve the interspinous ligaments or be associated with osteoarthritis of the articular processes. Their severity can be established using the same grading system; their clinical incidence seems higher.

The incidence of kissing spines seems to vary according to the discipline/use of the horse and biomechanical effects of specific gaits and exercises on the back. In general, these lesions are commonly found in racing Thoroughbreds and seem to be tolerated in many of them. They are quite rare in

Standardbreds, but when present, their likelihood of causing pain seems higher. Intermediate frequency and signs are seen in sport horses. Kissing spines can be found in performance race and sport horses without back pain and even with normal thoracolumbar active and passive mobilization. Thus, in each case, the clinical significance of these lesions must be carefully assessed. Diagnosis can be aided by injection of local anesthetic into the affected interspinous spaces. Medical management includes local injections of steroids and/or shockwave therapy, as well as rehabilitation using tolerated exercises after progressive warm-up at a slow canter. Surgical treatment has been advocated for this condition, with surgical resection of the affected spinous processes being most commonly performed and being described as efficacious in managing this condition. A number of differing techniques have been described for this surgical management.

Fractures

Multiple fractures of the spinous processes of T4–T10 are sometimes seen in horses that have reared and fallen over backward. The summits and centers of ossification are fractured and displaced laterally. After the initial pain and local reaction have subsided, recovery is often satisfactory, with usually no permanent effect on performance, although a persistent deformation of the withers may require some adaptation of the saddle.

Desmopathies

(Supraspinal ligament injuries)

Acute or subacute desmopathies can be identified ultrasonographically, because they demonstrate dorsoventral or transverse thickening of the ligament, altered echogenicity, and obvious alteration of the linear longitudinal pattern. They can be seen both in the median plane or asymmetrically. In old or chronic injuries, the ligament often remains thicker, with a reduced echogenicity and an irregular architectural pattern. Hyperechogenic images with or without acoustic shadows are compatible with mineralization or calcification of the supraspinous ligament. Alteration of the bone surface of the top of the spinous processes indicates insertional desmopathy (enthesopathy) of the supraspinous ligament. The significance of findings can be difficult to definitively prove, because ultrasonographic abnormalities can be seen in healthy as well as injured horses.

ARTICULAR PROCESS–SYNOVIAL INTERVERTEBRAL ARTICULATION COMPLEXES

The articular process-synovial intervertebral articulation complex is located dorsally to the vertebral canal. It is composed of the caudal articular process of one vertebra, the synovial joint (with articular cartilage, synovial fluid and membrane, and articular capsule) located at the base of the interspinous space, and the cranial articular process of the following vertebra. It is also known as the dorsal articular facet joint. Osteoarthritis of this joint has been described radiographically, with a number of different types described, with sclerosis, periarticular new bone, and narrowing of joint space frequently being identified. Commonly two to five joints are affected, usually in the caudal thoracic and cranial lumbar region. In some cases, there will be abnormal nuclear scintigraphic uptake of the region, which can aid with diagnosis. Further ultrasonographic abnormalities can be identified, particularly relating to periarticular osteophytes and proliferation. Treatment and management include periarticular ultrasonographic-guided injections of steroids, use of NSAIDs, and rehabilitation using exercise protocols after progressive warm-up at a slow canter.

VERTEBRAL BODIES AND DISCS

The most common lesion of vertebral bodies and discs is ventral, ventrolateral, or lateral bony proliferation (often called vertebral spondylosis); it is mainly found in the mid-thoracic area (mostly between T11 and T13) but can also be seen in the lumbar area. They can be found on asymptomatic horses but can also be responsible for acute pain or chronic back stiffness. Spondylosis is a rare cause of back pain; in one survey, only 3.4% of 670 horses with back pain demonstrated this abnormality. Congenital abnormalities with vertebral body deformation (triangular or trapezoidal shape) are rare and usually found in the thoracic vertebrae. Vertebral body osteomyelitis, leading to neurologic signs, can be seen in the thoracolumbar spine in foals. Vertebral body fractures occur in horses that have had severe trauma or falls, particularly in racehorses in jumping races. Complete or partial paraplegia results from damage to the spinal cord. The prognosis is usually grave.

MUSCLE STRAIN AND SORENESS

See also MYOPATHIES IN HORSES, p 1176.

Damage to the muscles is probably the most common cause of back soreness in

horses. This most commonly involves the longissimus dorsi muscle, which acts to extend and laterally flex the vertebral column. All or part of the longissimus muscles usually are strained during ridden exercise, and clinical signs are associated with altered performance and acute or chronic back pain. The principal sites of damage are the caudal withers and cranial lumbar regions (just in front of and behind the saddle area). Most of these injuries respond to rest and physiotherapy, although several weeks may be needed for full recovery. Abnormalities of the thoracolumbar musculature are also frequently seen in exertional rhabdomyolysis (tying-up syndrome, *see* p 1178).

LUMBOSACRAL JUNCTION ABNORMALITIES

Abnormal findings of the lumbosacral junction causing back pain are often detected with ultrasonography and include 1) congenital abnormalities such as lumbosacral ankylosis (sacralization of L6) or intervertebral ankylosis between L5 and L6; 2) disc degenerative lesions, especially affecting the lumbosacral disc (lesions include fissuration or cavitation of the disc, dystrophic mineralization, and ventral herniation); 3) intervertebral malalignment (spondylolisthesis) of the lumbosacral joint or the joint between L5 and L6; and 4) intertransverse lumbosacral osteoarthritis (periarticular osteophytes or remodeling at the joint margins).

SACROILIAC JOINT ABNORMALITIES

Acute and severe strain of the sacroiliac ligaments is associated with a history of injury and severe pain in the pelvic or sacroiliac region, often with marked hindlimb lameness. Subacute or chronic sacroiliac strain and osteoarthritis of the sacroiliac joint cause typical back soreness. There is often a history of poor performance, with an intermittent, often shifting, hindlimb lameness. This may be associated with some restriction in hindlimb action and dragging of the toes of the hindlimb(s).

A diagnosis of sacroiliac pain and lesions can be made in clinical practice with a combination of physical examination and exclusion of other causes of lameness. A demonstration of improvement in gait after local anesthetic infiltration of the sacroiliac joint region is occasionally performed to confirm diagnosis. Ultrasonographic assessment of the ventral aspect of the

sacroiliac can be performed using a rectal probe. Abnormal ultrasonographic findings seen at the ventral aspect of the sacroiliac joint in clinical cases include bone modeling of the sacrum and/or ileum, narrowing of the joint space, remodeling or periarticular osteophytes of the caudal border of the articular surface of the sacrum and caudal articular margin of the ileum, periarticular bone fragmentation, and ventral sacroiliac ligament desmopathy and enthesopathy.

Treatment and management of sacroiliac disease is usually supportive and nonspecific. Therapies include periarticular injections of steroids and rehabilitation using progressive warm-up at a slow canter and exercises that develop the gluteal muscles.

DEVELOPMENTAL ORTHOPEDIC DISEASE

Developmental orthopedic diseases of horses constitute an important group of conditions that includes osteochondrosis, physeal dysplasia, acquired angular limb deformities, flexural deformities, and cuboidal bone malformations.

OSTEOCHONDROSIS

(Osteochondritis dissecans, Dyschondroplasia)

Osteochondrosis is one of the most important and prevalent developmental orthopedic diseases of horses. Although its specific etiology is not known, it is considered to arise from a focal disturbance in endochondral ossification, with subsequent trauma or physiologic loading resulting in lesion formation. The term osteochondrosis is currently used to describe the clinical manifestation of the disorder; however, the term dyschondroplasia is preferred when referring to early lesions.

Osteochondrosis has a multifactorial etiology that includes rapid growth, high carbohydrate diet, mineral imbalance, and biomechanics (ie, trauma to cartilage). Genetics has been implicated, with some breeds predisposed (eg, Standardbred and Swedish Warmblood). The condition mainly affects articular growth cartilage, but the metaphysis may also be involved. If the physeal metaphyseal cartilage is affected, bone contours and longitudinal growth are disturbed (see p 1149). Dyschondroplasia at articular surfaces may progress to formation of cartilage flaps or osteochondral fragments (osteochondrosis). At some sites, subchondral cysts may develop (see p 1062). Axial

skeletal involvement includes vertebral articular facets, which may be associated with stenosis of the vertebral canal and, therefore, ataxia and proprioceptive deficits (ie, wobblers syndrome), but the relationship between these conditions is not clear.

Clinical Findings: The clinical signs of equine osteochondrosis are difficult to characterize specifically because of the wide range of lesions and sites involved. In young horses, many cases have no detectable clinical signs and are identified only on presale radiographs. Furthermore, lesions of dyschondroplasia may not progress to osteochondrosis, and radiographically observed osteochondrosis lesions may resolve over time without producing clinical signs. In severe cases, other signs of developmental orthopedic disease also may be apparent.

The most common presenting sign of osteochondrosis is a nonpainful distention of an affected joint (eg, gonitis, bog spavin). The exceptions to this are joints in which swelling is difficult to detect (eg, shoulder joint, medial femorotibial joint), in which case lameness is more often the first sign observed. Clinical signs may be divided broadly into two categories: those seen in foals <6 mo old and those seen in older animals. Often the first sign noted in foals is a tendency to spend more time lying down. This is accompanied frequently by joint swelling, stiffness, and difficulty keeping up with other animals in the paddock. An accompanying sign may be the development of upright conformation of the limbs. Fetlock osteochondrosis is particularly seen in younger foals (<6 mo old).

Lameness is usually absent or mild except for those sites mentioned above for which the earlier sign of joint swelling is difficult to detect. For example, lesions in the shoulder frequently result in moderate to severe lameness, muscle atrophy, and pain on joint flexion. In the stifle, some horses with subchondral bone cysts in the medial femoral condyle present with lameness severe enough that a fracture may be suspected, and swelling may only be detected on careful examination. More severe signs are also observed when osteochondral fragments come loose within the joint. This is often seen in yearlings or older horses that present with stiffness, flexion responses, and varying degrees of lameness. These signs are usually associated with the onset of training.

Diagnosis: Clinical diagnosis can often be made on the basis of signalment and signs.

More definitive diagnosis requires use of some specific clinical aids. Radiographic examination has been the traditional way to confirm diagnosis; however, early lesions involving cartilage without significant subchondral bone damage may not be visualized. In the distal limb, oblique views may be helpful; in the hock, because the most common site of a lesion is the distal intermediate ridge of the tibia, the best view is a plantarolateral/dorsomedial oblique.

Ultrasonographic examination of the swollen joints can help delineate articular damage and synovial inflammation and determine whether osteochondral fragments are intra- or extra-articular. The most accurate way to confirm diagnosis is by arthroscopy, and most of the predilection sites are accessible.

Scintigraphy has limitations in growing horses because of normal high activity in physes and sites of active endochondral ossification. It is a useful technique to detect subchondral cysts and secondary degenerative changes in older horses. MRI is ideal for diagnosis of both early and late lesions but is usually not necessary. Also, sites that are most diagnostically challenging are generally in the proximal limb, where access is difficult. Clinical pathology and the evaluation of synovial fluid is rarely helpful but can be used to eliminate inflammatory causes of swollen joints.

Treatment and Management: Management of osteochondrosis depends on the site and severity of signs. Mild cases recover spontaneously, and a conservative approach may be appropriate. In young animals (<12 mo old), this involves restricted exercise for some weeks combined with reduced feed intake to slow the growth rate. Particular care should be taken to ensure appropriate mineral supplementation (eg, in cases of suspected copper deficiency). It is controversial whether correcting the diet, once signs have developed, will actually assist resolution, but it may help limit or prevent further cases on stud farms. Intra-articular medication with hyaluronic acid may be beneficial, but injection of long-acting corticosteroids is not recommended in young, growing horses.

Cases considered for surgery are treated arthroscopically. This technique has been successful in most affected sites, particularly the hock, stifle, and fetlock. Damaged cartilage, osteochondral fragments, and compromised subchondral bone are removed and the joint flushed extensively with sterile fluid. Prognosis after removal of discrete osteochondral fragments is good.

In cases with more extensive osteochondral damage, prognosis depends on the extent of the joint surface that must be removed. Prognosis is poor for cases with instability resulting from joint surface loss or in which secondary osteoarthritis (degenerative joint disease) is advanced. This is often the case with shoulder osteochondrosis because of the difficulty in detecting early signs. Cases involving subchondral cysts have a guarded prognosis, because these cysts are often in important weightbearing areas of the joint, and restoration of the joint surface is rarely possible.

PHYSITIS

(Epiphysitis, Physeal dysplasia, Dysplasia of the growth plate)

Physitis involves swelling around the growth plates of certain long bones in young horses. Suggested causes include malnutrition, conformational defects, excessive exercise, obesity, and toxicosis. The condition is seen frequently in well-grown, fast-growing, heavy-topped foals during the summer when the ground is dry and hard, and on stud farms where the calcium:phosphorus ratio in the diet is imbalanced. This suggests that it is a result of overload of the physal area due to excessive loading or weakened bone and/or cartilage, or a combination of these factors.

Physitis in the distal tibia of a horse. Courtesy of Dr. Chris Whitton.

Phytitis most commonly involves the distal extremities of the radius, tibia, third metacarpal or metatarsal bone, and the proximal aspect of the first phalanx. It is characterized by flaring at the level of the growth plate, giving a typical "boxy" appearance to the affected joints. Radiographs aid clinical assessment.

Treatment consists of reducing food intake to reduce body weight or at least growth rate; confining exercise to a yard or a large, well-ventilated loose box with a soft surface (eg, peat moss, deep straw, shavings, or sand); ensuring that the feet are carefully and frequently trimmed; and correcting the diet if necessary. The calcium:phosphorus ratio should be adjusted to 1.6:1, and protein content limited to <10% of dry matter. In general terms, bran should not be fed, and dicalcium phosphate or bone flour (10–30 g daily) should be added to the diet. Vitamin D supplements (PO or parenteral) are indicated, but the dosage must be monitored closely to avoid hypervitaminosis D.

As a preventive measure, older foals or yearlings that are fat or heavy-topped should be watched carefully for clinical signs, especially when the ground is hard and dry. When these conditions prevail, feed rations and exercise should be restricted.

FLEXURAL DEFORMITIES

(Contracted tendons, Club foot, Knuckling)

Flexor tendon disorders are associated with postural and foot changes, lameness, and debility. They may be congenital and therefore identified in newborn foals or acquired at an older age. Uterine malposition, teratogenic insults (arthrogryposis), and genetic defects have been either implicated or proved to cause contracted limbs in newborn foals. Chronic pain is the most common cause of acquired tendon contracture. Pain can arise from phytitis, osteochondrosis, degenerative joint disease, pedal bone fracture, or soft-tissue wounds and infection. Pain induces reflex muscle contraction with shortening of the flexor musculotendinous units. The horse walks on its toes or knuckles in the fetlocks or occasionally the pastern joint. Nutritional errors referable to problems associated with bone growth (ie, osteochondrosis and phytitis) are intimately associated with the syndrome and must be addressed as part of treatment. (See *also* CONTRACTED FLEXOR TENDONS, p 1042, and ANGULAR LIMB DEFORMITIES, p 1046.)

Acquired flexural deformity of the distal interphalangeal joint in a foal. Courtesy of Dr. Chris Whitton.

Clinical Findings: Signs vary widely in newborn foals. Some cannot stand, some attempt to walk on the dorsum of their fetlocks, and others can stand but knuckle in the fetlocks or carpi. One foal may improve spontaneously, yet another, seemingly healthy at birth, may become progressively worse. In older foals, onset tends to be rapid; such animals may walk around on their toes with their heels off the ground. A slower onset is characterized by an upright hoof with an elongated heel and concave toe. Phytitis frequently is evident in these horses. Involvement of both forelimbs is common, with a tendency to be worse in one leg. Toe abscesses are a frequent complication of the hoof and locomotion changes, and they add to the pain and deformity.

Older horses (1–2 yr old) commonly knuckle in the metacarpophalangeal joints. Yearlings usually are more severely affected and more difficult to treat than younger animals. It is important to attempt to identify any underlying bone or joint disease, but this is often difficult and may have resolved.

Treatment: Mild cases in newborn foals often require no treatment. More severe cases require supportive therapy, and it is essential to correct failure of passive transfer of immunity if the foal has not been

able to nurse adequately. Use of splints necessitates careful fitting and management, because rubbing sores are common and can be severe. Casts are generally safer if used only for short periods (5–7 days). High-dose oxytetracycline therapy is commonly used (40–60 mg/kg).

Early acquired cases in older foals and weanlings can be managed conservatively with nutritional correction, proper hoof trimming, and analgesia; however, once the deformity is present for >1 wk, this is rarely successful. Surgical treatment can be simple or complex, depending on the degree of involvement. Desmotomy of the accessory ligament of the deep digital flexor tendon (inferior check desmotomy) is the most successful and commonly used

procedure for flexural deformity of the distal limb and does not interfere with future performance. Superior check ligament desmotomy may be included for horses with fetlock deformities. For carpal deformities, sectioning of the tendons of insertion onto the ulnaris lateralis and flexor carpi ulnaris is performed. In hindlimbs, tenotomy of the medial head of the deep digital flexor is performed, because the inferior check ligament is often vestigial. In severe cases, tenotomy of the deep digital flexor tendon can be used as a salvage procedure. Nutritional correction, proper foot trimming, and analgesia are integral to recovery when surgery is performed. The prognosis is fair to good for horses diagnosed early and managed properly.

LAMENESS IN PIGS

Lameness has been an issue in swine production for many years and continues to be a problem worldwide. Although lameness can be caused by congenital or developmental abnormalities, most lameness in production animals is caused by pain associated with infections, trauma-related injuries, or underlying metabolic diseases. As such, it has become an area of focus for swine farm audits of animal well-being. It is also an economic issue, because an increasing prevalence or incidence of lameness in a herd is likely to affect viability, growth, or reproduction of pigs. Pig flow may be affected if farrowing targets are not met because of high rates of breeding stock removal or if growth of grower/finisher pigs is slowed by high lameness incidence. As with diseases of other body systems, lameness problems in a swine herd require a comprehensive approach if a diagnosis (or diagnoses) is to be reached so that preventive or curative measures can be instituted.

Signalment: The types and causes of lameness can vary widely by age of the pig and, to a lesser extent, by gender and breed. Traumatic injury can obviously cause lameness in pigs at any age, but some types of lameness arising from infectious or physiologic causes can have a more limited age range or set of circumstances under which lameness develops. It should also be

remembered that some infectious agents can affect and cause lameness in multiple species, so understanding the signalment of not only the group of pigs under evaluation, but also other pigs or species recently in contact or proximity with the affected group, is part of the comprehensive approach required for lameness investigations.

In addition to the signalment of the individual pigs in a population, the signalment of the composite group (ie, demographics) is also an important consideration. Examples of group signalment are the proportion of gilts in farrowing groups because gilts are more likely to pass pathogenic bacteria to their progeny, or the herd immune status with respect to a particular pathogen based on, for example, time since the most recent vaccination against erysipelas. Even the relative body condition of sows going into a cold season can predispose populations to increased or decreased susceptibility to herd health problems.

History: History taking must be thorough and should include information on age of onset, typical clinical signs, and progression of the lameness. Morbidity and mortality associated with any lameness and the number of groups, pens, rooms, or buildings with affected pigs are all relevant. Morbidity information should include treatments and

the responses observed. Culling rates can also provide information on morbidity, although recorded reasons for culling sows are notoriously inaccurate. Condemnations at slaughter can be another way to secure objective data on morbidity, when condemnations for limb abnormalities or fractures have a direct bearing on lameness and for polyserositis or downer pigs, which have an indirect bearing on lameness.

Mortality data can be evaluated as an absolute rate or, more usefully, as incidence by stage or week of production. For sows, body condition score at the time of death or euthanasia can help reveal underlying lameness conditions because recorded reasons for cause of death are also prone to inaccuracy, and lame sows tend to lose body condition before death or euthanasia.

The investigation of a lameness problem on a farm also requires an understanding of the operation of the farm itself. The logistics underlying the establishment of the group of pigs under investigation should be explored: the source(s), transport, and placement of the pigs. The history of replacement breeding stock accessions is relevant, especially if new herds of origin or different genetic lines were introduced.

Health program and practices should be considered. It is important to determine whether vaccination or medication protocols were changed. If possible, it is equally important to determine whether protocols were followed correctly. Audits of product consumption or antibody testing for vaccine titers, if available, can be used as verification methods.

Investigating nutrition programs as a possible contributor to lameness problems can become extensive. However, the fundamental questions can be reduced to determining what rations were formulated, mixed, and delivered to the pigs. Problems are relatively rare but possible during each stage of the process. At the formulation stage, lameness problems can result, for example, when book values of phosphorus are different than actual amounts present in the product used, or vitamin D or phytase activities are not at expected levels because of storage, processing, or other issues, which can affect calcium and phosphorus metabolism. At the mixing stage, mills can have time constraints that do not allow adequate mixing of feed batches, so the feed composition can be uneven. At the point of delivery, feed density differences in sow gestation feed can result in over- or underfeeding when volumetric feeders are not adjusted to

keep pace with weight and nutrient density changes in the ration.

Experiences with a series of lameness problems collectively referred to as metabolic bone disease—variably concerning problems in calcium, phosphorus, and/or vitamin D metabolism—have put more focus on the need to test feed constituents more thoroughly before inclusion in the diets, to test mixed feed for adherence to the formulation, and to monitor pigs more closely for serum vitamin D levels and bone densities so problems can be detected earlier.

Farm staff have a large role in caring for pigs on farms and, therefore, are a key source of information and possible solutions to lameness problems. Personnel working with the pigs must also be evaluated as possible contributors to lameness problems. Pig handling and movement are obvious potential causes of lameness, so understanding the level of staffing and extent of staff training are important parts of the case history. Observing the interaction between the pigs and the farm staff can help reveal the nature of interactions likely to occur routinely on the farm.

Understanding the farm hygiene practices is important to determine risks of injury and disease from slippery surfaces or contamination from transport vehicles. If bedding is used, determining the sources and management of the bedding is also significant to characterize disease risks.

Finally, the history of diagnostic results for the farm and the area are critically important to have a starting point for further investigation of lameness problems. If possible, the disease history among neighboring farms can help understand disease risks. At a minimum, a review of all the pertinent diagnostic testing results for the specific herd is required.

Clinical Evaluation: Diagnosis of lameness can be complex. At least three body systems (musculoskeletal, nervous, and integumentary) may be affected independently or in combination. Because of the different organ systems potentially involved, a consistent and thorough approach to evaluate all components of lameness is essential. When examining a herd with a locomotor problem, the focus should not be solely on a group of affected pigs. Younger pigs should be evaluated to identify potential underlying causes or predispositions to the problem under investigation. Other groups of pigs of similar ages and older pigs housed in other pens or

buildings should also be evaluated to determine whether they have similar or different problems. The conditions potentially causing the problem should not be assumed to be restricted to those most often associated with one particular age group.

When evaluating a population of pigs, it is useful to first consider an inverted pyramid approach of the entire room, followed by pens of pigs and finally individual pig evaluations. The entire room evaluation is intended to provide a general sense of the overall health, activity, and behavior of the group. Pen-by-pen evaluations provide an opportunity to make counts or estimates of the prevalence and severity of the lameness. The individual pig assessments are intended to focus on the specific cause(s) of the lameness.

The pen evaluation is intended to identify the lame pigs. Pigs should be made to move around (in pens or into alleyways), to stand, and if housing allows, to walk, watching for behavior typical of lame pigs. The pen ahead and pen behind the last pigs to stand up and first pigs to lie down should be observed. Pigs that take advantage of the diversion caused by the evaluation to access feed or water should be noted. Abnormal gait and posture, body condition (thin pigs are more likely to be lame), and physical evidence of trauma, infection, or malformation (swelling, vesicles, etc) should be watched for in individual pigs.

If an individual pig warrants a more extensive physical examination, some degree of restraint may be required. If less restraint is sufficient, the pig can remain free in a pen or stall, or a sorting panel can be used to prevent the pig from moving away. If more restraint is needed, small pigs can be lifted or manually held for examination. Larger pigs can be snared or cast using ropes. The advantage of this type of restraint is that it immobilizes the pig. Disadvantages are that the pig is placed in an unnatural posture, excess muscle tone is normally stimulated, and help from additional people is usually required.

Anesthesia is another possible means of greater restraint. The advantage is that muscles are relaxed, allowing manipulation of skeletal structures such as potential fractures. Additionally, muscle mass can be assessed, joint taps or other diagnostic procedures can be performed, and more extensive evaluations such as radiography or other scanning are possible if warranted. Disadvantages are the management of controlled substances used as anesthetics, required withdrawal times, and the

challenge of managing recovery from anesthesia with other pigs present or in facilities that may not be set up for such procedures.

Some farms may have lift chutes to immobilize boars, sows, and gilts for foot trimming or other procedures. These chutes allow good restraint with full access to the feet and lower limbs, with none of the disadvantages of chemical restraint. However, availability of lift chutes on sow farms is limited.

A general physical examination of an individual pig for lameness requires a thorough, systematic, and consistent process by individual clinicians. One such approach is to proceed from the bottom up and front to back of the pig, ie, the feet are evaluated first, followed by the limbs and torso in a front-to-back progression.

The feet can be examined most easily when the pig is lying laterally recumbent or lifted (manually for small pigs or using a mechanical chute for sows). Standardized guides exist to score foot lesions by type. Prevalence and severity of foot lesions in a sow herd can be estimated by scoring the feet using statistical sampling. Using a good flashlight enhances scoring foot lesions. Feet may need to be cleaned for pigs housed on non-slatted floors. Exploring lesions by trimming with a hoof knife, clipper, or grinder requires adequate restraint and safety protocols. Foot lesions have been well defined but do not always correlate with lameness on an individual pig basis, because the pain associated with foot lesions depends on exposure or infection of the sensitive tissues underlying the claw, heel, and sole of the toes.

Limb and joint palpation and manipulation should also be conducting using a consistent approach. The amount and type of restraint again depends on age of the pig. Cardinal signs of inflammation, ie, heat, swelling, pain, and redness, should be noted. Strength, range of motion, crepitus, and weight-bearing distribution should be evaluated. Joints embedded in muscle mass (eg, hip, stifle, shoulder) require deep palpation, which may not be possible on large, heavily muscled pigs. Fracture of the head of the femur (epiphysiolysis capitis femoris), a common cause of downer sows, is difficult to diagnose antemortem. Because it is buried under a large muscle mass, even infectious arthritis in the stifle, a site commonly affected by *Mycoplasma hyosynoviae*, can be missed on individual pigs on cursory examination.

The torso can be evaluated and palpated for muscle mass, tone, and symmetry. Ribs

should be examined for evidence of fractures or knobby thickening (rachitic rosary), and the spine examined for kyphosis.

A neurologic examination is indicated in cases when neurologic disease is suspected and should be performed in a similar fashion to that for dogs, cows, and horses (see p 1213).

Postmortem examination of lame pigs is often required to reach a definitive diagnosis for a herd lameness problem. Field necropsy of baby, nursery, and grower pigs is relatively easy to accomplish. However, for larger finisher pigs, gilts, sows, and boars, the process is laborious because of the size of the animal and the need to examine numerous joints and bones, often including the spine if appropriate to the clinical presentation. At a minimum, developing expertise in opening joints on dead pigs that may not be ideal candidates for diagnostic sampling can help direct diagnostic efforts when more suitable pigs are available. Examination of greater numbers of pigs improves the odds of accurately characterizing the cause(s) of lameness.

Although on-farm necropsies are feasible, it may be better to submit entire or even live pigs to a full-service diagnostic laboratory. In particular, submitting live pigs to a laboratory allows greater odds of successfully culturing live bacteria, which are needed for antimicrobial susceptibility determination or production of autogenous vaccines. Additionally, diagnostic laboratories have the facilities and personnel to perform more complete and careful dissections of joints, the spine, and brain. This is particularly true of sow lameness problems. For example, an extensive dissection of the pelvis is required to reveal an apophysiolysis of ischial tuberosity in young sows with characteristic dogsitting posture after farrowing. Likewise, vertebral abscessation can be a common cause of downer sows, and the vertebral column must be split sagittally to make a definitive diagnosis of this condition.

If pigs are to be submitted to a diagnostic laboratory, appropriate pigs must be selected and delivered, accompanied by an accurate history and a list of differential diagnoses. Adequate numbers of representative, acutely lame, untreated pigs are essential.

If tissues are to be submitted for a lameness evaluation, the diagnostic laboratory should be contacted to determine what tests will be done and what tissues will be needed. In general, tissues from three euthanized pigs with characteris-

tic clinical signs, acutely affected, and untreated (if available) are a reasonable starting point. Alternatively, three freshly dead pigs can be examined and sampled. Samples should be packaged and identified individually for each pig. Whole blood in EDTA and serum should be collected antemortem if possible. For small pigs, postmortem samples can include intact joints with the skin wiped clean and cooled for transport. For larger pigs, two joint swabs of synovial membranes of affected joints should be collected, along with chilled and formalin-fixed synovial membrane samples. Affected bones can also be submitted chilled.

The bone of choice (based on the recommendation of the laboratory) for bone density determination should be submitted if warranted. Protocols to evaluate bone density using front feet have been developed and may be available in some laboratories.

For suspected neurologic cases, one half of the brain should be submitted chilled and the other half fixed in buffered 10% formalin. Additionally, vertebral sections from the cervicothoracic and lumbosacral region should be submitted chilled, with 5-cm segments of spinal cord also submitted fixed in formalin. If muscle disease is suspected, a sample of diaphragm and muscle from affected areas should be submitted fixed in formalin.

As part of the postmortem examination, a rib should be removed and manually snapped (like a twig) to gain an appreciation of the bone mineral density. Depending on the age of the pig, the rib should snap sharply. With practice, clinicians can develop skill in evaluating bone mineralization in this manner.

Evaluation of affected or cull pigs at a slaughter plant is not usually productive, because processing lines run too fast to evaluate all the elements of the musculoskeletal system, and all joints cannot be thoroughly examined. However, specific conditions can be evaluated even at line speed. For example, rachitic lesions may be apparent on ribs on hanging carcasses. Condemned carcass or euthanized slow or down pigs can sometimes be made available for examination. Some abattoirs are willing to cooperate on specific projects to retrieve lower limbs for investigative purposes if asked.

Environment and Management: Housing and the manner in which pigs and their environment are managed are central to potential lameness problems, especially the

interface between the pig and the floor. Flooring type is a major determinant, and all types have forms of lameness associated with them. Dirt and pasture lots can range from too dry to too wet, leading to vertical hoof wall cracks or foot infections, respectively. Bedding can serve as a source of bacteria that cause infectious arthritis, such as *Erysipelothrix rhusiopathiae* in straw bedding. Solid, partial slat, and fully slatted floors also have relative advantages and disadvantages in terms of associated lameness conditions.

In addition to type of flooring, the adjustment and state of repair can have considerable influence on lameness. Holes, gaps, and sharp edges on concrete floors can traumatize the feet and lower legs. Abrasiveness of the flooring surface may be too little, which makes floors slippery and leads to injuries, or too much, which can wear down the claws and promote heel overgrowth.

Cleanliness and moisture are additional factors to evaluate. Buildup of manure in bedded areas can lead to foot infections, whereas excess moisture from misting cooling systems running out of adjustment can lead to softening of the claws, hoof wall cracks, and excess wear.

Interactions among the pigs are also important factors to evaluate. The sourcing and mixing of discrete pig populations can influence whether infectious diseases are maintained as endemic within the population or can become epidemic outbreaks as pigs become susceptible over time with the loss of maternal immunity and have commingling exposure. Stocking density and space for animals to exhibit social behaviors can influence how much aggressive social behavior occurs within groups of pigs. Distance and conditions pigs are required to traverse to access feed and water can affect wear on the feet and trauma to joints.

Group size and stability also have an impact on development of lameness. Sows housed in individual stalls are restricted in terms of movement but tend to develop fewer lameness problems than confined group-housed sows. Pigs kept in very large group sizes have fewer aggressive interactions than pigs housed in small groups. Sorting growing pigs to allow for more variation in size within pens can reduce the time required for social structures to become established at weaning or regrouping times.

Nutrition: Skeletal development may be affected by relatively short-term nutritional deficiencies, especially consider-

ing expectations for rapid growth and muscle development in modern hybrid pigs. Problems early in the production cycle may be reflected as abnormal bone growth in nursery or growing pigs, whereas recurrent deficiencies or those seen later in the finishing phase may result in weak bones in slaughter pigs or replacement breeding stock.

During the growing phase, the goal of the nutritional program should be to ensure the development of a strong skeleton so that incidence of spontaneous bone fractures in the finishing barn or during the slaughter process is low, thus preventing large numbers of culls or partial and complete condemnations of carcasses. Fractures of the femur, humerus, ribs, or vertebrae may be induced by strong muscle contractions during the slaughter process; however, if the problem is seen frequently, it may be a reflection of the overall integrity of the skeleton and warrant further evaluation of the minerals and vitamins in the ration. Clinical signs of hypocalcemia can develop before slaughter and can include lameness, including spiral fracture of the femur, leg weakness and posterior paresis, recumbency and paddling, and even sudden death.

In breeding animals especially, foot lesions can cause lameness. Research has demonstrated the need to balance diets carefully for macro and trace minerals, as well as key vitamins such as vitamin D and biotin. Excessive water hardness or high concentrations of iron or heavy metals in water can antagonize trace mineral absorption, leading to foot lesion development.

Viruses: Some acute infectious causes of lameness in pigs can affect pigs of multiple ages. In particular, vesicular diseases caused by several viruses can cause lameness in breeding and growing swine: foot-and-mouth disease, Seneca Valley virus, swine vesicular disease, vesicular stomatitis, and vesicular exanthema all fit this clinical picture. Prevalence and clinical severity among these viruses is variable, but because of the concern over foot-and-mouth, any episode of vesicular disease in pigs is cause for a full diagnostic investigation involving regulatory personnel.

Therapeutic Considerations: Therapies to treat or prevent lameness should, of course, be tailored to the presumed or confirmed underlying cause of lameness but can also be symptomatic to reduce pain and improve function. However, the regulatory landscape for use of products to treat or prevent lameness in pigs is changing. This is true not only for federal regulations

regarding use of antimicrobials and analgesics but also for the patchwork of commercial marketing programs that are typically more restrictive on product use through contractual agreements. Thus, any product type, dose, form, and use should be carefully considered in light of pertinent regulations for the jurisdictions in which the pigs are being raised and marketed.

Production practices and conditions are also changing. In certain parts of the world, pig farming is becoming more intensive, whereas others are becoming more extensive. These changes can alter the epidemiology of diseases, posing both a challenge and an opportunity to intervene more effectively to reduce lameness.

Diagnostic regimens are becoming more sensitive, increasing the likelihood of detecting and characterizing disease-causing agents. Distinguishing between presence and significance of a disease-causing agent becomes more difficult, but a more precise understanding of exposure and transmission of agents should help develop more effective control strategies.

Pigs with acute diseases that may result in death typically require parenteral therapy with a drug of choice (using approved products first) based on tentative diagnosis and the clinician's experience until results of a necropsy and antimicrobial sensitivity profiles are available. Virtually all the parenteral products available to treat infections that cause lameness are given IM, with the site of choice behind the ear for all age categories. It may be feasible to provide medication in the water or feed after the initial parenteral treatment. Infectious agents sensitive to a drug *in vitro* may not be sensitive *in vivo*, so clinical experience on the farm is essential.

In addition to antimicrobials to treat infectious arthritides, the use of anti-inflammatory agents to relieve pain can be useful and beneficial to the pig. Flunixin meglumine is approved for use in pigs for symptomatic treatment of fever in outbreaks of swine respiratory disease, but anti-inflammatory and analgesic qualities can help relieve pain in a swollen joint or bruised muscle (extra-label). Dexamethasone has been recommended in pigs with streptococcosis and is labeled for glucocorticoid therapy in pigs. Another glucocorticoid, isoflupredone acetate, is specifically approved for musculoskeletal pain that causes lameness in pigs. In a controlled study in Europe, the COX-2 inhibitor meloxicam proved useful to alleviate painful, noninfectious lameness in pigs. This product is approved for use in swine

in Canada but not in the USA. All these products are administered by IM injection, so treatment of large numbers of pigs is time consuming and potentially costly. Acetylsalicylic acid and sodium salicylate are allowed for analgesia in swine if manufactured under cGMP and may be a useful adjunct therapy as a water treatment. Additionally, meloxicam and ibuprofen can be compounded from FDA-approved human products. An important consideration with use of any pharmaceuticals in pigs near time of slaughter is observance of withdrawal times recommended by the manufacturer.

Whenever feasible, introduction of a vaccination protocol to protect populations of pigs against a particular infectious agent is desirable. If a suitable vaccine is not commercially available, an autogenous product can be created for some pathogens for use in an individual herd and, provided it is cost-effective, can be used to prevent regular outbreaks of disease. Regular monitoring for causal organisms, serotype, etc., is essential for effective use of either antibacterial agents or vaccines.

Removing lame pigs from competitive group housing environments to hospital pens improves the chances of recovery. Research is inconclusive as to the optimal flooring and husbandry conditions for recovery pens.

PIGS IN FARROWING HOUSES

Neonatal Polyarthrititis (Joint-ill):

Neonatal septic polyarthrititis, which causes death in up to 1.5% of affected pigs, is caused by various facultative and specific pathogens that cause localized infections that precede septicemia. Healthy, suckling pigs typically "paddle" with their legs, abrading the skin of the carpi or coronary bands; an infection often becomes established under scabs that develop. Poor hygiene at tail docking, ear notching, or castration, and careless clipping of needle teeth can also result in localized infections. If an infected wound leads to bacteremia, organisms can cross the synovial membrane, and polyarthrititis is likely. Microorganisms can also gain entry to the circulatory system via the tonsils or oropharynx or as a result of an ascending omphalophlebitis. Pigs with exudative epidermitis (*see p 860*) are also prone to polyarthrititis, but this may be a reflection of the same skin damage discussed above.

Affected pigs are lethargic and may fail to suckle. Joints are swollen, painful, and warm, and lameness affecting one or more

limbs is severe. With time, the soft, fluctuant swellings become firm. At necropsy, the umbilicus should be examined to see whether it is hard and swollen. Typically, cream or green pus is found in and around swollen joints (particularly the elbows, carpi, stifles, and hocks), in the umbilical stalk, and sometimes over the meninges or in the fissure between the cerebrum and cerebellum. Organisms isolated from baby pigs included streptococci (including *Streptococcus suis*), staphylococci, *Actinobacillus suis*, *Trueperella pyogenes*, *Escherichia coli*, and occasionally, *Pasteurella multocida*, *Erysipelothrix rhusiopathiae*, or *Haemophilus* spp. If untreated, affected pigs become runts that fail to thrive in the nursery.

Treatment must be based on bacterial culture and antimicrobial sensitivity profiles and applicable regulations on product use. Antimicrobial therapy should be initiated early in the course of the disease if it is to be effective, and treating all pigs in the group at risk may be prudent, especially if *S. suis* is implicated. Penicillins have been the drugs of choice, depending on the causal agent and sensitivity. However, a broader range of drugs is available, including lincomycin, trimethoprim/sulfonamide, and tylosin, provided causal organisms are sensitive. The range of suitable drugs is increased further if streptococcosis caused by *S. suis* develops (see p 731).

Regardless of the cause of a local infection, if there is an ongoing problem with septic polyarthritis, it is important to observe the practices used in farrowing rooms and to look for opportunities for improvement. An "all-in/all-out" flow of pigs is important, and scrupulous hygiene in farrowing crates helps to reduce environmental contamination and incidence of neonatal polyarthritis. Prevention may be difficult because most types of floors, including those bedded with straw, can cause skin abrasions. Plastic-covered woven wire provides a smooth, relatively soft, self-cleaning floor and may help; plain woven wire is similar if it is smooth. If replacement of flooring is not economically viable, sections of clean, soft carpeting may help reduce skin abrasions.

Separate instruments should be used for teeth and tail clipping, and they should be cleaned and disinfected between pigs, preferably using a dry paper towel. Soaking instruments in contaminated disinfectant solution between pigs or litters promotes contamination and infection. If teeth are not clipped or if there are sharp remnants of clipped teeth, pigs that suckle aggressively

can lacerate the faces of other pigs, resulting in pyoderma. Castration equipment must be kept sterile and sharp. If tail stumps are infected, antiseptic solution may be used as a spray to improve hygiene.

Litters from gilts are more prone to neonatal polyarthritis. Colostral protection against this syndrome and other infectious diseases of baby pigs increases as a sow ages. Because pigs in large litters have to compete more to suckle and are, therefore, more prone to lesions on their faces and forelimbs, cross-fostering within 24 hr of birth to balance litter sizes may help. Piglets nursing sows with hypogalactia or agalactia spend more time nursing, leading to more forelimb lesions.

Diseases of the Foot: Neonatal foot lesions fall into two main categories: either the sole or heel is damaged by the floor, or the hoof wall is traumatized by the sow standing on a pig's foot or by entrapment in the flooring.

Bruises or lacerations develop on either the sole or heel. The lesions are associated with worn and rough floor surfaces and with floors that have solid as well as perforated surfaces. Rough flooring can also cause bruising in soft tissue below the hoof wall. If spaces between slats are large, digits can be entrapped, and lameness results from bruising or infection at the coronary band. Pigs on expanded metal floors can incur heel and wall injuries leading to loss of accessory digits. Second and third digits may be damaged as the pigs thrust with their feet during suckling and catch their toes against sharp metal edges. Sharp spicules on woven wire cause lacerations and predispose to infectious laminitis and polyarthritis.

Prevention is based on selecting floors that minimally injure feet or skin. Because of similarities with infectious polyarthritis, the approach to treatment and prevention is similar (see above). Improved hygiene within the environment may help reduce septic laminitis and allow injuries to heal.

Muscular Disorders: Splayleg or spraddleleg (see p 1049) is precipitated by weakness and immaturity of skeletal muscles at birth because myotubular development is impaired. Forelimbs, hindlimbs, or all four limbs may be affected so that the piglet either walks with difficulty or cannot stand. The disorder appears sporadically in litters, and only a few pigs in a litter are typically affected. There is a hereditary component in European Landrace and, to a lesser extent, in Large

White pigs. Male, premature, and small pigs, and pigs from older sows seem more susceptible. Deficiencies of choline, methionine, and thiamine in the sow's diet may precipitate the syndrome, and zearalanone toxicity via the sow's milk has been implicated, but there is controversy as to the exact cause. To varying degrees, affected pigs are unable to move around and die either because the sow crushes them or they become hypoglycemic because they cannot feed. Alternatively, skin and foot abrasions develop, predisposing to arthritis, polyarthritis, or pododermatitis and osteomyelitis of the digits.

Timely management practices are essential to ensure that pigs can feed and avoid hypoglycemia and hypothermia. If only the hindlimbs are affected, they can be hobbled so that the pig can lever itself up using forelimbs and hop around to nurse. Various hobbles, including a figure-8 tape or bandage, have been successful. Some recommend taping the pelvic limbs so they are directed cranially on the belly. By using the limbs or pushing against a bellyband, the pig potentially develops and strengthens muscles, which can enable to pig to walk after a few days. Hobbles must be removed within a few days of pigs walking, to avoid ischemic necrosis of skin and other tissues as the pigs grow.

Pigs with splayleg may require assistance to suckle colostrum and milk for the first few days of life. Some advocate the use of "hot boxes" to nurture these and other ailing pigs, relying on milk replacers as the main source of food once the pig has had colostrum. Because slippery floors exacerbate the condition, temporary use of sanitized mats may help. Any nutritional deficiency or mycotoxin contamination of food should be addressed.

Iron toxicosis in piglets (*see* p 3077) after injection with iron preparations soon after birth may be associated with muscle fiber fragility, especially if there is a selenium deficiency in the sow and, therefore, the piglet. Inadequate hygiene or technique when baby pigs are injected with an iron preparation can lead to bruising and septic myositis. This problem can be resolved by adequate training of farrowing room staff.

Neurologic Disorders: Meningoencephalocoele and cerebellar hypoplasia interfere with locomotion in affected pigs, as can infections with *Listeria monocytogenes* and *Streptococcus suis*. Thus, *S. suis* can cause locomotion problems as a result of meningitis and neurologic signs, or a suppurative arthritis can be the primary

complaint. Congenital tremors cause pigs to shake when awake and remain still when sleeping. Either heredity or viral infections may cause the problem. In the USA and other parts of the world, porcine circovirus has been implicated in congenital tremors. The tremors usually are most severe during the first week of life and make it difficult for pigs to nurse. Affected pigs must be assisted with nursing until the tremors subside.

Hereditary and Congenital Disorders:

Mycotoxins in the sow's feed can cause arthrogryposis, which leads to deformity of limb bones, but the primary effect may be on neuromuscular function. Pigs affected by hereditary hyperostosis have thickened thoracic limbs and a domed forehead and generally do not survive. Polydactyly and syndactyly are occasional abnormalities that may affect locomotion of the baby pig; syndactylous or mule-footed pigs have been propagated and sold by some producers with no obvious disabilities for the pigs. When causal agents contaminate the feed, sources of these products should be found and avoided; if hereditary disease is suspected, the source(s) of replacement stock must be investigated.

PIGS IN NURSERIES

By the time pigs are weaned, diseases that affected the locomotor system during the nursing phase most likely will have resolved spontaneously, responded to aggressive therapy, or resulted in death. Because pigs that survive episodes of polyarthritis generally remain lame, have one or more swollen "knotty" joints, and are in poor condition, they should be culled.

In a swine producer survey in the USA, CNS and meningitis problems were considered the second most frequent cause of death in weaned pigs, representing 13%–19% of losses. In this survey, *Streptococcus suis* meningitis, Glässer's disease, and edema disease, respectively, were perceived to cause illness or death in one or more pigs in 50%, 17%, and 9% of surveyed herds.

Infectious Arthritis or Polyarthritis:

Causes of polyarthritis in this group of pigs usually include *Mycoplasma hyorhinis*, *Haemophilus parasuis*, *S. suis*, or *Erysipelothrix rhusiopathiae*, and less commonly *Streptococcus dysgalactiae* subspecies *equisimilis*, *Actinobacillus equuli* subspecies *equuli*, and other bacteria prone to achieve bacteremia. The birth canal and upper respiratory tract of the sow are often the sources of the

organisms for the baby pig, which becomes infected in the farrowing room. *M hyorhinis* and *H parasuis* circulation in the sow herd can be predictive of infection levels in growing pigs. Alternatively, older pigs act as carriers and are a source of infection for their peers. Pigs affected by *E rhusiopathiae* also shed organisms in their feces and urine. Essentially, all are systemic diseases with a septicemic phase, and each may manifest as different clinical syndromes or as a mix of clinical signs.

As with many infectious diseases, management or environmental factors that stress the pig or depress the immune response can precipitate systemic disease or an infectious arthritis. Moving and mixing pigs (particularly if all-in, all-out management is not used); overcrowding; cold, damp, poorly ventilated, or cold, drafty environments; and changing rations are all major stresses that can lead to development of infectious arthritides or neurologic diseases that affect movement. It is also likely that active viral infections associated with porcine reproductive and respiratory syndrome virus (see p 729) or circovirus may predispose groups of nursery pigs to bacterial polyarthritis.

Initially, shifting-leg lameness occurs, and joints can be warm, swollen, and painful. If pigs are febrile, they may have no interest in standing and become inappetent. Chronic forms of polyarthritis with polyserositis result in unthriftiness, runt pigs and, in the case of chronic erysipelas (see p 1160), runt pigs may be lame with hard, swollen joints.

The clinical signs seen in infections caused by *M hyorhinis* and *H parasuis* (Glässer's disease, see p 720) are similar, because both cause painful polyarthritis and polyserositis. The conditions cannot be differentiated grossly at necropsy. Infection with *M hyorhinis* usually results in lameness with moderate morbidity and low mortality, but *H parasuis* can cause infection in 50%–75% of pigs and mortality of up to 10%. Outbreaks of Glässer's disease have been particularly severe in SPF and other naive herds. *H parasuis* may also play a part as a primary or concomitant agent in swine respiratory disease complex and cause disease in association with porcine reproductive and respiratory syndrome virus or influenza virus. Fever is associated with mycoplasmosis but can be highest in Glässer's disease ($>107^{\circ}\text{F}$ [41.7°C]) as pigs become anorexic and lame; sometimes *H parasuis* causes neurologic signs.

At necropsy, polyarthritis and polyserositis are seen with both mycoplasma infection and Glässer's disease, and pneumonia may

have developed. The initial, exudative response is usually serous or serofibrinous with a mycoplasmal infection; however, it is fibrinous or fibrinopurulent with Glässer's disease. Hence, *M hyorhinis* causes a mild synovitis with villous hypertrophy and hyperplasia; an excess of clear, yellow, or brown synovia; and a serofibrinous pericarditis, pleuritis, and peritonitis. Otitis media has also been reported. With *H parasuis*, a fibrinopurulent synovitis with periarticular edema, polyserositis with pseudomembranes, and sometimes fibrinopurulent meningitis are seen. The articular surfaces are usually unaffected in either condition.

Diagnosis is based on clinical signs, necropsy findings, and detection of the organism. PCR tests are available to detect *M hyorhinis* and *H parasuis*. This is important, because bacterial culture of both bacteria can be challenging if any treatment has been instituted or if the pig has been dead more than a few hours. Treatment for either disease must be aggressive and start soon after the onset of clinical signs if it is to be effective. The effectiveness of treating *M hyorhinis* infections with tylosin, tetracycline, or lincomycin has been variable. Organisms may be susceptible in vitro and resistant in vivo. Treatment of Glässer's disease is discussed in the relevant chapter (see p 720). With chronicity, success in treating either disease is unlikely.

Appropriate changes in management to reduce stress, strict all-in/all-out housing, and control of viral infections should all minimize the impact of Glässer's disease. Herds that maintain an SPF status may be free of both *M hyorhinis* and *H parasuis*, but in herds with documented outbreaks of Glässer's disease, morbidity and mortality were high and productivity was decreased. Some 15 serovars of *H parasuis* have been identified, with much strain variation. Vaccination with commercial or autogenous *H parasuis* bacterin may alleviate clinical disease in SPF herds. It is important to vaccinate SPF pigs that are to be shipped to conventional herds with vaccine effective against the serovars present in the recipient herd. There is cross-protection among some serovars. Vaccination of sows against *H parasuis* reduces the prevalence of the problem in nursery pigs through passive immunity.

Streptococcosis: The streptococcal disease of main concern to the pig industry is caused by *S suis* (see p 731). Although this organism can cause arthritis, CNS signs and pneumonia are the most common clinical presentations.

Erysipelas: Although acute erysipelas can be seen in nursery pigs, it may be more typical of growing/finishing pigs (see p 1160). If the acute form of the disease affects nursery pigs and is not treated appropriately, the subsequent progression of the disease to the chronic form is seen in the grower/finisher pigs. Adequate vaccination protocols are essential to controlling erysipelas. (See also SWINE ERYSIPELAS, p 626.)

Vertebral Deformities: Kyphosis or lordosis and cuneiform deformities of vertebrae have been seen in weaned pigs. The condition has been reproduced experimentally using gestation and nursery diets deficient in calcium, phosphorus, and vitamin D. "Humpy back" pigs are seen sporadically in some herds; the spine is curved in the vertical plane such that the lumbar vertebrae are higher than the thoracic vertebrae, and there is a "kink" between the two segments. Rickets is usually not seen clinically until the grower phase, but lesions must be initiated earlier, giving time for typical pathologic changes to develop by ~10 wk of age.

PIGS IN GROWER/FINISHER AREAS

Lameness in pigs is of increasing interest in North American swine production. *Mycoplasma hyosynoviae* in particular has received more attention due, in part, to more intensive diagnostic efforts. Metabolic bone disease has also been an area of focus as problems have arisen after more complex formulations for gestation and grow-finish diets.

Arthritis: Arthritis caused by *Mycoplasma hyosynoviae* and *Erysipelothrix rhusiopathiae* emerge as important causes of lameness in pigs that have been moved to the grower/finisher areas. Again, mixing and moving groups of pigs; overcrowding; cold, drafty environments; or changes in management and feed may precipitate outbreaks of lameness.

In the case of *M hyosynoviae*, the upper respiratory tract of sows and older pigs in peer groups is the likely source. As colostral immunity wanes at 4–8 wk of age, pigs become susceptible to infection. Generally, morbidity is low to moderate, but up to 50% of pigs may be affected; mortality is very low. An acute lameness, lasting up to 10 days, develops in groups of grower/finisher pigs or selected replacement stock. Arthritis may be exacerbated by trauma or stress,

and pigs exhibit pain in major joints (eg, elbows, stifles, and hocks) that may develop soft, fluctuant swellings. On necropsy, lesions are restricted to the joints, especially the stifles, and include an excess of clear, yellow synovial fluid that may have fibrin flakes, and yellow synovium with obvious villous hypertrophy. Articular surfaces and periarticular tissues usually are unaffected. *M hyosynoviae* has been isolated at slaughter or necropsy in pigs with degenerative joint disease that is part of the osteochondrosis syndrome, but it is a secondary rather than a causal agent.

Diagnosis is based on the age of onset of clinical disease and clinical signs, including lameness in one or more legs that may be accompanied by fluctuating swelling and puffiness around joints. Typically, pigs are afebrile and there is no evidence of pneumonia, pleuritis, and peritonitis. If a definitive diagnosis is to be made based on detection of the organism, samples of synovium and synovial fluid should be collected from untreated pigs within 3–4 days of the onset of clinical signs. However, *M hyosynoviae* can be cultured from healthy joints and is not always recovered from affected joints.

Lack of a response to penicillin in acute cases has been used to differentiate this disease from erysipelas. Unlike polyarthritis caused by *M hyorhinis*, response to treatment with tylosin and lincomycin is generally good if administered promptly, and tiamulin or tetracycline may be effective where allowed. Mycoplasmal arthritis may exacerbate clinical signs associated with degenerative joint disease and osteoarthritis and vice versa.

Erysipelas: *Erysipelothrix rhusiopathiae*, the cause of erysipelas, is acquired from healthy carrier pigs or the environment, in which the organism can survive for short periods. Erysipelas can be peracute, acute, or chronic. In the peracute form, pigs die without clinical signs. In the acute form, pigs become febrile and may be lethargic and anorectic and unwilling to rise because of painful joints and cyanosis of the extremities; the latter is associated with vasculitis in peripheral vessels. After 2–3 days, the classic "diamond" skin lesions (focal urticaria) develop over the body surface. In some outbreaks, lameness is seen without the skin lesions. In the chronic form, arthritis progresses such that the stifles and hocks become swollen and feel firm on palpation; skin necrosis can result in extensive sloughing of portions of the integument. In chronic cases, discospondylitis also may

develop if intervertebral joints are affected. As the arthritis progresses and joints fuse, pain in the lumbar vertebrae may reduce boar libido. Cyanosis in the extremities in chronic cases may be related to heart valve failure. A presumptive diagnosis of acute disease is based on the clinical signs, of which the "diamond" skin lesions are most consistently useful. All three forms of the disease may be seen in the same herd if the problem has not been investigated and treatment has been delayed.

If the chronic form of erysipelas is investigated as a lameness problem and pigs are necropsied, early changes in the disease process will have subsided (eg, hemorrhages in lymph nodes, kidneys, and muscles). An excess of synovial fluid accumulates during the acute phase, but in chronically affected joints, there is villous hypertrophy and hyperplasia, hyperemia, and periarticular fibrosis. If pannus has formed, the articular surface becomes disrupted. Raised, focal skin lesions progress to sloughed areas and, in extreme cases, the ears and tail may have sloughed. Vegetative, valvular endocarditis is another finding.

Isolation of the causal organism is important for a definitive diagnosis and is most successful if acutely affected, untreated pigs are necropsied and joint fluid is cultured. PCR testing of chronic lesions (eg, endocarditis) can be used to detect the bacteria in chronic cases. A bacterial culture with an antibiotic sensitivity profile is useful during treatment of the herd. Sometimes, a rapid response of the acute condition to penicillin is a diagnostic aid. Provided the *E. rhusiopathiae* is sensitive to penicillin, this may still be an economic choice for treatments. However, tylosin and lincomycin are also labeled for treatment of erysipelas, and tetracycline may be successful if the organism is susceptible.

Vaccination with either modified-live or killed organisms effectively controls erysipelas in a herd, and outbreaks may be related to noncompliance with vaccination protocols rather than to changes in the virulence of the causal organism or the nature of the disease. Therefore, any investigation of the problem should begin with a detailed vaccination history to ensure that sows are regularly vaccinated. Even with sow vaccination, infection is seen in grower/finisher pigs in some herds. On these farms, growers must be vaccinated in addition to the sows. In the face of an outbreak, concurrent use of killed vaccine and antibiotic is likely to be the most effective control measure (see p 626).

Osteomyelitis: Osteomyelitis can be seen in pigs of any age. If the integument is damaged, sepsis develops and a suppurative lesion extends to the periosteum and bone. Alternatively, organisms can invade bone from the synovium of infected joints. Poor processing or injection techniques can initiate abscesses that can extend into adjacent bone. Disruption of the integrity of the hoof wall initiates cellulitis and osteomyelitis of a phalangeal bone. Ear and flank biting wounds are other foci of infection. Tail biting can result in local infections that ascend the spinal canal and lead to epidural abscesses that can invade and affect vertebral bodies. Lesions and clinical signs may develop slowly.

Depending on the site of infection, the pig may become ataxic and, ultimately, paralyzed in the pelvic limbs. If bones or joints of a limb are affected, the condition is usually chronic and the pig becomes three-legged lame. Young pigs cease to grow.

At necropsy, cream or green caseous pus is seen at the site of the lesion. If *Trueperella pyogenes* is involved, there are abundant pockets of green, semiliquid pus. Other organisms isolated from these abscesses may include streptococci, staphylococci, and enterobacteria. Treatment is not usually feasible, and pigs should be culled for humane reasons. However, when applicable, hygiene can be improved, and problems such as tail biting controlled or prevented.

Osteochondrosis and Osteoarthritis:

Lameness associated with these problems may become clinically relevant by the time the pigs are 4–6 mo old, but the major ramifications are in gilts, sows, and boars (see p 1158). Because there is a hereditary component, the importance of these problems increases if affected replacement breeding stock is brought into a herd that was previously free of either condition.

Rickets: Although now uncommon, rickets (see p 1051) is occasionally seen, usually associated with a feed formulation or mixing error. Rickets affects rapidly growing, young pigs with a clinical onset at ~10 wk of age. Morbidity is high, and affected pigs become crippled, anorectic, and unthrifty. Limbs are stunted and bowed, joints are swollen, and the head may seem disproportionately large. Long bones of the limbs can spontaneously fracture so that the pig becomes severely lame and unwilling to move. Ribs may fracture. Some pigs develop posterior paresis and sit on the ground if vertebral bodies fracture and damage the spinal cord.

Absolute deficiencies of calcium, phosphorus, or vitamin D, or an imbalance of the calcium:phosphorus ratio causes cessation of mineralization at the metaphysis and thickening of the growth plate and epiphyseal growth cartilage.

On necropsy, bones should be dissected to determine whether there are any fractures or healing fractures, particularly in the ribs, humeruses, and femurs. The costochondral junctions of most ribs are enlarged to form a rachitic rosary, and ribs may bend with moderate manual force. Bone remodeling is inadequate and, radiographically, long bones and ribs are poorly mineralized. Failure of calcification and endochondral ossification results in thickened, irregular growth plates and epiphyseal growth cartilages in which hemorrhages may be seen grossly if slab sections of the ends of long bones are cut on a band saw. In chronic cases, bones can be cut with a knife. A sudden increase in carcass condemnations or partial condemnations because of fractured limb bones, ribs, or vertebrae at slaughter should trigger investigation of rations and their ability to meet the nutritional needs of growing pigs, particularly with some of the fast-growing, lean contemporary hybrids. Ration analysis is useful, but current batches of feed may have been mixed correctly or with different lots of ingredients, thus making it difficult to relate cause and effect. Keeping frozen samples of each batch of feed for retrospective analysis is a good practice.

Although rations can be corrected and vitamin D given parenterally, there is no effective treatment, and attempts to rear large numbers of affected pigs have been economically disastrous. Culling affected pigs may thus be the most cost-effective alternative.

Foot Disorders: On occasion, grower/finisher pigs have overgrown claws or bruises and cracks in the wall or sole of the hoof. The floor type and condition is perhaps the single greatest factor in determining whether lesions develop or resolve. Floors with wide slots enable digits to fall between the slats, causing damage. Floors kept too wet can soften the hoof wall, making them more prone to trauma. If the floor is too smooth, the balance between growth and wear of the horn is lost; if it is too rough, the hoof wall, coronary band, or skin above the hoof is damaged so that infectious agents can penetrate the foot or adjacent joints, resulting in abscess formation.

An absolute or intermittent deficiency of biotin results in weak, flaky keratin that

makes hoof walls susceptible to cracking; flaky skin accompanies hoof lesion and there is generally poor reproductive performance in the herd. As gilts are prepared for breeding, supplementing biotin may be helpful. Recommended inclusion rates of biotin are 250–400 mcg/kg complete feed. Trace mineral deficiencies or imbalances can also contribute to compromised hoof wall and heel epidermis formation.

Selenium toxicosis can cause coronary band swelling and necrosis in addition to more generalized signs such as anorexia or even paralysis (*see* p 3085). Selenium and ergot toxicity can result in hoof sloughing in pigs.

Nutritional Myopathy (White Muscle Disease): In contemporary systems with adequate ration preparation and storage, nutritional myopathy should not be problematic (*see* p 1174). Although unexpected deaths are typical of selenium and/or vitamin E deficiency, sometimes pigs are found recumbent and unable to rise and walk. At necropsy, a variety of pathologic changes may be seen, including pale muscle masses, epicardial hemorrhages (mulberry heart disease), and a pale, scarred liver with an uneven surface (hepatosis dietetica).

Prevention includes supplementation with selenite so that the total ration concentration is 0.3 ppm selenium. If the condition is diagnosed in a batch of pigs, injectable selenium/vitamin E can be given as a stopgap measure until supplemented feed is part of the nutrition program.

BREEDING GILTS, SOWS, AND BOARS

After reproductive failure, lameness is typically the most important reason for removal of breeding stock from the herd. Lameness in breeding swine can result in the following: 1) higher rate of breeding stock replacement with attendant increased risk of disease introduction; 2) an inability to maintain a breeding schedule due to an unreliable pool of breeding pigs and, ultimately, an impact on pig flow in the grower/finisher area; 3) increased cost of maintaining additional breeding stock; 4) poorer reproductive performance due to regular replacement of lame sows with gilts; 5) poorer growth and feed efficiency in progeny pigs due to a higher proportion of pigs produced by first-parity sows; 6) reduced pigs born alive because of higher stillborn rates in lame sows and reduced subsequent litter size due to poor lactation feed intake; 7) increased preweaning

mortality due to clumsy, lame sows that tread or lie on baby pigs; 8) reduced weaning weights of pigs due to reduced feed intake of sows in lactation; 9) reduced salvage value of cull sows due to increased lactation weight loss and sow mortality; and 10) reduced fertility in sound boars that are overworked while others are lame or being replaced. In sum, the impact of breeding herd lameness on the biologic and economic performance of a farm can be substantial.

Many diseases that affect grower/finisher pigs (see p 1160) can also affect young gilts and boars selected as breeding stock. Arthritis caused by *Mycoplasma hyosynoviae* or acute or chronic erysipelas can cause an incapacitating lameness. Polyarthritis and polyserositis caused by *M hyorhinis* are seen occasionally in these older pigs. Susceptible, stressed adult pigs can succumb to *M hyorhinis* with a higher fever and a more severe lameness than is seen in nursery pigs. Likewise, *Haemophilus parasuis* can develop as an acute epidemic disease in gilts sourced from herds free of the bacteria after entering a herd endemically infected. High morbidity and even mortality that is quite refractory to treatment can result.

If rickets or skeletal weakness was a problem in the growing phase, pigs that could have been affected should not be retained as breeding stock. Ambulation should be assessed as a component of breeding stock selection. Pigs with conformational abnormalities of their limbs or restricted or abnormal ambulation should be culled. Feet should be evaluated for uniformity among and angulation of the digits and for integrity of the wall, sole, and heel. If any problems are identified, including abnormal traits such as overgrowth of the major or secondary digits in a particular line of pigs, these pigs also should be culled.

Rickets, Osteomalacia, and Osteoporosis: These syndromes can affect older age groups of pigs, with various clinical outcomes. Most pigs, including breeding stock, are slaughtered before their skeleton has fully matured; some growth plates are functional up to 3.5 yr of age and, therefore, are susceptible to rachitic or other changes.

Osteomalacia is characterized by an excess of unmineralized or poorly mineralized osteoid that forms as bone remodeling occurs (or does not occur). Hence, osteomalacia is the component of rickets (see p 1161) that affects the growth plate and is described in younger pigs. In contrast, osteoporosis develops when

established bone loses mineral and mass by a process of osteolysis, a different pathogenesis from that of either rickets or osteomalacia.

Gilts that have normal skeletal development and are selected as breeding stock must continue to have their nutritional needs met, both for their own growing skeleton and, once pregnant, that of the growing fetuses. This may precipitate as osteomalacia if amounts of calcium, phosphorus, or vitamin D are inadequate or, in the case of the minerals, inappropriately balanced. The problem is further compounded once the sow farrows, due to secretion of calcium in the milk. A first-parity sow may soon draw on her skeletal reserves and become osteoporotic. Because sows can become pregnant within 7 days of weaning, there is little time for recovery of skeletal mass between one breeding cycle and the next, so the skeleton becomes progressively weaker. Limited exercise may also exacerbate calcium mobilization and bone loss. Consequently, in sows late in gestation, during lactation, or soon after weaning, bones that have become weak are susceptible to fractures. It is not surprising that considerable numbers of first- and second-litter sows are culled because of fractures and lameness.

Factors that may lead to bone fractures include entrapment of a limb in or under the bars of a farrowing crate, activity as sows are moved from their farrowing crates, and fighting as new groups of weaned sows reestablish a social order in the breeding or gestation area in group housing conditions. Sows mounted by other sows that are in estrus are also prone to injury. The most frequent sites of fractures are femurs, humeruses, lumbar vertebrae, and occasionally ribs. Whatever the factors that precipitate the fractures, affected sows are in pain and are either severely lame and unwilling to move or paraplegic.

Diagnosis is based on a history of acute lameness or paraplegia in pregnant, lactating, or recently weaned gilts or sows. Sometimes, crepitus can be detected in affected limbs. A neurologic examination can help locate spinal lesions if a sow is paralyzed in the pelvic limbs. Affected sows should be culled or euthanized after an early diagnosis. Prevention through adequate nutrition and exercise for gilts and sows curtails the problem.

Osteomyelitis and Spinal Abscesses:

In addition to the causes discussed under grower/finisher pigs, osteomyelitis may also develop secondary to a vertebral fracture or

an epiphyseal separation. It is reasonable to assume that occasional "showering" with organisms from superficial wounds, abscesses, or the respiratory or GI tracts can be a source of infection. *Trueperella pyogenes* seems to be a frequent cause of the suppurative and abscessation. Osteomyelitis of the ulnar epiphysis in young boars and sows has been reported.

Vertebral osteomyelitis and epidural abscesses can cause a variety of signs, including nonspecific lameness, hypermetria, ataxia, or bilateral flaccid paralysis of the pelvic limbs. Except for the temporal nature of the infectious process, clinically it is difficult to differentiate a destructive or space-occupying abscess from a fracture. Regardless of underlying cause, recovery is unlikely, and the pigs should be culled.

Osteochondrosis and Leg Weakness Syndrome (Degenerative Joint Disease, Dyschondroplasia):

Degenerative joint disease (DJD) and leg weakness syndrome are generic terms for a clinical syndrome that is a major cause of lameness and culling for lameness in swine breeding stock. Although the conditions are more often investigated in purebred stock, they can cause major losses in commercial pig herds. Given the increased scale of production in many herds and the shift toward pigs that grow faster, are more muscular, and finish heavier, DJD and leg weakness are critical issues.

Osteochondrosis is a specific developmental condition that represents the major cause of DJD. Osteochondrosis is a defect in the development of cartilage of the growth plates or articular cartilage in growing pigs. The pathogenesis of osteochondrosis is increasingly but still incompletely understood. In osteochondrosis, growth plates are more prone to fracture because of areas of retained hypertrophic cartilage that focally thicken and weaken the cartilage. Lesions develop when articular cartilage on the interior aspect of the joint surface becomes necrotic, ostensibly due to loss of vascular supplies. The necrotic cartilage interferes with the advancing ossification front, and the resulting irregular ossification underlying the weight-bearing cartilage surfaces is prone to cleaving (displaced cartilage "chips," or osteochondrosis dissecans), exposing the endochondral bone and causing pain and lameness. The developmental lesions have a very high prevalence in young pigs but mostly resolve with age and further development.

Osteochondrosis is apparently seen in all the major breeds of purebred and commer-

cial hybrid pigs. Dyschondroplasia results in deformed long bones, particularly the ulna. Pigs that have valgus deformity or permanently flexed carpi tend to be unsuitable for sale as breeding stock and may be lame. In addition, epiphyseolysis and epiphyseal separation may be precipitated by weakening of underlying growth plates and cause an incapacitating lameness.

Although lesions that precede or develop into DJD or result in limb deformities begin to develop in younger pigs, clinical problems are not usually seen until pigs are >4–8 mo old. Frequently, the fastest growing, most muscular, and heaviest pigs are affected. Given time, some pigs (if not culled) recover from episodes of lameness, but deformities remain. Clinical signs vary with the site and extent of lesions and can range from stiffness and a shortened stride or a stride affected by an angular limb deformity to a three-legged lameness or an inability to stand. Most commonly, these animals have a weight-bearing, shifting lameness because of bilateral lesions that affect multiple joints in the same pig. Pigs that "walk" on flexed carpi usually have severe DJD in the elbows, and pigs that tuck their pelvic limbs under their abdomen in a stance that resembles a "circus elephant balancing on a ball" often have DJD that affects stifles, tibial tarsal bones, or joints on intervertebral processes.

If epiphyseal separation of the femoral head has occurred, the pig has difficulty standing and initially will not use the affected limb. A pig that has unilateral separation of the ischiatic tuberosity also has difficulty standing and a tendency to slip; if both tuberosities are affected, the pig has a hopping gait for a few steps after being lifted and then collapses. The severity of clinical signs in any of these conditions varies, and joints with less extensive lesions appear to be protected by the gait if they are more painful than other degenerating joints. Severe joint lesions also have been seen in pigs that did not appear to be lame.

In pigs that have limb deformities (eg, dyschondroplasia affecting the distal ulnar growth plate), thickened, irregular growth plates are seen on radiographs or at necropsy. In degenerating joints, there is an excess of yellow synovia, and synovial villi may have proliferated. There are various irregularities of the articular surface, including folds in the cartilage, clefts into the cartilage, flaps of cartilage, and in severe cases, craters and exposed subchondral bone. In chronic cases, osteophytes develop, detached fragments of cartilage

become embedded in the synovium and start to ossify, and craters fill with fibrocartilage. If vertebral joints are affected, vertebrae eventually fuse. Growth plates that are most severely affected by dyschondroplasia are those of the distal part of the ulna and the ribs, whereas joints most often affected by DJD include the elbow, stifle, and hock, or the intervertebral synovial joints.

Many potential causes of DJD or osteochondrosis have been investigated. There is evidence of a genetic component, because within breeds, specific boars have been identified to have progeny with a higher incidence of osteochondrosis. Breeds and lines of pigs that are heavy and well muscled, particularly in the hams, are commonly affected; therefore, crossbreeding for hybrid vigor (ie, to create faster growing, muscular hybrids) does not solve the problem. The fastest growing pigs in a group seem to have a greater propensity for lesions to develop in either growth plates or joints, but once slower-growing pigs reach the body weight of their faster-growing peers, lesions are comparable. Growth hormone may affect chondrocyte metabolism and thereby influence the onset of articular lesions.

Research into manipulating the energy, protein, and mineral concentrations of the ration in an attempt to influence the development of lesions has been inconclusive, even contradictory. None of the imbalances or deficiencies of nutrients that typically are associated with lesions of cartilage or bone (calcium, phosphorus, and vitamins A, C, and D) seemed to exacerbate osteochondrosis. Deficient or excess zinc and manganese may be causal factors in osteochondrosis, but there is a paucity of evidence from research.

The stress of mixing pigs appears to have little impact on the frequency of osteochondrosis, but trauma from handling or housing conditions have been found to affect clinical osteochondrosis. The culling rate due to lameness for sows kept on solid floors is less than that for those kept on slats, but the benefits of placing pigs with DJD on dirt lots or pasture is equivocal. Although such pigs usually become clinically sound within 6 wk, they are potential carriers of the syndromes.

Because osteochondrosis and DJD interfere with production efficiency, the prognosis for affected pigs is poor. At best, the following practices are recommended: selecting against replacement pigs that are lame or have poor conformation, providing adequate rations for the growth of a strong

skeleton, housing gilts in pens with ≥ 12 sq ft (1.1 sq m) per animal, and promoting exercise on nonslip floors. In problem herds, providing a "hardening off" period for gilts is encouraged. This includes purchasing gilts at <75 kg live weight, restricting their feed intake to slow their growth rate, providing ≥ 1.1 sq m per animal in pens with solid or only partially slatted floors, waiting to breed gilts until they are 8–10 mo old, and housing gilts in pens until they farrow. If replacements are purchased, suitable breeding stock must be found and inferior pigs rejected at the time of arrival at the farm.

Foot Disorders: Foot lesions can be quite prevalent and severe among sows and boars and have been shown to cause lameness and reduce productivity and longevity of breeding stock. Specific lesions particularly associated with lameness include white line lesions, heel-sole cracks, and heel overgrowth with erosions, but any of the lesions can be significant in individual cases.

As with finishing pigs, floor type and condition are important with respect to lesion development. Housing type and management are also important risk factors for various types of foot lesions. Nutrition, including water quality, can affect the growth rate and quality of the horn wall and heel epithelium.

Bacterial infections of the foot can develop in any age pig but cause serious losses in breeding pigs. Bacterial infections are often a sequelae of foot lesions that allow penetration of bacteria into underlying sensitive foot structures. Foot infections are seen in both confinement and semiconfinement systems, with morbidity of 20%–68%. Often a single limb is affected, and the lameness progresses to the point that the pig is three-legged lame.

Lesions usually develop gradually, and the foot becomes swollen. Lesions vary in severity and can include heel erosions, separation along the white line, toe erosions, sole erosions, vertical hoof wall cracks, deep necrotic ulcers, sinuses at the coronary band, and chronic fibrosis. A mix of organisms has been isolated from the lesions or identified in smears from lesions and tissue sections. These included *Trueperella pyogenes*, *Fusobacterium necrophorum*, *Borrelia suis*, and a mixture of gram-negative and gram-positive cocci and rods.

A diagnosis is made from the clinical signs and a thorough evaluation of the feet. Ideally, the whole foot should be examined in a recumbent or suitably restrained pig. If there is a herd problem, all sows in crates

or pens should be examined. Whenever possible, feet of pigs from affected herds should be evaluated at the slaughterhouse. Superficial examination of some less extensive lesions may lead to inappropriate cause-effect conclusions. Therefore, to ensure that lesions are severe enough to be the cause of the lameness, some pigs can be culled for diagnosis of the problem and their feet sectioned or claws removed after immersing the foot in 140°F water for 60 min to determine whether the soft tissues and bones within the foot are infected.

Treatment of apparent foot infections with penicillin has been commonly practiced (200,000 U into the lesion or 600,000 U, IM), but effectiveness has not been proved and success decreases with chronicity of the lesion. Prevention is a more productive longterm strategy, and it involves improving the nature and cleanliness of the flooring, reducing moisture, resurfacing rough, abrasive areas, and ensuring nutritional adequacy for hoof health. As replacement gilts mature, biotin and trace mineral supplementation enhances the quality and strength of the hoof, and use in breeding sows is recommended.

Trauma: Trauma associated with overexertion can cause detachment of

muscle tendons and a proliferative osteitis on the medial humeral epicondyle and the greater trochanter of the femur in sows. Mixing gilts or sows before or after breeding or at weaning commonly results in pigs becoming injured as they reestablish a social order. This can lead directly to fractures of long bones or skin abrasions that may cause secondary bacterial infections.

Traumatic injuries can also result from movement of groups to and from farrowing facilities, especially movements of gilts into farrowing. Gilts typically are more anxious and flighty than older sows. Carrying a heavy, gravid uterus over potentially slippery flooring over some distance poses a high enough risk of injury without adding other stressors. Movement should be calm and deliberate, with small groups of gilts and sows moved at a time to reduce potential injuries.

Sows housed in stalls with concrete slats may tear their dewclaws when they attempt to stand. Treatment with appropriate antibiotics, protection of the wound with a dressing, and isolation in a hospital pen that has clean, deep bedding should enable a lesion to heal. Prevention by trimming elongated dewclaws is a prudent and simple management practice.

LAMENESS IN SHEEP

Lameness in sheep may be caused by a number of systemic diseases, some of which include navel/joint ill (*Escherichia coli* and *Erysipelothrix*), tetanus, white muscle disease, frostbite, chlamydial polyarthritis, rickets, enzootic ataxia (copper deficiency), mastitis, orchitis, nutritional osteodystrophies, selenium toxicosis, laminitis, dermatophilosis, bluetongue, ulcerative dermatosis, and in some countries, foot-and-mouth disease. Weakness, ataxia, and neurologic problems may be misinterpreted as lameness in diseases such as scrapie, listeriosis, and visna. Additional information on differential diagnosis, treatment, and prevention can be found under the specific topics (see p 1039 and p 1209).

Lamenesses are often due to injuries. Broken legs are common in young lambs, which are frequently injured inadvertently by adults. Usually, these can be easily

splinted and will heal within 3 wk. However, leaving the limb splinted and unobserved for too long may also lead to iatrogenic lameness. The general principles of treatment and prevention of these are the same as in other species.

Lameness can be caused by a group of infections specific to the feet. The most well known of these is contagious footrot, a mixed infection with *Fusobacterium necrophorum* and the obligate pathogen *Dichelobacter nodosus*. The skin between the claws is the primary site of invasion; it is predisposed to infection by breaks in the epidermis from injury or maceration from prolonged exposure to moisture. *F. necrophorum* and *Trueperella pyogenes* induce a transient condition called ovine interdigital dermatitis or foot scald, which may lead to more serious problems.

INTERDIGITAL DERMATITIS

(Foot scald)

This necrotizing condition of the interdigital skin usually precedes or accompanies footrot. In Australia, it is considered to be caused by less virulent strains of *Dichelobacter nodosus* and is termed benign footrot (see below). Wet weather, damp pastures, and mud are predisposing factors. In milder cases, the interdigital skin is red, hairless, swollen, and moist. In severely affected cases, the integrity of the interdigital skin is compromised, exposing subcutaneous tissues. Suppuration and swelling of the deeper interdigital tissues may develop. Lameness can affect as many as 90% of sheep, and all four feet may be affected. The characteristic smell associated with virulent *D nodosus* infections is not present if *D nodosus* is not present. Healing is rapid when conditions dry out, but the disease may recur when conditions again become wet.

Because scald usually precedes a footrot outbreak, it is prudent to treat the condition as if it were footrot. Other diseases to consider in the differential diagnosis include dermatophilosis (strawberry footrot, see p 858), which affects the hairy skin of the coronet and pastern. Viral diseases such as ulcerative dermatitis, contagious ecthyma, and foot-and-mouth disease may be excluded by flock history, clinical signs, electron microscopy, and serology. Currently, the treatment of choice consists of external application of 10% w/v zinc sulfate disinfectants via a footbath or aerosol.

CONTAGIOUS FOOTROT

When there is concurrent invasion by *Dichelobacter nodosus* of foot scald, contagious footrot results. The Australians separate footrot into two categories, benign or virulent, depending on the strain of *D nodosus* present. In the USA, however, benign and virulent footrot are considered to be the same (due to the difficulty of differentiating the two) and are treated accordingly.

Benign Footrot

The infection is confined largely to the interdigital skin, with only minimal underrunning of the adjacent horn. Clinically, benign footrot appears similar to ovine interdigital dermatitis, but *D nodosus* is involved—a situation that is hard to assess because culture of *D nodosus* is difficult and rarely done. The odor, however, is characteristic. Lameness is common but less severe

than in virulent footrot. The etiology and pathogenesis are the same, but the strains of *D nodosus* are less virulent and lack the hoof-invasive properties of the strains that cause virulent footrot. *D nodosus* may also be isolated from cattle, but strains affecting cattle usually cause only the benign form of footrot in sheep. The economic effect of benign footrot is much less than that of virulent footrot. Running the sheep through foot baths containing 10% w/v zinc sulfate once every 14 days during the wet season is usually adequate for control. Since the advent of long-acting antibiotics such as tetracycline, their use has been adopted with good results.

Virulent Footrot

Virulent footrot is a specific, chronic, necrotizing disease of the epidermis of the interdigital skin and hoof matrix that begins as an interdigital dermatitis and extends to involve large areas of the hoof matrix. Because the sensitive lamina and its network of capillaries are destroyed by the infection, the hoof wall (corium) loses its blood supply and anchorage to the underlying tissue and becomes detached. Footrot is extremely contagious and, under suitable conditions and susceptible genetics, morbidity may approach 100%. The infection is also rarely found in goats, deer, and cattle. The potential for genetic selection for increased resistance to footrot has been established.

Etiology: *Fusobacterium necrophorum*, a gram-negative anaerobic bacteria, is a normal resident of manure-contaminated environments. Under favorable environmental conditions, it colonizes the moist, macerated interdigital skin and provides ideal conditions for invasion by *D nodosus* at the skin/hof interface. By action of proteases, *D nodosus*, also a gram-negative anaerobe and obligate pathogen, liquefies the cells of the stratum granulosum and stratum spinosum, causing the separation of the hoof wall from the basal epithelium. It works its way down the interdigital horn to the heel, then to the sole, and finally to the lateral side of the hoof. *D nodosus* has been found to survive <3 wk outside the host, but it can remain sequestered in cavities, cracks, or deformities of the affected foot for the life of the sheep. There are at least 20 different strains of *D nodosus*, with varying pathogenicity. Transmission occurs most rapidly when conditions are warm and moist; however, cold, moist conditions are also conducive to transmission.

Clinical Findings: The most obvious sign is lameness, but the foot is seldom carried or packed. In chronically infected sheep, the hoof becomes gnarled and distorted. When more than one foot is infected, some sheep become recumbent or walk on their knees. Brisket and knees tend to become hairless and ulcerated. Affected sheep do not compete well for food, lose body condition, and produce less wool. Rams with infected hindfeet may be unwilling to breed, and ewes with hindfeet lesions may be unable to bear the weight of a ram at service.

In early cases, examination of the feet generally reveals nothing more than interdigital dermatitis. In slightly more advanced cases, in which the infection has begun to extend into the hoof matrix, there is slight detachment of the hoof wall at the interface of the interdigital skin and hoof. As the disease progresses, the separation of the horn spreads further under the heel and sole. Running one's thumb between the wall and the underlying tissue in the interdigital space often detaches the wall from the heel and sole, revealing a white, slightly moist (but not purulent), odorous substance. Finally, the outer wall is affected. The horny hoof may eventually be attached only at the toe and the coronet on the lateral side of the foot. The odor of the necrotic tissue is characteristic and helps to diagnose the disease. Myiasis is a common sequela during fly season; it may extend to the area of the sheep where the infected feet come into contact with the body when the sheep is recumbent. The clinical disease persists until the environment dries or the sheep are treated. After apparent healing, *D nodosus* remains hidden in small pockets within the foot, where it is detectable only by extensive trimming, and becomes active again when moist conditions recur. These sheep are carriers and generally remain infected for life. Immunity to footrot after infection does not seem to occur, because relapses are the norm.

Diagnosis: In flocks with virulent footrot, underrunning and separation of the hard horn of the hoof of one or more feet, complete with the characteristic odor, is diagnostic. If the problem is discovered early when interdigital dermatitis is the only sign, it should be assumed that the condition is an early stage of contagious footrot, and treatment should be initiated immediately.

Treatment: Treatment efforts may be directed toward temporary control of the disease or total eradication. At certain

times, eg, during a wet season, temporary control may be the only realistic goal.

Traditionally, treatment consisted of foot bathing using antibacterial solutions after careful hoof trimming to remove all dead horn and expose infected tissue and bacteria to air. However, foot soaking for 30–60 min has been shown to be more effective even when trimming is not done. In fact, Australian research has shown that trimming may do more damage than good. The most effective solution is 10% w/v zinc sulfate with 0.2% v/v of laundry detergent containing nonionic surfactants such as sodium lauryl sulfate. Aerosol sprays have been used in lieu of foot bathing and include zinc sulfate, tincture of iodine, tetracycline, copper sulfate, formalin, chlorine bleach, and other disinfectants. However, sprays are not as effective as foot bathing or soaking in zinc sulfate.

The advent of long-acting antibiotics used in combination with topical foot treatments has improved recovery and reduced carrier animals. Parenteral treatment using a long-acting oxytetracycline at 13.6 mg/lb gives a duration of effect in cattle of 7–8 days and probably a similar duration of effect in sheep. However, sheep must be placed in a "clean" area (ie, one in which no sheep have been kept for at least 3 wk) or in a completely dry lot after they are run through a foot bath and given the antibiotic. Sheep will become reinfected as soon as the antibiotic is cleared if returned to a contaminated environment. The feet of treated sheep should be examined once a week to identify those not responding to treatment. Sheep that do not respond should be isolated and preferably culled. *D nodosus* is extremely difficult to eradicate from animals that have relapsed numerous times. Furthermore, subclinical or relapsing cases take valuable time to handle, identify, and isolate, and they remain a source of infection for other animals.

Prevention and Control: Animals from unknown premises or auction houses should not be purchased. Any sheep to be added to the flock should be quarantined for several weeks to prevent the spread of footrot and other chronic diseases. During the quarantine period, the animal's feet should be lightly trimmed and examined closely for pockets and other malformations that suggest a previous *D nodosus* infection. Vehicles (eg, trucks, trailers) or facilities in which unknown or infected sheep have been held should be thoroughly cleaned and disinfected before placing uninfected sheep in them. If it is not

possible to thoroughly disinfect transport vehicles, zinc sulfate can be liberally scattered over the floor to reduce viable bacteria.

Because the incubation period of footrot is ~14 days, foot bathing at 10-day intervals will control spread of the organism in affected flocks during periods of the year when the sheep are in wet conditions. Footrot has been controlled by placing foot baths with 10% w/v zinc sulfate solution around water troughs, forcing sheep to walk through them and stand in order to drink. Lamé sheep should be separated for treatment and not returned to the flock until all evidence of footrot is gone.

D nodosus vaccines accelerate healing in affected sheep and aid in protecting unaffected sheep. They are recommended as an additional tool to control or eradicate the disease. However, their effectiveness depends on the strain(s) causing the infection and those present in the vaccine. No vaccine contains all the various strains of *D nodosus*, and use of vaccination without other means of control will most likely select for strains not contained in the vaccine. Alum-precipitated vaccines require two doses 4–6 wk apart to establish effective immunity, which persists for 2–3 mo. Lesions heal within 4–6 wk if immunity is established. Oil-emulsion vaccines induce immunity within 3 wk of the initial dose and may persist for 3–4 mo. In endemic areas, revaccination is recommended at intervals of 3–6 mo. Reaction to the vaccine is common, resulting in large granulomas and occasional abscesses. Vaccines for *F necrophorum* have not generally shown much benefit in either treatment or prevention. Lately, the vaccine appears to be unavailable in the USA.

Addition of zinc to trace mineral salt, reportedly effective in reducing hoof rot in cattle, has not been shown to be particularly helpful for sheep footrot. However, zinc is important for immunity and skin/hoof health. Providing it in a well-balanced trace mineral mix may be helpful in locations deficient in zinc.

Eradication: A successful eradication program requires planning, commitment, and an investment of time and money. Eradication can be achieved only by eliminating all cases of *D nodosus* infection in a flock and preventing its reintroduction. This may be done by replacing affected stock with footrot-free sheep or by rigorously treating all new infections and culling affected sheep that do not respond readily to treatment. Eradication is easiest

when the environment is dry; at other times, treatments should be directed more toward control of transmission. Affected sheep have to be identified by close examination of all four feet; no other diagnostic tests are available (although some exciting European research using PCR and interdigital swab samples is showing great promise as a diagnostic tool). Subclinical cases constitute a major problem. They will relapse as soon as they are placed in wet conditions and the infection spreads rapidly. Other ruminants (goats, deer, cattle) are potential sources of *D nodosus*. If they are in contact with the sheep, they should be considered in the eradication program.

To begin, the feet of all sheep should be trimmed and carefully examined. The flock should then be divided into affected and unaffected groups. Sheep with no visible lesions are foot bathed, isolated, and placed on “clean,” dry ground. (This group may have some degree of genetic resistance, and identifying them in some way is recommended. Retaining offspring from this group could further help control the disease.) This group should receive an injection of long-acting tetracycline at 13.6 mg/lb, and any lame sheep should be removed immediately. The group of sheep with footrot lesions are culled or, after careful hoof trimming, the feet are soaked for at least 30 min, and the animals are treated with antibiotic and kept separated from the lesion-free group. This second group should undergo foot soaking once a week for a total of three times and/or be medicated with long-acting oxytetracycline at the time of soaking. At the end of this period, their feet should again be examined and trimmed. Any sheep with an active case of footrot should be culled. This group must be monitored closely during the next wet period to detect any carriers, which are usually the first animals to show lameness. When no relapses have occurred for 1 mo or longer, this group may be placed with the clean flock. However, placing a single active or subclinical case in the clean flock can negate all of the previous hard work.

Australia has implemented an effective eradication program involving many flocks. The program has three phases. The **control phase** is used during periods of active spread or to reduce the number infected. During this phase, vaccination, foot bathing, and parenteral antibiotics can all be used. The **eradication phase** must take place during the dry season and cannot begin until several weeks after the use of all medications has been stopped and 10–12 wk after vaccination. Foot bathing and vaccination

tend to mask the presence of infection.

During this phase, all four feet of every sheep are inspected every 3–4 wk. Infected sheep can be treated with parenteral antibiotics at the first inspection only. After this, infected sheep are culled at each inspection. This continues until there are two completely negative, consecutive flock examinations. In the **surveillance phase**, all lame sheep in the flock are examined immediately. If footrot is present, the flock goes back to phase 1 or 2 again.

FOOT ABSCESS

(Infective bulbar necrosis, Heel abscess, Bumblefoot)

Bumblefoot is a necrotizing or purulent infection involving the distal interphalangeal soft tissues and sometimes the joint. The incidence is usually sporadic, but as much as 25% of the flock may be affected.

The two organisms most consistently recovered from bumblefoot are *Fusobacterium necrophorum* and *Trueperella pyogenes*. Foot abscesses may develop as a complication of ovine interdigital dermatitis by extension of the necrotic process into the subcutis and then into the distal interphalangeal joint. They also commonly develop after penetration of the interdigital skin by sharp objects (eg, crusted snow, frozen or stiff stubble of alfalfa and grain), bruising of the foot and injury of the skin when slipping on frozen rocks, or even careless paring of the hoof. This joint is vulnerable to infection on the interdigital aspect where the joint capsule protrudes above the coronary border as the dorsal and volar pouches. At these sites, the joint capsule is protected only by the interdigital skin and a minimal amount of subcutaneous tissue.

Foot abscesses often develop when the soil and pastures are wet or frozen. The disease causes an acute lameness that is usually restricted to one foot, which the sheep will not place on the ground. It may be possible to express necrotic material through an opening in the interdigital skin caused by the bacterial invasion, but more commonly the swollen sinuses break open and drain at one or more points above the coronet. If this does not occur, the swelling will have to be lanced. In some instances, movement of the affected digit is exaggerated, indicating that the ligaments about the distal interphalangeal joint have ruptured. Displacement of the digit during locomotion and permanent deformity are likely in those cases.

Acute lameness with the sheep packing a foot, swelling of one digit, and discharging sinuses distinguish foot abscess from footrot.

Early treatment with parenteral long-acting antibiotics is sometimes effective and may prevent joint infection. The therapy aims to maintain the integrity of the joint ligaments by draining the abscess and applying an antibacterial preparation and a self-adhesive bandage. This reduces stress on the ligaments, keeps the lesion out of the mud, and counters the bacterial infection. Although the prognosis for complete recovery is poor, in most cases the foot heals sufficiently to allow adequate locomotion. Once the infection becomes established in the joint, conservative treatment is not effective. However, a toe can be surgically removed (if the other digit is healthy) with relatively good success.

Control depends on early treatment and moving the sheep to avoid conditions that lead to ovine interdigital dermatitis or other causes of abscess. Although *F. necrophorum* vaccines are available, they have not proved to be very effective.

IMPACTED OR INFECTED OIL GLAND

Sheep have a sebaceous (oil) gland in the skin of the interdigital space. A thick, oily, translucent secretion is stored in a small pouch lying between the phalanges and is discharged to the skin surface through a duct in the skin. Occasionally, the gland and its contents are mistaken for an abscess. However, the duct can become occluded, causing distention of the oil pouch. It rarely causes lameness. The oil sac also may become infected, resulting in a local cellulitis or abscess that may be confused with bumblefoot. Expression of the contents by manual pressure relieves impaction. Infected glands can then be treated with local or systemic antibiotics or both, depending on the extent and severity of the infectious process. Unlike bumblefoot, this condition generally responds readily to treatment.

INTERDIGITAL FIBROMA

An interdigital fibroma is a mass of fibrous tissue between the toes that may resemble a papilloma. If not removed, it enlarges, spreading the toes. Tendrils grow upward between the first phalanges, causing severe lameness. If the fibroma is detected early,

surgical removal (cryosurgery and electrocautery) may be successful; however, by the time it causes lameness, the tendrils cannot be totally removed from between the phalanges, and the fibroma tends to recur.

SEPTIC LAMINITIS

(Lamellar suppurative, Toe abscess)

Septic laminitis is an acute bacterial infection of the laminar matrix of the hoof that is usually restricted to the toe and abaxial wall. The disease is sporadic and the cause variable, but cases due to *Fusobacterium necrophorum* and *Trueperella pyogenes* usually are more severe and extensive than those involving streptococci

or other organisms. The organisms probably enter through fissures between the wall and sole and through vertical and horizontal fractures of wall horn. Sometimes, infection is enhanced by impaction with sand, mud, or feces; by overgrowth of the hoof; or by separation of the wall after laminitis.

Forefeet are affected more commonly. Lameness is severe, and the affected digit may be hot and tender. There may be a draining sinus above the lesion at the coronet, or the abscess may be found above the sole on the bottom of the foot. Applying pressure to various sections of the sole with the thumbs will elicit pain and help locate the pocket of infection. Affected sheep usually recover rapidly after paring of the horn to provide dependent drainage.

MYOPATHIES IN RUMINANTS AND PIGS

INFECTIOUS MYOPATHIES

Clostridial Myonecrosis

(Blackleg, Malignant edema, False blackleg, Gas gangrene, Gangrene)

Clostridial infection of skeletal muscle is a noncontagious cause of acute myonecrosis. *Clostridium chauvoei*, *C. septicum*, *C. sordellii*, occasionally *C. novyi* type B, *C. perfringens* type A, *C. carnis*, or mixed infections involving several agents are common (see p 601). *Clostridia* or their spores are ubiquitous in the environment, feces, intestinal tract, and other internal organs of a variety of species. Clostridial myonecrosis may develop after introduction of spores via an IM injection or penetrating wound or through sporulation of organisms already present in muscle when suitable anaerobic conditions are created with muscle trauma. Any skeletal muscle group in the body can be involved, but most infections affect the limb or trunk muscles. Occasionally, muscles such as those around the vulva, tongue, and diaphragm can be involved, or the udder in a cow may be the primary site of sepsis. The release of powerful exotoxins by multiplying clostridia is responsible for the local tissue damage, systemic toxemia, and widespread organ dysfunction. The toxins of *C. sordellii* are the most potent of all the

clostridial species, and myonecrosis caused by this organism is fatal.

Infections are characterized by a rapid clinical course, fever (104°–106°F [40°–41°C]), lameness, systemic toxemia, tremors, ataxia, and dyspnea, often followed in 12–24 hr by recumbency, coma, and death. Mortality may approach 100%. Initially, the skin over the area may be swollen, hot, and discolored; however, as the disease progresses, the skin over the area may become cool and insensitive with progressive sloughing. Crepitus may be detectable, indicating subcutaneous gas production. If a wound is present, malodorous, serosanguineous discharge may be seen. Hematology and serum biochemical analyses usually reflect hemoconcentration and a stress/toxic leukogram with increased activities of serum CK and serum AST that often do not reflect the toxicity of clostridial myonecrosis. A definitive diagnosis is made from direct smear examination, fluorescent antibody testing, or anaerobic bacterial culture of aspirates of affected tissues. Differential diagnoses include other fulminant disease processes in which there is rapid debilitation or death of the animal.

Clostridial myonecrosis generally has characteristic pathologic lesions that are absent in most other conditions, making diagnosis relatively straightforward. Swelling and autolysis are rapid in animals

that have died from clostridial myonecrosis, and the carcass usually has a foul odor similar to that of rancid butter. This odor is a characteristic of most cases of clostridial myonecrosis. *C chauvoei* infection is characterized by engorgement of the subcutis and adjacent tissues with bloodstained fluids and gas bubbles. Cut tissue from the affected area reveals moist, dark-colored muscle in the periphery of the lesion, with lighter-colored, drier muscle with gas bubbles between the separate bundles of muscle toward the center. Lesions are similar in sheep and cattle, except that there is usually less gas and the muscles are not as dry in affected sheep. Myonecrosis resulting from *C sordelli* is most often associated with lesions of the neck or brisket area of cattle; death is frequently so rapid that subcutaneous gas accumulation is rare. In addition to local myonecrosis, animals often have massive subendocardial hemorrhages in the left ventricle of the heart and hemorrhage in the trachea, bronchi, and thymus. Extensive perirenal edema and hemorrhagic renal calyces and severe congestion of the lungs are common findings.

Antibiotic therapy and aggressive surgical debridement may be attempted in the individual animal; however, most cases are usually fatal. Penicillin at a dosage of 44,000 U/kg, IV, every 2–4 hr is given until the animal is stable (1–5 days). Use of specific antitoxins is recommended when possible. Supportive fluid therapy and use of analgesics and anti-inflammatory agents for control of pain and swelling are recommended. Short-acting corticosteroids may be used for initial therapy of systemic and toxic shock, but continued use is contraindicated in the face of overwhelming sepsis.

Vaccination beginning at 4–6 mo in cattle with bacterins containing antigens against two or more clostridial species, including *C chauvoei*, *C septicum*, *C novyi*, *C sordelli*, and *C perfringens* is recommended. For all clostridial species except *C chauvoei*, two doses of vaccine are necessary to establish good protection. Booster vaccinations should be administered every 6–8 mo if protection is to be maintained.

Sarcocystosis

Cysts of *Sarcocystis* are common in the heart, esophageal, and skeletal muscle of cattle, sheep, goats, and other species but rarely cause disease. Heavy infestations of sarcocystis may cause fever, mild anemia, chronic myositis, and muscle wasting.

S cruzi, *S hirsuta*, and *S hominis* are known to infect cattle, whereas *S ovicanis* and *S capracanis* infect sheep and goats. The most common mechanism for natural infection in cattle is by ingestion of feeds contaminated with infected carnivore feces. (For complete discussion of sarcocystosis, see p 1058.)

NUTRITIONAL MYOPATHIES

Nutritional Myodegeneration

(White muscle disease, Stiff lamb disease, Nutritional muscular dystrophy)

Nutritional myodegeneration (NMD) is an acute, degenerative disease of cardiac and skeletal muscle caused by a dietary deficiency of selenium or vitamin E in young, rapidly growing calves, lambs, and kids. Dams usually consumed selenium-deficient diets during gestation. Selenium deficiency appears to be more important than vitamin E in preventing NMD. NMD occurs worldwide in areas where the soil (and therefore the derived grains and forage) is deficient in selenium, and storage conditions do not preserve vitamin E in forages. Soil in the northeastern and eastern seaboard and northwestern regions of the USA are particularly deficient in selenium. Vitamin E deficiency occurs most commonly when animals are fed poor-quality hay, straw, or root crops.

Selenium is an essential component of five antioxidant selenoproteins, and vitamin E acts as an antioxidant within lipid bilayers. Muscle degeneration is the result of oxidant damage to cell membranes and proteins, leading to a loss of cellular integrity. Young, rapidly growing animals usually are affected, although the disease has also been reported in yearling and adult cattle. When cardiac muscle is primarily affected, animals may be found in respiratory distress, have cardiac arrhythmias, or be found dead. In such cases, the clinical course is frequently short, with death occurring commonly in <24 hr despite medical therapy. When skeletal muscle is primarily affected, signs of muscle weakness, stiffness, and difficulty rising are seen. Most affected animals are able to remain standing only for short periods, and locomotor muscles may be firm and painful on palpation. If the respiratory muscles are affected, the animal may show respiratory distress and evidence of increased abdominal effort when breathing. The muscles of the tongue may be involved, resulting in dysphagia. Animals with

skeletal NMD often respond favorably to treatment and rest. Improvement is evident after a few days; within 3–5 days, animals can often stand and walk.

Differential diagnoses include infectious diseases resulting in septicemia, pneumonia, and toxemia; cardiac anomalies; cardiotoxic agents such as those found in plants (oleander, senna, yew, white snakeroot, and gossypol toxicity from cottonseed); and the ionophore antibiotics. Other diseases causing stiffness of gait, weakness, and recumbency with no change in mental status include spinal cord compression, cerebellar disease, suppurative and nonsuppurative meningitis/nyelitis, polyarthritis, neurotoxins such as organophosphates, tetanus, pelvic fractures, parasitic myositis, clostridial myositis, and traumatic injuries.

Supportive evidence of NMD includes increased levels of CK, AST, and LDH. Definitive diagnosis is based on demonstration of low whole blood selenium (normal range >0.1 ppm) or liver content (normal cattle 0.9 – 1.75 mcg/g of dry matter, sheep 0.9 – 3.5 mcg/g dry matter). The critical concentration of vitamin E (α -tocopherol) in plasma is 1.1 – 2 ppm in large animals. Vitamin E deteriorates rapidly in plasma samples. Therefore, plasma samples for α -tocopherol analysis should be put on ice immediately, protected from light by wrapping in foil, and stored at -21°F (-70°C) if analysis is to be delayed.

Bilaterally symmetric myodegeneration is a consistent finding in NMD. Skeletal muscle degeneration is characterized by pale discoloration and a dry appearance of affected muscle, white streaks in muscle bundles, calcification, and intramuscular edema. The white streaks seen in cardiac and skeletal muscle bundles represent bands of coagulation necrosis or, in chronic cases, fibrosis and calcification. In calves, the left ventricle and septum are most frequently involved, but both ventricles are usually involved in lambs. Histologically, affected muscle fibers may be hypercontracted and fragmented, with some mineralization of muscle fibers and others undergoing macrophage infiltration.

The cardiac form of NMD is often incompatible with life, whereas the skeletal form may respond to injectable selenium products. The label dosage for selenium is 0.055 – 0.067 mg/kg (2.5 – 3 mg/45 kg), IM or SC. Dosage of these injectable products should not be greatly increased above that on the label to prevent an inadvertent selenium toxicosis. When using vitamin E/selenium combinations, the amount of

vitamin E is insufficient for supplementation; it is present only as a preservative for the solution. Injectable vitamin E products that contain 300 and 500 IU vitamin E per mL as $\text{D-}\alpha$ -tocopherol are available. Oral supplementation is the general approach to provide additional dietary levels of vitamin E. Recommended levels of supplementation for calves range from 15 to 60 mg of DL- α -tocopherol acetate per kg of dry feed. Antibiotics may be indicated to combat secondary pneumonia. Provision of adequate energy intake and attention to the fluid and electrolyte balance are critical if recovery is to be successful.

Under current federal regulations in the USA, selenium can be incorporated into the total ration of ruminants and other species to a level of 0.3 ppm. In salt/mineral mixtures formulated for free-choice feeding, selenium can be incorporated at 90 ppm for sheep and 120 ppm for cattle. In certain areas or in herds, levels as high as 200 ppm selenium in salt/mineral mixtures may be necessary to maintain adequate selenium levels. Federal regulations limit the intake of supplemental selenium to 0.7 mg/head/day in sheep and 3 mg/head/day in cattle. The use in ruminants of rumen-reticular boluses, which release a precise amount of selenium daily, is common in many countries; however, under current FDA guidelines such products are not available in the USA. These slow-release boluses can replace supplementation by salt mixtures or by injections and are extremely valuable in extensive grazing systems. Alternatively, individual animals can be supplemented by periodic (30 - to 60 -day intervals) injections of selenium/vitamin E preparations to help maintain body concentrations and assist in transplacental transfer of selenium.

Regardless of the method of supplementation, periodic blood (or tissue) sampling of animals at risk is recommended to ensure desired levels of selenium. Feeding animals properly prepared and stored hay and grain or allowing access to high-quality, green forage should ensure adequate vitamin E intake.

Hypokalemic Myopathy

Hypokalemic myopathy in dairy cattle occurs when serum potassium concentrations are <2.5 mmol/L, producing severe signs of muscle weakness. Anorexia and enhanced potassium excretion due to the administration of one or more doses of isoflupredone acetate to ketotic cows are common causes of hypokalemia. Isoflupre-

done acetate has both glucocorticoid and mineralocorticoid activity, resulting in a decrease in mean plasma potassium concentration by 25% 2 days after a single injection (20 mg) and 46% in cows 3 days after two injections.

Clinical signs of hypokalemic myopathy include severe weakness, recumbency, abnormal position of the head and neck, rumen hypomotility or atony, abnormal feces, anorexia, and tachycardia. Cardiac dysrhythmia is also common. Diagnosis is based on clinical signs combined with serum potassium of <2.5 mmol/L. Other common clinical chemistry abnormalities include ketosis, metabolic alkalosis, and increased serum CK and AST activities. Muscle biopsies reveal a vacuolar myopathy.

Restoration of whole-body potassium balance can be difficult, and serum potassium concentrations do not necessarily reflect muscle potassium concentrations. Recommended supplementation includes potassium chloride given IV (16 g/100 kg) and PO (26 g/100 kg) for approximately 5 days. Treatments should also be directed at resolving the primary cause of ketosis and anorexia as well as providing supportive care. Survival has been reported to be 22%–79%.

Nutritional Myopathy of Pigs

(Hepatositis dietetica, Mulberry heart disease)

There are several specific diseases of pigs in which muscle degeneration may be extensive (eg, mulberry heart disease) and others in which the degeneration is frequently less conspicuous (eg, hepatosis dietetica). Yellow fat disease (*see* p 1200) may be seen with accompanying myopathy.

Etiology: Mulberry heart disease and hepatosis dietetica are associated with diets low in selenium or vitamin E. Administration of iron dextran to piglets having low vitamin E status may precipitate a severe myopathy (*see* p 3077) with lesions identical to those of selenium or vitamin E deficiency. Other factors that may increase the selenium requirement include diets with low concentrations of protein (especially sulfur-containing amino acids), diets with an excess of selenium antagonistic compounds, and possibly genetic influences on selenium metabolism. Vitamin E may be less available in diets with high concentrations of polyunsaturated fatty acids, vitamin A, or mycotoxins.

Clinical Findings: These conditions have certain characteristics in common. Losses

tend to occur sporadically, and rapidly growing pigs 2–16 wk old are affected. Death almost invariably occurs suddenly and is often precipitated by exercise.

Lesions: In mulberry heart disease, the characteristic lesions are a pericardial sac grossly distended with straw-colored fluid that contains fibrin strands, and extensive hemorrhage throughout the epicardium and myocardium. Microscopically, the heart shows both vascular and myocyte lesions; in addition to interstitial hemorrhage, there is usually extensive myocardial necrosis together with fibrin thrombi in capillaries. If pigs survive for a few days, nervous signs may be seen as a result of focal encephalomalacia.

In hepatosis dietetica, there is often subcutaneous edema and varying amounts of transudate in serous cavities. Fibrin strands adhere to the liver, which has a characteristic mottled appearance caused by irregular foci of parenchymal necrosis and hemorrhage. Acute lesions may appear as scattered, red, swollen lobules and edema of the gallbladder wall. Focal lesions of myocardial necrosis and, less frequently, skeletal myonecrosis may be apparent.

Many pigs that die with selenium or vitamin E deficiency have esophagogastric ulceration or preulcerative changes.

Diagnosis: The history and gross necropsy findings may be distinctive, but histology to demonstrate specific cardiac and skeletal muscle lesions may be necessary. Differential diagnoses for mulberry heart disease include acute septicemic diseases (eg, salmonellosis, erysipelas, and streptococcosis), pericarditis, polyserositis, and edema disease. For hepatosis dietetica, pitch poisoning and gossypol toxicosis should also be considered, as should porcine stress syndrome for pigs with prominent skeletal muscle lesions. Cases of selenium or vitamin E deficiency in pigs can be identified, as in other species, by decreased levels of selenium, vitamin E, and glutathione peroxidase in the serum and tissues and by increased levels of CK and AST in the serum.

Prevention and Treatment: Rations may be supplemented with selenium or vitamin E, or both (as for ruminants). Affected pigs and their herdmates may be given injections of selenium/vitamin E to increase tissue levels rapidly. Injection of sows in late gestation increases tissue levels in newborn piglets.

TOXIC MYOPATHIES

Plant Toxins

Plant toxins affect both cardiac and skeletal muscle. Clinical signs are not specific for the toxin and include anorexia, cardiac failure with tachycardia, dyspnea, diarrhea, stiffness, muscular weakness, recumbency, and myoglobinuria. Myonecrosis may occur when gossypol is fed. Monogastrics, including young calves, should not ingest feed containing >200 ppm gossypol, whereas mature ruminants may tolerate 20 g of gossypol/head/day. *Senna obtusifolia* (sicklepod) is prevalent in the southeastern USA, and ingestion of its seeds by swine or ruminants may cause a degenerative skeletal and/or cardiomyopathy. Trematone is a toxic component of white snakeroot (*Eupatorium rugosum*), which grows in shaded areas of the eastern and central USA, as well as rayless goldenrod (*Isocoma wrightii*), which is common in the Southwest on open pastures. Ingestion of these plants in quantities of ~2% of body weight can cause a fatal cardiomyopathy and severe skeletal muscle degeneration. Trematone remains active in hay and in the stalks of the dead plants on pasture.

Ionophores

Ionophores added to feeds in excess of recommended levels can cause cardiac and skeletal muscle necrosis. Experimental studies have indicated that LD₅₀ values for monensin are 12, 17, 26, and 21–36, for sheep, pigs, goats, and cattle, respectively. Feed concentrations of 100 g/ton and 400 g/ton have been fatal to sheep and cattle, respectively. Newborn calves dosed with 100 mg lasalocid tid for cryptosporidiosis experience muscle necrosis. Other ionophores include naracin, salinomycin, and laidlomycin. At necropsy, pale areas of myocardial necrosis and pulmonary congestion are usually prominent in cattle. Pigs and sheep tend to have mainly skeletal muscle lesions that appear quite similar grossly and histologically to those of nutritional myodegeneration. Diagnosis requires history of exposure with development of characteristic clinical and pathological alterations.

TRAUMATIC MYOPATHIES

Muscle Crush Syndrome of Cattle

Muscle damage commonly accompanies bovine secondary recumbency (see p 1188). Tearing of adductor or semitendinosus/

membranosus muscles may arise as animals weakened by hypocalcemia attempt to rise. Additionally, the weight of a recumbent animal on dependent muscle groups creates significant increases in intramuscular pressure, resulting in decreased perfusion and ischemia of muscle and nerve. Muscle trauma leads to edema and inflammation, both of which may exacerbate local tissue degenerative changes. Mild increases in serum CK can be expected in recumbent cows, but increases >5000 U/L usually indicate traumatic muscle damage. Treatment requires correcting the underlying cause of recumbency, fluid therapy if renal damage is evident, NSAIDs, good nursing care, adequate footing and bedding, and lifting or rolling the animal several times a day. Aquatherapy using float tanks for cattle also appears to help relieve pressure on muscle groups.

GENETIC MYOPATHIES

Caprine Myotonia

Myotonia congenita in goats is due to an autosomal dominant mutation that has incomplete penetrance in the skeletal muscle chloride channel. Goats with this mutation have been selected for as a breed and are commonly referred to as “fainting goats.” Clinical signs ranging from stiffness after rest to marked general rigidity after visual, tactile, or auditory stimulation usually develop by 6 wk of age. These signs remain throughout the animal's life but are not progressive. A diagnosis of myotonia is made by identifying the characteristic “dive bomber” discharges in electromyography and/or by genetic testing.

Congenital Muscular Dystonia in Belgian Blue Cattle

Congenital muscular dystonia in Belgian Blue calves is caused by an autosomal recessive mutation in the gene encoding the neuronal glycine transporter. Affected calves exhibit signs of lateral recumbency, low head carriage, and transient muscle spasms after tactile or auditory stimulation.

Phosphorylase Deficiency in Charolais Cattle

A mutation in the myophosphorylase gene in Charolais cattle produces signs of exercise intolerance and muscle necrosis very similar to nutritional myodegeneration. The disease has been recognized in many countries, including the USA and New

Zealand. Animals become exercise intolerant, may collapse when forced to exercise, and develop muscle necrosis characterized by increased serum CK and prolonged recumbency. Supportive care during episodes has allowed many young animals to survive and, unknowingly to the owner, enter the breeding herd.

Porcine Malignant Hyperthermia

Malignant hyperthermia in swine (see p 1027) is due to an autosomal recessive genetic mutation in the skeletal muscle ryanodine receptor 1 gene (*RYR1*) that causes abnormal meat quality in swine. Pietrain, Poland China, and certain strains of Landrace pigs are affected. During transportation or anesthesia, pigs develop increased body temperature, extreme rigidity of the skeletal muscles, and lactic acidosis. At slaughter, affected muscles become pale, soft, and exudative, which diminishes meat quality. A genetic test is available to diagnose affected and carrier animals.

Porcine RN(–) Glycogen Storage Disease

The RN(–) (rendement Napole) phenotype is common in Hampshire pigs. It is due to an autosomal dominant mutation in the protein kinase AMP-activated gamma 3 subunit gene (*PRKAG3*), which encodes the gamma 3 isoform of AMP-activated protein kinase (AMPK). Clinically, pigs appear healthy; however, the 70% increase in glycogen content in skeletal muscle causes poor meat quality at slaughter.

Pseudomyotonia in Cattle

Bovine congenital pseudomyotonia is an impairment of muscle relaxation induced by exercise that prevents animals from performing rapid movements. Different mutations in the ATP2A1 gene that encodes the Ca^{2+} -ATPase in skeletal muscle sarcoplasmic reticulum have been identified in the Chianina, Belgian Blue, and Romagnola breeds.

MYOPATHIES IN HORSES

Muscle disorders in horses present with a variety of clinical signs ranging from muscle stiffness and pain to muscle atrophy, weakness, exercise intolerance, and muscle fasciculations. The most common clinical presentation is muscle pain, stiffness, and reluctance to move due to rhabdomyolysis. Rhabdomyolysis, defined as disruption of striated skeletal muscle, can broadly be grouped into causes associated with exercise (exertional rhabdomyolysis) and causes unrelated to exercise.

Differential diagnoses for reluctance to move, acute recumbency, and discolored urine include lameness, colic, laminitis, fracture, pleuropneumonia, tetanus, aorto-iliac thrombosis, neurologic diseases resulting in recumbency or reluctance to move, intravascular hemolysis, and bilirubinuria. Causes of non-exercise-associated rhabdomyolysis include infectious (eg, *Clostridium* sp, influenza, *Streptococcus equi*, *Sarcocystis*) and immune-mediated myopathies, nutritional

TABLE 1 DIFFERENTIAL DIAGNOSES OF EQUINE MYOPATHIES

NON-EXERCISE-ASSOCIATED RHABDOMYOLYSIS

Inflammatory myopathies
Clostridial myositis
Influenza myositis
<i>Sarcocystis</i> myositis
Immune-mediated myopathy
Nutritional myopathy
Vitamin E and selenium deficiency

TABLE 1 DIFFERENTIAL DIAGNOSES OF EQUINE MYOPATHIES (continued)

- Toxic myopathies
 - Ionophore toxicity
 - Senna occidentalis*
 - Pasture myopathies
 - Rayless goldenrod/white snakeroot
 - Hypoglycin A in box elder and European sycamore trees
- Traumatic myopathies
 - Compressive anesthetic myopathy
 - Trauma
- Genetic myopathies
 - Glycogen branching enzyme deficiency in Quarter horses
 - Polysaccharide storage myopathy types 1 and 2
 - Malignant hyperthermia in Quarter horses

EXERTIONAL RHABDOMYOLYSIS

- Focal muscle strain
- Sporadic tying-up (overexertion)
- Chronic tying-up
 - Dietary imbalances, vitamins, minerals, electrolytes
 - Polysaccharide storage myopathy types 1 and 2
 - Malignant hyperthermia
 - Recurrent exertional rhabdomyolysis
 - Idiopathic chronic exertional rhabdomyolysis

EXERTIONAL MYOPATHY WITH NORMAL CK

- Mitochondrial myopathy
- Polysaccharide storage myopathy type 2

MUSCLE ATROPHY

- Myogenic atrophy
 - Severe rhabdomyolysis
 - Disuse
 - Cushing disease
 - Immune-mediated myositis (rapid atrophy)
 - Vitamin E-deficient myopathy
 - Homozygous polysaccharide storage myopathy type 1
 - Polysaccharide storage myopathy type 2
- Neurogenic atrophy
 - Equine protozoal myelitis
 - Local nerve trauma
 - Equine motor neuron disease
 - Idiopathic peripheral neuropathy
 - Toxic peripheral neuropathies

MUSCLE FASCICULATIONS

- Pain, fear
- Weakness (botulism, chronic debilitation)
- Electrolyte abnormalities
- Equine motor neuron disease
- Hyperkalemic periodic paralysis
- Hypokalemia
- Otobius megnini* (ear tick) infestation
- Myotonic dystrophy
- Stiff horse syndrome
- Shivers

myodegeneration (vitamin E or selenium deficiency), traumatic or compressive myopathy, idiopathic pasture myopathy, and toxic muscle damage from the ingestion of ionophores (eg, monensin, lasalocid, rumensin). Plants, including white snake root and vitamin D–stimulating species, should also be considered (see TABLE 1). Genetic causes of nonexertional rhabdomyolysis include glycogen branching enzyme deficiency (foals), malignant hyperthermia (Quarter horses), and polysaccharide storage myopathy.

EXERTIONAL MYOPATHIES

Exertional myopathy in horses is a syndrome of muscle fatigue, pain, or cramping associated with exercise. Less common exertional myopathies that cause exercise intolerance without muscle necrosis include mitochondrial myopathies and forms of polysaccharide storage myopathy in Warmblood horses. Most commonly, exertional myopathies produce necrosis of striated skeletal muscle and are termed exertional rhabdomyolysis. Although exertional rhabdomyolysis was previously considered a single disease described as azoturia, tying-up, or cording up, it is now known to comprise several different myopathies, which, despite similarities in clinical presentation, differ significantly in etiopathology.

Clinical signs usually are seen shortly after onset of exercise. Excessive sweating, tachypnea, tachycardia, muscle fasciculations, reluctance or refusal to move, and firm, painful lumbar and gluteal musculature are common signs. Episodes range from subclinical to severe muscle necrosis with recumbency and myoglobinuric renal failure. The severity varies extensively between individuals and to some degree within the same individual. A diagnosis of exertional rhabdomyolysis is based on demonstration of abnormal increases in serum CK, lactate dehydrogenase, and AST.

Exertional rhabdomyolysis can be either sporadic, with single or very infrequent episodes of exercise-induced muscle necrosis, or chronic, with repeated episodes of rhabdomyolysis and increased serum CK or AST with mild exertion.

Sporadic Exertional Rhabdomyolysis

All breeds of horses are susceptible to sporadic exertional rhabdomyolysis. The most common cause is exercise that exceeds the horse's state of training. The

incidence of muscle stiffness also has been found to increase during an outbreak of respiratory disease. Dietary deficiencies of sodium, vitamin E, selenium, or a calcium:phosphorus imbalance may also be contributory factors.

A diagnosis of sporadic exertional rhabdomyolysis is made on the basis of a horse with no previous history, or a brief history, of exertional rhabdomyolysis, signs of muscle cramping and stiffness after exercise, and moderate to marked increases in serum CK and AST. Immediately on detection of signs of exertional rhabdomyolysis, exercise should stop and the horse should be moved to a well-bedded stall with access to fresh water. The objectives of treatment are to relieve anxiety and muscle pain and to correct fluid and acid-base deficits. Tranquilizers or opioids may be given. NSAIDs can be given to a well-hydrated horse. Most horses are relatively pain free within 18–24 hr.

Severe rhabdomyolysis can lead to renal compromise due to ischemia and the combined nephrotoxic effects of myoglobinuria, dehydration, and NSAID therapy. The first priority in horses with hemoconcentration or myoglobinuria is to reestablish fluid balance and induce diuresis. In severely affected animals, regular monitoring of BUN and/or serum creatinine is advised to assess the extent of renal damage. Diuretics are contraindicated in the absence of IV fluid therapy and are indicated if the horse is in oliguric renal failure.

Horses should be stall rested on a hay diet with a dietary vitamin and mineral ration balancer supplement for a few days. For horses with sporadic forms of exertional rhabdomyolysis, rest with regular access to a paddock should continue until serum muscle enzyme concentrations are normal. Because the inciting cause is usually temporary, most horses respond to rest, a gradual increase in training, and dietary adjustment. Endurance horses should be encouraged to drink electrolyte-supplemented water during an endurance ride and monitored particularly closely during hot, humid conditions.

Chronic Exertional Rhabdomyolysis

Some horses have recurrent episodes of rhabdomyolysis, even with light exercise. Four forms of chronic tying-up have been identified using muscle biopsies or genetic testing: type 1 polysaccharide storage myopathy (PSSM), type 2 PSSM, malignant hyperthermia, and recurrent exertional rhabdomyolysis.

Type 1 polysaccharide storage myopathy is seen frequently in Quarter horse–related breeds (especially halter and Western pleasure horses), Morgans, and draft horses but is also present in at least 20 other horse breeds. It is caused by a dominantly inherited mutation in the glycogen synthase 1 (*GYS1*) gene. A diagnosis can be made by genetic testing of blood or hair samples. Quarter horse–related breeds and other crossbred or light breeds of horses with type 1 PSSM often develop episodes of rhabdomyolysis at a young age with little exercise. Rest for a few days before exercise is a common triggering factor. Episodes are characterized by a tucked-up abdomen, a camped-out stance, muscle fasciculations, sweating, gait asymmetry, hindlimb stiffness, and reluctance to move. Some horses paw or roll, resembling colic. Serum CK and AST are increased during an episode (usually >1,000 U/L) and, unlike in other forms of rhabdomyolysis, subclinical episodes characterized by persistently abnormal CK levels are common. Clinical signs in draft horses may include loss of muscle mass, progressive weakness, and recumbency. CK and AST may be normal in draft horses with this syndrome. When draft horses develop rhabdomyolysis, CK and AST may be markedly increased, and horses can become myoglobinuric, weak, and reluctant to rise.

Type 2 polysaccharide storage myopathy occurs in light breeds such as Arabians, Morgans, Thoroughbreds, a variety of Warmblood breeds and some Quarter horses. A diagnosis is made by identifying an abnormal pattern of glycogen storage in muscle biopsies in a horse with a negative *GYS1* genetic test. In Quarter horses <1 yr old, it may cause difficulty rising from a recumbent position and increased serum CK activity. Chronic episodes of muscle stiffness, soreness, and muscle atrophy with normal to modest increases in serum CK are common in horses with type 2 PSSM. The most common presentation of this disorder in Warmbloods is a gait abnormality, exercise intolerance, and loss of muscle mass when out of work that is not necessarily accompanied by a concomitant rise in serum CK.

Malignant hyperthermia is caused by an autosomal dominant mutation in the skeletal muscle ryanodine receptor gene (*RYR1*). The mutation is responsible for both anesthesia-related and non-anesthesia-related causes of rhabdomyolysis in Quarter

horses. A diagnosis can be made by genetic testing of blood or hair roots. Signs related to inhalation anesthesia include tachycardia, tachypnea, hyperthermia, muscle rigidity accompanied by a severe lactic acidosis, increased serum CK, and electrolyte derangements. Exertional rhabdomyolysis in Quarter horses with malignant hyperthermia can result in sudden death. Signs are preceded by excessive sweating, tachycardia, tachypnea, hyperthermia, and muscle rigidity. Some Quarter horses have both malignant hyperthermia and PSSM, which results in more severe signs of exertional rhabdomyolysis than those seen in horses with PSSM alone.

Recurrent exertional rhabdomyolysis is seen frequently in Thoroughbreds, Standardbreds, and Arabian horses. It is likely due to abnormal regulation of intracellular calcium in skeletal muscles. It appears there is intermittent disruption of muscle contraction, particularly when horses susceptible to the condition are fit and have a nervous temperament. In Thoroughbreds, it is likely inherited as an autosomal dominant trait.

Diagnostic tests to determine the cause of chronic tying-up include a CBC, serum chemistry panel, serum vitamin E and selenium concentrations, urinalysis to determine electrolyte balance, dietary analysis, exercise testing, muscle biopsy, and genetic testing. An exercise challenge test is useful to detect subclinical cases; serum CK is measured before and 4 hr after light exercise. In addition, quantifying the extent of exertional rhabdomyolysis during mild exercise is helpful in deciding how rapidly to reinstate training.

A diagnosis of type 1 PSSM is based on identification of the *GYS1* mutation and/or the presence of muscle fibers with subsarcolemmal vacuoles, dark periodic acid-Schiff (PAS) staining for glycogen, and most notably, amylase-resistant abnormal complex polysaccharide accumulation. A diagnosis of type 2 PSSM is based on the absence of the *GYS1* mutation and the presence of muscle fibers with aggregates of amylase-sensitive PAS-positive staining glycogen and occasionally small amounts of amylase-resistant PAS-positive material. A diagnosis of recurrent exertional rhabdomyolysis is based on history, clinical signs, increases in serum CK and AST, and muscle biopsy.

Horses with type 1 PSSM have constitutively active glycogen synthase that is further stimulated by increased blood insulin concentrations, resulting in high

muscle glycogen concentrations. When fed a starch meal, these horses take up a higher proportion of the absorbed glucose in their muscles than healthy horses. Horses with type 2 PSSM also have abnormal glycogen storage, but the cause of this myopathy is unknown. Thus, the ideal diet for PSSM is based on feeding forage at a rate of 1.5%–2% body wt, providing >15% of digestible energy as fat and limiting starch to <10% of daily digestible energy by limiting grain or replacing it with a fat supplement. Caloric needs should be assessed first to prevent horses becoming obese on a high-fat diet. Improvement in signs of exertional rhabdomyolysis for horses with PSSM requires both dietary changes and gradual increases in the amount of daily exercise and turn-out.

Horses with malignant hyperthermia may benefit from premedication with dantrolene (4 mg/kg, PO) 60–90 min before exercise, particularly under hot conditions.

Management of recurrent exertional rhabdomyolysis is aimed at decreasing the triggering factors for excitement and pharmacologic alteration of intracellular calcium flux with contraction. Management changes that may decrease excitement include minimizing stall confinement by using turn-out or a hot walker, exercising and feeding horses with recurrent exertional rhabdomyolysis before other horses, providing compatible equine company, and the judicious use of low-dose tranquilizers during training. A high-fat, low-starch diet is beneficial, possibly by decreasing excitement. In contrast to horses with PSSM, those with recurrent exertional rhabdomyolysis often require higher caloric intakes (>24 Mcal/day). At these high caloric intakes, specialized feeds designed for exertional rhabdomyolysis are necessary, because additional vegetable oil or rice bran cannot supply enough calories for equine athletes in intense training. Hay should be fed at 1.5%–2% body wt, and high-fat, low-starch concentrates should be selected that provide ≤20% of daily digestible energy as nonstructural carbohydrate and 20%–25% of digestible energy as fat.

Dantrolene (4 mg/kg, PO) given 1 hr before exercise may decrease the release of calcium from the calcium release channel. Phenytoin (1.4–2.7 mg/kg, PO, bid) has also been advocated as a treatment for horses with recurrent exertional rhabdomyolysis. Therapeutic levels vary, so oral dosages are adjusted by monitoring serum levels to achieve 8–12 mcg/mL. However, long-term treatment with dantrolene or phenytoin is expensive.

INFECTIOUS MYOPATHIES

Virus-associated Myositis

Necrosis of skeletal and cardiac muscle may occur in association with viral diseases such as equine influenza and equine infectious anemia. In most situations, viral-induced muscle damage represents a component of systemic multiple organ system involvement. Equine influenza 2 has been found to cause severe rhabdomyolysis, and equine herpesvirus 1 has been reported to induce primary muscle stiffness and clinical signs resembling exertional rhabdomyolysis.

Sarcocystis Myositis

Cysts of the sporozoan parasite *Sarcocystis* are present in 90% of esophageal muscles from horses >8 yr of age and in 6% of gluteal muscle biopsies from healthy horses. Occasionally, heavy infestations occur through contamination of feed with canine feces, resulting in signs of fever, anorexia, stiffness, weight loss, muscle fasciculations, atrophy, and weakness. Diagnosis of sarcocystosis requires history, clinical signs, laboratory evaluation, and the demonstration of an inflammatory reaction to immature cysts in muscle biopsies. Treatment includes NSAIDs and drugs such as trimethoprim sulfa and pyrimethamine or ponazuril. (See also SARCOCYSTOSIS, p 1058.)

Anaplasma-associated Rhabdomyolysis

Horses that acquire *Anaplasma phagocytophilum* from tick infestations can rarely develop clinical signs of severe muscle stiffness in addition to fever, malaise, and limb edema. Hematologic findings include anemia, thrombocytopenia, neutropenia, morula visible in granulocytes, and marked increases in serum CK and AST levels. A diagnosis is confirmed by PCR testing of blood for *A. phagocytophilum*. A direct toxic effect of *A. phagocytophilum* on muscle cells is postulated. Treatment should include IV oxytetracycline and supportive care.

Streptococcus equi Rhabdomyolysis

Severe rhabdomyolysis can occur in horses with *Streptococcus equi equi* submandibular lymphadenopathy and/or guttural pouch empyema. A stiff gait is the initial clinical sign, which progresses rapidly to severely painful, firm, swollen epaxial and gluteal muscles. Many horses become recumbent with unrelenting pain that may warrant euthanasia. It is not clear whether myonecrosis is a direct toxic effect of *S. equi*

on muscle cells or is due to profound nonspecific T-cell stimulation by streptococcal superantigens and the release of high levels of inflammatory cytokines. A diagnosis is based on hematologic abnormalities typical of *S. equi* infection, marked increases in CK ($>100,000$ U/L), and PCR or bacterial culture. Titers to the M protein of *S. equi* are low in affected horses, unless they have recently been vaccinated for strangles. At postmortem, large, pale areas of necrotic muscle are evident in hindlimb and lumbar muscles. The histopathologic lesions are characterized by severe acute myonecrosis with a degree of macrophage infiltration. Sublumbar muscles often show the most severe and chronic necrosis, as indicated by greater macrophage infiltration of myofibers. The prognosis becomes guarded if animals become recumbent.

Appropriate therapy includes IV penicillin combined with an antimicrobial that inhibits protein synthesis, such as rifampin. Flushing infected guttural pouches and draining abscessed lymph nodes will diminish the bacterial load. NSAIDs and possibly high doses of short-acting corticosteroids may diminish the inflammatory response. Control of unrelenting pain is a major challenge in horses with severe rhabdomyolysis. Constant-rate infusion of lidocaine, detomidine, or ketamine may provide better anxiety and pain relief than periodic injections of tranquilizers. Horses should be placed in a deeply bedded stall and moved from side to side every 4 hr if they are unable to rise. Some horses may benefit from a sling if they will bear weight on their hindlimbs when assisted to stand.

Clostridial Myositis

A variety of clostridial bacteria can sporulate at the site of an injection or deep wound, causing focal muscle swelling and systemic toxemia in horses. *Clostridium septicum*, *C. chauvoei*, *C. sporogenes*, and mixed infections are associated with a high fatality rate, whereas *C. perfringens* type A has a mortality rate of 20% with early and aggressive treatment. Clostridial spores may lie dormant in skeletal muscle, or spore deposition directly into the tissue may occur in association with penetration. If suitable necrotic conditions exist, the spores convert to the vegetative form, releasing powerful exotoxins. Within 48 hr, horses show depression, fever, toxemia, tachypnea, and swelling and variable crepitus at the injection site. Tremors, ataxia, dyspnea, recumbency, coma, and

death may occur in the next 12–24 hr. Myocardial damage occurs in some horses. Hematology and serum biochemical analyses usually reflect a generalized state of debilitation and toxemia (eg, hemoconcentration and a stress/toxic leukogram may be present). Serum CK and AST are usually moderately increased; however, they often do not reflect the toxicity of clostridial myonecrosis.

Ultrasonographic evaluation of swollen areas may reveal fluid and characteristic hyperechoic gas accumulation. Aspirates of affected tissues examined via direct smears or fluorescent antibody staining should show characteristic rod-shaped bacteria. Anaerobic bacterial culture of freshly acquired samples may also be of value. Cut tissue from the affected area may reveal abundant serosanguineous fluid with an odor of rancid butter. At postmortem, swelling, crepitus, and autolysis are rapid, and bloodstained fluid is often seen discharging from body orifices.

Wound fenestration and aggressive surgical debridement over the entire affected area is required for successful treatment. Additional treatment includes high doses of IV potassium penicillin every 2–4 hr until the horse is stable (1 to 5 days), combined with or followed by oral metronidazole along with supportive fluid therapy and anti-inflammatory agents. Extensive skin sloughing over the affected area is common in surviving horses.

Muscle Abscesses

Staphylococcus aureus, *Streptococcus equi*, and *Corynebacterium pseudotuberculosis* are common causes of skeletal muscle abscessation, which develops after penetrating injuries or by hematogenous or local spread of infection. Initially there is an ill-defined cellulitis, which may heal or progress to a well-defined abscess. An abscess may heal, expand, or fistulate, usually to the skin surface with potential for a chronic granuloma with intermittent discharge. Prognosis is usually good for superficial abscesses. Deep abscesses are more difficult to manage successfully. The effect of an abscess on the horse's gait depends on its location and can vary from mild stiffness to severe lameness. Ultrasonography and culture of aspirated fluid are the best means of diagnosis in superficial sites. Abscesses lying deep within muscles can be difficult to diagnose. There may be an increased fibrinogen and nucleated WBCs. The synergistic hemolysin inhibition test, which detects antibodies to

C pseudotuberculosis, can be helpful for detection of internal abscesses. Treatment consists of poulticing, lancing, flushing, and draining. Occasionally, surgical removal may be required for complete excision. If antimicrobial therapy is used, it should be continued for several weeks.

IMMUNE-MEDIATED MYOPATHIES

Infarctive Hemorrhagic Purpura

Purpura hemorrhagica is often associated with mild increases in serum CK activity; however, horses vaccinated for, or exposed to, *Streptococcus equi* within the last month rarely may develop extremely high serum CK activity, variable edema, acute colic, firm swellings within muscle and under the skin, and unilateral lameness. Clinical signs are due to painful infarctions of skeletal muscle, subcutaneous tissue, focal areas of the GI tract, and lungs resulting from a severe immune-mediated vasculopathy. Hematologic abnormalities include leukocytosis, hyperfibrinogenemia, hypoalbuminemia, and marked increases in serum CK and AST. A diagnosis is often established based on clinical signs, a leukocytoclastic vasculitis in skin and affected tissues, and a very high *S equi* M protein titer.

Successful treatment requires early detection, penicillin for 14 days, and prolonged high doses of dexamethasone (0.12–0.2 mg/kg) for at least 10 days, followed by tapering doses of prednisolone at an initial dosage of 2 mg/kg. Without aggressive steroid treatment, the condition progresses to intestinal infarction and death.

Immune-mediated Polymyositis

Immune-mediated polymyositis is characterized by rapidly developing atrophy of the epaxial and gluteal muscles. It is seen in Quarter horses, although other breeds may be affected. The condition shows a bimodal age distribution, affecting horses <8 yr or >16 yr of age. In approximately one-third of affected horses, a triggering factor appears to have been exposure to *S equi* or a respiratory disease. Rapid onset of atrophy of the back and croup muscles is accompanied by stiffness and malaise. Atrophy may progress to involve 50% of the horses' muscle mass within a week and may lead to generalized weakness. Focal symmetric atrophy of cervical muscles has been reported in a pony with immune-mediated polymyositis. Hematologic

abnormalities are usually restricted to mild to moderate increases in serum CK and AST. However, in some chronic cases serum muscle enzyme activities are normal. Muscle biopsy of epaxial and gluteal muscles shows lymphocytic vasculitis, anguloid atrophy, myofiber infiltration with lymphocytes, fiber necrosis with macrophage infiltration, and regeneration in acute stages. Biopsies of semitendinosus or semimembranosus muscles may show some evidence of atrophy and vasculitis, but significant inflammatory infiltrates may be absent. The extent of the inflammatory infiltrates in epaxial muscles is such that a diagnosis can often be established from several formalin fixed-core needle biopsy samples. The reason why specific muscle groups are affected is unclear.

Treatment involves antibiotic therapy for horses with concurrent signs of infection and administration of dexamethasone (0.05 mg/kg for 3 days), followed by prednisolone (1 mg/kg for 7–10 days) tapered by 100 mg/wk throughout 1 mo. Serum CK often normalizes after 7–10 days of treatment. Generally, muscle mass gradually recovers throughout 2–3 mo even without corticosteroid treatment. Recurrence of atrophy in susceptible horses is common and may require reintroduction of corticosteroid therapy.

MUSCLE CRAMPING

Muscle cramping is a painful condition that arises from hyperactivity of motor units caused by repetitive firing of the peripheral and/or central nervous system. The origin of the cramp in most cases is believed to be the intramuscular portion of the motor nerve terminals. Most muscle cramps are also accompanied by fasciculations in the same muscle and normal serum CK activity. Muscle cramps can be induced by forceful contraction of a shortened muscle, by changes in the electrolyte composition of extracellular fluid, and by ear tick infestations. In contrast, muscle contractures, like those seen in exertional rhabdomyolysis, are painful muscle spasms that represent a state of muscle contracture unaccompanied by depolarization of the muscle membrane. Muscle contractures are invariably accompanied by markedly increased serum CK activity.

Electrolyte Disturbances

Muscle cramping in endurance horses is most frequent in hot, humid weather. Horses may lose fluids at a rate of up to

15 L/hr in the form of sweat and develop remarkable deficits in sodium, potassium, chloride magnesium, and calcium. Clinical signs of electrolyte derangements include muscle stiffness and periodic spasms of muscle groups. In addition, exhausted horses are often dull, depressed, and clinically dehydrated with increased heart and respiratory rates and persistently increased body temperature. Synchronous diaphragmatic flutter may be seen in association with cramping. Affected horses do not generally develop myoglobinuria or have marked increases in serum CK and AST levels.

Mild muscle cramping is self-limiting, and the signs abate with rest or light exercise. However, exhausted horses with metabolic derangements require immediate treatment, including plasma volume expansion with oral or IV isotonic polyionic fluids and cooling (using water and fans). Because most horses with this condition are alkalotic, administration of solutions containing sodium bicarbonate is contraindicated. Daily direct addition of 2 oz of sodium chloride and 1 oz of potassium chloride to the feed is recommended for horses with recurrent cramping, in addition to electrolyte supplementation before and after endurance rides.

Hypocalcemia

Hypocalcemia is a relatively rare disorder in horses that has also been referred to as lactation tetany, transport tetany, idiopathic hypocalcemia, and eclampsia. Clinical signs, diagnosis, and treatment are discussed elsewhere (*see* p 987). In addition to hypocalcemia, a metabolic alkalosis, hypomagnesemia/hypomagnesemia, and hyperphosphatemia/hypophosphatemia may be present and need correction before a return to normal function is seen. Relapses do occur.

Synchronous Diaphragmatic Flutter

("Thumps")

Synchronous diaphragmatic flutter is due to firing of the phrenic nerve in synchrony with atrial depolarization, causing the diaphragm to contract with each heartbeat. This occasionally produces an audible thumping sound. Inciting causes include endurance exercise, hypocalcemia, hypoparathyroidism, digestive disturbances, and repeated administration of calcium-containing fluids to performance horses. Synchronous diaphragmatic flutter may be a singular occurrence or a chronic

recurring problem. The most consistently reported metabolic derangement is low serum ionized calcium concentrations usually associated with hypochloremic metabolic alkalosis. Metabolic alkalosis may alter the ratio of free to bound calcium (increasing calcium binding to protein and decreasing ionized calcium), which possibly induces diaphragmatic flutter.

Most horses undergo rapid remission of signs when given calcium solutions IV. Although hypomagnesemia is often present with synchronous diaphragmatic flutter, horses do not respond to magnesium supplementation unless calcium is administered concurrently. Response to therapy is also reflected by improved mental status, return of appetite, and gut motility. For horses with chronic diaphragmatic flutter, providing chloride, potassium, sodium, calcium, and magnesium during prolonged exercise may help reduce fluid losses and the metabolic alkalosis. Alternative approaches involve reducing dietary calcium for a few days before competition in horses prone to diaphragmatic flutter. This reduction in dietary calcium may stimulate the endocrine homeostatic mechanisms and increase osteoclastic activity. Limiting alfalfa hay, which has a relatively high calcium concentration, may be indicated in chronically affected horses.

Ear Tick-associated Muscle Cramping

Otobius megnini infestations in the ear canal can produce remarkably painful intermittent muscle cramps not associated with exercise that last from minutes to a few hours and often resemble colic. Horses may fall over when stimulated. Between muscle cramps, horses appear to be normal. Percussion of triceps, pectoral, or semitendinosus muscles results in a typical myotonic cramp. Horses have increased serum CK, ranging from 4,000 to 170,000 IU/L. Numerous ear ticks can be identified in the external ear canal of affected horses. *O. megnini* is found in the southwestern USA. Without treatment, the spasms continue; however, local treatment of the ear ticks using pyrethrins and piperonyl butoxide results in recovery within 12–36 hr. Acepromazine may be helpful to relieve painful cramping.

Shivers

"Shivers" is a spastic condition of the hind- and occasionally forelimbs of horses that is

usually only evident when horses are backing or having their feet picked up. It is most common in adult draft horse breeds, Warmbloods, Warmblood crosses, and Thoroughbreds >16.3 hands tall. The condition is characterized by periodic, involuntary spasms of the muscles in the pelvic region, pelvic limbs, and tail that are exacerbated by backing or picking up the hindlimbs. The affected limb is elevated, abducted, and may actually shake and shiver; the tail head is usually elevated concurrently and trembles. When more severely affected animals are backed up, the hindlimb is suddenly raised, semiflexed, and abducted with the hoof held in the air for several seconds or minutes. The tail is elevated simultaneously and trembles. After a variable period of time the spasms subside, the limb is extended, and the foot is brought slowly to the ground. Some horses will refuse to pick up their hindlimbs and are very difficult to shoe. Suggested causes include genetic, traumatic, infectious, and neurologic diseases, although the exact etiology is unknown. The condition in draft horses is usually progressive and eventually debilitating; in Warmbloods and Thoroughbreds, it usually has less impact on performance and progresses more slowly. There are no known treatments, but avoiding stall rest and keeping horses fit appears helpful.

MYOTONIC DISORDERS

Myotonic muscle disorders share the feature of delayed relaxation of muscle after mechanical stimulation or voluntary contraction due to abnormal muscle membrane conduction. Horses have three known forms of myotonia: myotonia congenita, myotonia dystrophica, and hyperkalemic periodic paralysis (HyPP).

Myotonia Congenita and Dystrophica

The initial signs of myotonia in foals are well-developed musculature and mild pelvic limb stiffness. Bilateral bulging (dimpling) of the thigh and rump muscles is often obvious and gives the impression that the animal is very well developed. Percussion of affected muscles exacerbates the muscle dimpling below a large area of tight contraction that can persist for a minute or more with subsequent slow relaxation. Myotonia congenita usually does not show progression of clinical signs beyond 6–12 mo of age, and muscle stiffness may improve with exercise. The cause has not been identified.

Foals with myotonia dystrophica show a progression of signs in the first 1–2 yr of life to include areas of muscle atrophy fibrosis and stiffness that worsens with exercise. Retinal dysplasia, lenticular opacities, and gonadal hypoplasia have been seen in Quarter horse, Appaloosa, and Italian-bred foals with myotonic dystrophy.

A tentative diagnosis of myotonia can be made on the basis of age and clinical signs of stiff gait, muscle bulging, and prolonged contractions after muscle stimulation. Definitive diagnosis of myotonia requires electromyographic examination. Affected muscle manifests pathognomonic, crescendo-decrescendo, high-frequency repetitive bursts with a characteristic “dive bomber” sound. Myotonia dystrophica shows dystrophic changes in muscle biopsies not present in myotonia congenita. Dystrophic changes include ringed fibers, numerous centrally displaced myonuclei, sarcoplasmic masses, and an increase in endomysial and perimysial connective tissue. Fiber type grouping and atrophy of both type I and type II muscle fibers may be present.

Horses with myotonia congenita or dystrophica are rarely serviceable, and euthanasia is usually warranted in dystrophic foals because of the severity of stiffness and atrophy that develop over time. Conclusive evidence regarding the genetic basis of this disorder in horses is still not available.

Hyperkalemic Periodic Paralysis

HyPP is an autosomal dominant trait affecting Quarter horses, American Paint horses, Appaloosas, and Quarter horse crossbreeds worldwide. The point mutation in the voltage-dependent skeletal muscle sodium channel alpha subunit occurs in ~4% of Quarter horses, but this percentage is much higher in halter and pleasure horse performance types.

Clinical signs range from asymptomatic to intermittent muscle fasciculations and weakness and are first identified in foals to horses 3 yr of age. Homozygous horses are often more severely affected and may be identified at a younger age than heterozygotes. A brief period of myotonia is often seen initially, with some horses showing facial myotonia and prolapse of the third eyelid. Muscle fasciculations beginning on the flanks, neck, and shoulders may become more generalized. Although most horses remain standing during mild attacks, weakness with swaying, staggering, dog-sitting, or recumbency may be seen, with severe attacks lasting 15–60 min or longer.

Heart and respiratory rates may be increased, but horses remain relatively bright and alert. Respiratory distress occurs in some horses as a result of upper respiratory muscle paralysis. Once episodes subside, horses regain their feet and appear normal with absent or minimal gait abnormalities. Young horses that are homozygous for the HyPP trait may have respiratory stridor and periodic obstruction of the upper respiratory tract that can be fatal.

Common factors that trigger episodes include sudden dietary changes or ingestion of diets high in potassium (>1.1%), such as those containing alfalfahay, molasses, electrolyte supplements, and kelp-based supplements. Fasting, anesthesia or heavy sedation, trailer rides, and stress may also precipitate clinical signs. The onset of signs, however, is often unpredictable. Exercise per se does not appear to stimulate clinical signs; serum CK shows no or minimal increases during episodic fasciculations and weakness.

Descent from the stallion Impressive in a horse with episodic muscle tremors is strongly suggestive of HyPP. Hyperkalemia (6–9 mEq/L), hemoconcentration, and hyponatremia are seen during clinical episodes, but a definitive diagnosis requires DNA testing of mane or tail hair. Electromyographic examination of affected horses between attacks reveals abnormal fibrillation potentials and complex repetitive discharges, with occasional myotonic potentials and trains of doublets between episodes. Differential diagnoses for hyperkalemia include delay before serum centrifugation, hemolysis, chronic renal failure, and severe rhabdomyolysis.

Many horses recover spontaneously from HyPP episodes. Owners may abort early mild episodes using low-grade exercise or feeding grain or corn syrup to stimulate insulin-mediated movement of potassium across cell membranes. In severe cases, administration of calcium gluconate (0.2–0.4 mL/kg of a 23% solution diluted in 1 L of 5% dextrose) or IV dextrose (6 mL/kg of a 5% solution), alone or combined with sodium bicarbonate (1–2 mEq/kg), often provides immediate improvement. With severe respiratory obstruction, a tracheostomy may be necessary. Acute death is common, especially in homozygous animals.

Prevention requires decreasing dietary potassium to 0.6%–1.1% total potassium concentration and increasing renal losses of potassium. High-potassium feeds such as alfalfa hay, first cutting hay, brome hay, sugar molasses, and beet molasses should be avoided. Optimally, later cuts of timothy or Bermuda grass hay; grains such as oats, corn,

wheat, and barley; and beet pulp should be fed in small meals several times a day. Regular exercise and/or frequent access to a large paddock or yard are also beneficial. Pasture is ideal for horses with HyPP, because the high water content of pasture grass makes it unlikely that horses will consume large amounts of potassium in a short period of time. Complete feeds for horses with HyPP are commercially available. For horses with recurrent episodes even with dietary alterations, acetazolamide (2–4 mg/kg, PO, bid-tid) or hydrochlorothiazide (0.5–1 mg/kg, PO, bid) may be helpful. Breed registries and other associations have restrictions on the use of these drugs during competitions. Some horses have both HyPP and polysaccharide storage myopathy (PSSM) (see p 1178), which may result in an episode of rhabdomyolysis during a hyperkalemic paralytic event with subsequent increased serum CK activity and prolonged recumbency.

NUTRITIONAL MYOPATHIES

Nutritional Myodegeneration

Young, rapidly growing foals born to dams that consumed selenium-deficient diets during gestation can develop nutritional myodegeneration (NMD; see p 1172). Selenium deficiency has also been implicated in masseter muscle myopathy and occasionally nonexertional rhabdomyolysis in adult horses. Selenium and vitamin E appear to be synergistic in preventing NMD. Clinical signs in foals include dyspnea; a rapid, irregular heartbeat; and sudden death in those with myocardial involvement. Dysphagia, muscle stiffness, trembling, firm muscles, difficulty rising, and myoglobinuria may also be seen. Aspiration pneumonia is a frequent complication. Diagnosis is based on finding moderate to markedly increased serum CK and AST, combined with low whole blood selenium concentrations (<0.07 ppm) or vitamin E (<2 ppm). Hyperkalemia, hyperphosphatemia, hyponatremia, hypochloremia, and hypocalcemia can occur with severe rhabdomyolysis when the normal distinction between extracellular and intracellular compartments is destroyed by massive tissue necrosis. Selenium-dependent glutathione peroxidase formed in RBCs during erythropoiesis also provides an index of body selenium status. Treatment includes IM injection of selenium (0.055–0.067 mg/kg) and either injectable or oral vitamin E (0.5–1.5 IU/kg). Supportive therapy includes administering antibiotics to combat secondary pneumonia, feeding via nasogastric tube, providing adequate energy intake,

and maintaining fluid and electrolyte balance.

PLANTS CAUSING MYOPATHIES

Horses ingesting 0.5%–2% body wt of trematone-containing plants are likely to die from skeletal muscle and cardiac muscle necrosis. Horses present with marked depression, weakness, low head posture, and increased cardiac and respiratory rates. Serum AST and CK are often markedly increased, and serum electrolyte abnormalities such as hypocalcemia, hyponatremia, hypochloremia, hyperkalemia, and hyperphosphatemia may be present. Treatment is generally supportive. Trematone (see p 1175) has been identified in white snakeroot (*Eupatorium rugosum*) and rayless goldenrod (*Isocoma wrightii*). Trematone remains active in the hay and in the stalks of the dead plants on pasture, so both the fresh and dried forms of the plants should be kept from horses.

Muscle necrosis may also occur in horses ingesting *Senna occidentalis* seeds prevalent in the southeastern USA. Horses develop incoordination, recumbency, and death. Gross skeletal muscle lesions are not present, but histopathologic lesions include segmental myonecrosis.

● One of 70 horses poisoned with blister beetles (see p 3157) developed muscle necrosis.

Atypical Myoglobinuria

(Pasture myopathy)

Atypical myoglobinuria occurs sporadically in horses kept on pasture, usually with no supplemental feeding. It has been recognized most commonly in the UK and Europe, but a similar syndrome has been seen in North America. It occurs most often in autumn but can occur in early spring; it often follows very windy or rainy weather and a cool spring. Ingestion of seeds of *Acer* species trees such as the box elder (*Acer negundo*) in North America and European sycamore maple (*Acer pseudoplatanus*) are implicated in the pathophysiology of this myopathy. These seeds contain the toxic nonproteogenic amino acid hypoglycin A, the toxic metabolite of which irreversibly binds to multiple acyl CoA dehydrogenases, enzymes essential for metabolism of short- and medium-chain fatty acids and branched-chain amino acids.

The clinical signs are sudden in onset and rapidly progressive, frequently resulting in death. Several horses in a group may be affected, although some may have no signs.

Affected horses are reluctant to move, have muscle weakness and fasciculations, and may become recumbent. Choke may be present, and gut sounds may be reduced, with reduction in feces production, although appetite may be unaffected. Heart rates may be markedly increased, and pulmonary edema may be present. The horses do not show signs of pain, despite evidence of widespread myopathy at necropsy. Metabolic and respiratory acidosis, increased cardiac troponin I, substantial increases in serum CK and AST, and myoglobinuria also are common.

Necropsy reveals widespread myodegeneration in postural and respiratory skeletal muscles and the myocardium. A definitive diagnosis can be made by identifying a pattern of accumulation of short- and medium-chain serum acylcarnitines and specific urine organic acids and glycine conjugates typical of a deficiency in multiple acyl CoA dehydrogenases. Special stains for lipid reveal excessive lipid storage in the heart, diaphragm, and other oxidative postural muscles. Supportive therapy, including antioxidants (eg, vitamin C, vitamin E, riboflavin), and IV fluids containing dextrose are recommended. Fewer than 75% of horses survive.

TOXIC MYOPATHIES

Ionophores

Ionophores are commonly added to ruminant feeds for their growth promotion and coccidiostat properties. Horses, however, are 10 times more sensitive to the toxic effects of ionophores in feed than cattle. When equine feeds are inadvertently contaminated with ionophores or horses eat cattle feed, some animals may die acutely with colic-like signs, myoglobinuria, hypokalemia, cardiac arrhythmia, and tachypnea. Cardiomyopathy is the most common chronic sequela.

TRAUMATIC AND ANESTHETIC MYOPATHIES

Postanesthetic Myopathy

After anesthesia, horses may develop severe muscle pain and weakness in one or more muscle groups. Hypoperfusion of compressed muscle groups with resultant high intracompartmental pressure is the most important causative factor for focal muscle involvement. The dependent triceps muscle is most commonly affected after anesthesia in lateral recumbency, whereas the longissimus dorsi and gluteal muscles are usually affected in horses that have been in

dorsal recumbency. Generalized myopathies may develop in horses that were hypotensive during anesthesia. The longer the duration of anesthesia, the higher the risk.

Signs are evident when horses try to stand or may be delayed for up to 2 hr. A dropped elbow stance typical of radial nerve paralysis characterizes triceps myopathy. Gluteal myopathy results in unwillingness to bear weight on the hindlimbs. Horses may appear distressed, with profuse sweating, tachycardia, and tachypnea. The degree of distress depends on the severity of muscle damage. Affected muscles may feel very hard and show localized swelling. Serum CK may be normal immediately after the horse stands but rise substantially and peak ~4 hr after anesthesia. Pain relief is provided by sedation with detomidine, combined with opiate analgesics and NSAIDs. Constant-rate infusions of detomidine or butorphanol may be beneficial for pain control in severe cases. Fluid therapy helps maintain renal perfusion and urine output and ensures adequate muscle perfusion. The prognosis for unilateral myopathy is usually good, although with severe damage there may be residual muscle fibrosis, which may compromise function. The prognosis for generalized myopathy is more guarded.

Prevention requires minimizing the time under general anesthesia, carefully positioning the horse on the operating table, and maintaining arterial blood pressure >60 mmHg using fluid therapy and inotropic agents such as dobutamine (1–5 mcg/kg/min).

Malignant Hyperthermia

The ryanodine receptor gene (*RYR1*) mutation in Quarter horses (see p 1178) can cause fatal reactions under general anesthesia that are characterized by marked hyperthermia, acidosis, electrolyte derangements, and muscle necrosis. Unfortunately, once a fulminant episode is underway it is difficult to prevent cardiac arrest. Diagnosis is by clinical signs and genetic testing. Pretreatment with oral dantrolene (4 mg/kg) 30–60 min before anesthesia is the only potential means to prevent an episode.

Fibrotic Myopathy

Fibrotic myopathy describes a classic gait abnormality that develops when horses injure their semitendinosus and semimembranosus muscles at the point of a tendinous insertion during exercise that requires abrupt turns and sliding stops. Trauma (eg, catching a foot in a fence), IM injections, and a congenital form are other potential causes

of fibrotic myopathy. Affected muscles in acute cases are warm and painful on deep palpation. Chronically, hardened areas within the muscle may represent fibrosis and ossification. The associated gait abnormality is usually most apparent at the walk and is characterized by an abrupt cessation of the anterior phase of the stride of the affected limb, causing the leg to jerk suddenly to the ground rather than continue its forward motion. The stride has a short anterior phase with a characteristic hoof-slapping gait. The gait reflects a mechanical hindlimb lameness that restricts normal function. Pain is usually not a feature of chronic fibrotic myopathy. Serum CK and AST are usually only mildly increased. In addition to palpation, diagnosis can be confirmed by ultrasonography, thermography, or scintigraphy. Light microscopic evaluation of muscle biopsies is frequently normal in acute cases. Chronically, fibrous replacement of muscle fibers is apparent. Acute cases may benefit from rest and cold therapy followed by deep heating ultrasound and controlled stretching. Chronic cases may require surgical excision or transection of the fibrotic part of the muscle or tenotomy of the tibial insertion of the semimembranosus tendon.

HEREDITARY AND CONGENITAL MYOPATHIES

Mitochondrial Myopathy

A deficiency of Complex 1, the first step in the mitochondrial respiratory chain, was identified in a young Arabian filly with clinical signs similar to those of exertional rhabdomyolysis. However, this horse showed no changes in serum CK level after exercise. A marked lactic acidosis developed even with light exercise, and maximum oxygen consumption was drastically reduced, resulting in marked exercise intolerance. Histopathologic evaluation of muscle biopsies showed an abnormal increase in mitochondrial density, and biochemical analyses revealed a Complex 1 deficiency. The horse has shown slowly progressive signs of muscle atrophy but has otherwise remained healthy at rest.

Glycogen Branching Enzyme Deficiency

Glycogen branching enzyme deficiency (GBED) is a glycogen storage disorder causing abortion, seizures, and muscle weakness in Quarter horse–related breeds caused by an autosomal recessive mutation in the glycogen branching enzyme (*GBE1*)

gene. The mutation is carried by 9% of Quarter horses and Paint horses, and at least 3% of abortions are attributed to GBED in Quarter horses. Most foals diagnosed with GBED present at 1 day of age with hypothermia, weakness, and flexural deformities of all limbs. Ventilatory failure may also be a presenting sign in addition to recurrent hypoglycemia and collapse. All foals have died either from euthanasia because of muscle weakness or suddenly because of apparent cardiac arrhythmia. Persistent leukopenia, intermittent hypoglycemia, and high serum CK (1,000–15,000 U/L), AST, and γ -glutamyl-transferase activities are features

of affected foals. Gross lesions are not evident, and routine H&E stains of tissues may be normal or show basophilic inclusions in skeletal muscle and cardiac tissues. Frozen sections of muscle, heart, and liver show a notable lack of normal PAS staining for glycogen as well as abnormal PAS-positive globular or crystalline intracellular inclusions. Branching enzyme activity is minimal in skeletal and cardiac muscle as well as liver. A diagnosis is best obtained by confirming the presence of the genetic mutation in tissue samples or by identifying typical PAS-positive inclusions in muscle or cardiac samples. There is no successful treatment.

BOVINE SECONDARY RECUMBENCY

(Downer cow syndrome)

Recumbency in cattle is caused by numerous metabolic, traumatic, infectious, degenerative, and toxic disorders. If treatment of the underlying cause of recumbency is not successful and cattle are unable to rise for >24 hr after initial recumbency, they may develop a secondary recumbency from pressure damage to muscles and nerves, often termed "downer cow syndrome." An alert downer cow does not show signs of systemic illness or depression, is able to eat and drink, and remains in sternal recumbency for no apparent reason. A nonalert downer cow appears systemically sick and depressed. Downer cow syndrome also describes the pathology of pressure-induced muscle and nerve injuries after prolonged recumbency. The most important pathophysiologic event that develops during prolonged recumbency is a pressure-induced ischemic necrosis of the thigh muscles that frequently affects both hindlegs.

Nonambulatory disabled livestock are those that cannot rise from a recumbent position or that cannot walk. This includes, but is not limited to, those with broken appendages, severed tendons or ligaments, nerve paralysis, a fractured vertebral column, or metabolic conditions. Downer cows have been categorized according to potential diseases of the CNS into nonambulatory cows with progressive or nonprogressive neurologic findings.

Etiology and Pathogenesis: In most cases, downer cow syndrome is a complica-

tion of periparturient hypocalcemia (milk fever, *see* p 988) in cows that do not fully respond to calcium therapy. Calving paralysis after dystocia may also result in recumbency due to traumatic injury to tissues and nerves inside the pelvic cavity. Regardless of the initial cause of recumbency, all cattle develop pressure-induced damage to muscles and nerves of the pelvic limbs, especially when lying on a hard surface. The hindlimb muscles of the leg the animal is lying on are compressed between the bones and the skin by the physical pressure from the weight of the recumbent cow.

With prolonged recumbency (eg, if treatment of hypocalcemia is delayed), the lymphatic and venous drainage to muscle is decreased because of sustained pressure with no decrease in arterial blood flow. The net result of pressure-induced changes in blood flow is an increase in interstitial fluid volume and pressure within the muscle, because the fascia around each muscle cannot expand sufficiently to accommodate the increase in interstitial volume. In severe and prolonged cases of recumbency, the increase in intramuscular pressure is visible as a firm swelling of the muscle. The resulting compression of muscles, nerves, and blood vessels within an enclosed compartment induces ischemic pressure damage of muscle and nerves, also named compartment syndrome. The severity of pressure damage to the muscles depends on regional anatomic factors (bones), duration

of compression, and the surface on which the animal is kept.

Pressure myopathy in downer cows is often complicated by damage to and functional loss of the sciatic nerve and its peroneal branch. The sciatic nerve may be damaged by direct compression against the caudal femur, secondary swelling of the surrounding muscles, or both. The degree of damage to the sciatic nerve is thought to be a critical factor for recovery of downer cows. Damage to the peroneal branch of the sciatic nerve results from direct pressure on the nerve as it crosses over the lateral condyle of the femur.

Experimental sternal recumbency in halothane-anesthetized cattle for 6–12 hr, with the right hindlimb positioned under the body, resulted in a swollen and rigid limb and permanent (terminal) recumbency in 50% of the cases. Cattle able to stand after anesthesia showed hyperflexion of the fetlock, indicating peroneal nerve paralysis, and myoglobinuria with dark brown urine. Necropsy of terminal downer cases revealed extensive necrosis of the caudal thigh muscles and inflammation of the sciatic nerve caudal to the proximal end of the femur.

Additional complications of prolonged recumbency include acute mastitis, decubital ulcers, and traumatic injuries to the limbs (eg, laceration and rupture of muscle fibers in the thigh) from struggling and efforts to rise.

Clinical Findings: Periparturient cows may be found in lateral recumbency, which may indicate an unresolved metabolic problem such as hypocalcemia or hypomagnesemia. Inquiries into the severity and duration of parturition may suggest that the recumbency is at least partially due to exhaustion. In involuntary sternal recumbency, some cows may have a dull, listless appearance. This may indicate hypocalcemia in periparturient mature cows. The second most likely cause of depression is toxemia, the cause of which is most commonly found in the genital tract or mammary gland. Other cows found in involuntary sternal recumbency may be bright and alert in appearance—the most typical demeanor of the true problem downer cow. If the animal is young or not pregnant, the cause is likely to be either physical damage or a rare condition, either of which requires careful, detailed examination.

The environment of the animal can have a bearing on the cause. If the footing is slippery, physical damage to the musculoskeletal system should be suspected. This is much less likely among cows in open space with a dirt or well-bedded surface.

The positioning of the hindlimbs may indicate the cause of the recumbency. Limbs splayed out behind the animal may indicate obturator nerve paresis or paralysis, hip dislocation, or fracture of the femur or tibia. Fracture should be suspected whenever the upper limb is extended sideways in such a manner that a crease is formed in the skin.

Physical Examination: A thorough physical examination should be performed when the cow is first presented. The rectal temperature should be within the normal range. If it is lower than normal, some level of shock might be present. Recession of the eyes into the orbit or persistence of a skin fold for >2 sec indicates dehydration. Pallor of the mucous membranes suggests toxemia, in which case a weak pulse and tachycardia may be present. The respiration of a recumbent cow may be labored by virtue of the pressure of the abdominal contents on the diaphragm.

Vaginal exploration is mandatory in every peripartum, recumbent cow and may lead to discovery of a decomposing fetus. Damage to and infection of the wall of the vagina is common. Metritis and an associated toxemia can contribute to postpartum recumbency.

Rectal exploration is essential for differential diagnosis. The degree of uterine involution should be appropriate for the number of days postpartum. Ballotement of fluid in the organ or lack of tonicity should be noted. Unexpected anomalies may be palpated. Adhesions, lumps of necrotic fat, and enlargement or turgidity of the cervix or vaginal wall are all sequelae of a difficult birth. Hip dislocations and fractures of the pelvis may be palpated per rectum, particularly if an assistant vigorously manipulates the upper limb of a cow in lateral recumbency. Movement of the head of the femur in the obturator foramen may also be detected in cattle with caudoventral hip dislocation. Craniodorsal dislocation of the hip, the most common direction for hip dislocation, or fracture of the femoral neck or proximal femur should be suspected if the affected limb appears shorter than the contralateral limb. Pelvic fractures can be associated with sciatic nerve paralysis, whereas hip dislocation may be associated with some degree of obturator nerve paralysis. If either condition is suspected, the sensory state of the limbs should be evaluated by judicious and humane application of an electric prod to the distal limb. Involuntary sternal recumbency may be associated with lymphosarcoma of the spinal canal, vertebral abscesses, or bizarre traumatic injuries.

Mammary gland examination should always be performed on recumbent cows. A toxic infection of the udder with an organism such as *Escherichia coli* can be a primary cause of recumbency. However, such an infection may be precipitated by the recumbency, especially if the udder is engorged and remains unmilked.

Blood samples are not usually taken when treating routine cases of hypocalcemia. However, hypocalcemia, hypophosphatemia, and hypokalemia should be assumed to be present in all recumbent cattle, and determination of the biochemical status of cattle unresponsive to calcium therapy frequently helps guide treatment and prognosis. Hypokalemia and hypophosphatemia are commonly quoted causes of creeper cows (cows able to crawl but unable to stand). Alert downer cows may have normal serum concentrations of calcium, potassium, magnesium, and phosphorus. Downer cows have increased serum CK, AST, and LDH; cows that do not recover have higher serum AST and CK activities than cows that do recover. Increased serum CK activity is a specific indicator of muscle damage; however, CK activity peaks shortly after the start of muscle damage and declines noticeably within 4 hr. For this reason, increased serum AST activity is the best prognostic indicator in recumbent cattle, with higher AST activities indicating a poorer prognosis. In cattle with severe muscle damage, the urine may contain myoglobin as well as higher than normal concentrations of protein. The age and mean serum concentrations of phosphorus, magnesium, sodium, bilirubin, glucose, and urea are not significantly different between recovering and nonrecovering cows.

Lesions: Ischemic necrosis and rupture of muscles of the thigh region are common necropsy findings in downer cows. Hemorrhage and rupture of adductor muscles may be seen if the animal "spread-eagled" itself while struggling to rise on a slippery surface such as wet or icy concrete. Traumatic and inflammatory injuries to sciatic and peroneal nerves are also found in downer cows. Damage to intrapelvic nerves, such as the sciatic and obturator nerves, account for most cases. Decubital injuries to the lateral aspect of the stifle can be associated with damage to the peroneal nerve.

Treatment: Downer cows are often hypocalcemic. If an apparently hypocalcemic cow does not respond to calcium therapy, potassium, phosphorus, and magnesium should be given as additional

treatments pending results of laboratory tests. Monitoring blood mineral status is an important part of downer cow management.

In most cases, recovery depends on the quality of recumbency management and nursing care. Lateral recumbency must be corrected immediately to avoid regurgitation and inspiration of stomach contents. The animal should be rolled into sternal recumbency. However, if this posture is to be maintained, the limb on which the animal has been lying should be drawn from under the body. In other words, if the animal was presented in lateral recumbency on its left side, it should be rolled into sternal recumbency on its right side. Support (eg, straw bale) placed under the shoulder may be required for some animals to maintain sternal recumbency.

Attempting to stabilize a recumbent cow on a concrete surface is highly undesirable but sometimes unavoidable. Bedding the area around and under the cow with wet, sticky manure to a depth of >6 in. is a common practice. At least 10 in. of dry straw should be distributed over the wet mass. If the cow struggles and scrapes the wet manure, exposing concrete, more manure must be added. The manure pack provides good footing but also may soil the skin with urine and manure. Dermatitis can result, and cow comfort is reduced. More seriously, the risk of mastitis resulting from the contaminated environment is very high. A bed of sand >10 in. deep provides a more effective method to house a recumbent cow. A sand bed usually drains well, and good hygiene can be maintained if voided manure is removed several times a day.

Some recumbent cattle appear to lose interest in trying to stand; these cattle may benefit from use of a specially designed flotation tank that has a volume of ~2,500–3,000 L. Cattle are loaded into the flotation tank by being dragged on a mat into the empty tank. Doors are then put in place, and the tank is filled with lukewarm water. Cold or hot water should be avoided, because it can induce hypothermia or hyperthermia. Cattle should be encouraged to stand once the water reaches the level of the scapulohumeral joint. When the cow stands, the musculoskeletal and nervous systems should be thoroughly examined to identify underlying disease processes. Cattle that can support their own weight should be permitted to stand for 6–8 hr; however, the water in the tank should be removed as soon as cattle exhibit trembling. Cattle that remain standing should be encouraged to walk slowly from the tank on a nonslip surface. Cattle able to walk out of

the tank after the first flotation treatment are 4.8 times more likely to survive than those that do not walk out of the tank. Cattle that stand on all four limbs during the first flotation treatment are 2.9 times more likely to survive than those that had an asymmetric stance or were unable to stand. Reported success rates in returning recumbent cattle to normal ambulation range from 37%–46%.

Hobbling may be considered in cows suspected to have obturator or sciatic nerve damage to prevent overabduction that can lead to muscular damage. Ropes should never be used for this purpose. A soft nylon strap may be wrapped twice around the middle of each metatarsus, allowing a distance of at least 3 ft between the legs.

Assisting Cows to Rise: On every day of the recumbency, an attempt should be made to bring the cow to its feet. Several simple but effective techniques can be tried. In one method, the clinician stands with feet pressed under the cow at a point below the scapulo-humeral joint. A sharp blow is delivered by driving the knees into the muscle mass below and caudal to the scapula. This method must not be used on the thoracic wall unprotected by the muscle mass to avoid fracturing the ribs. If the animal struggles to rise, an assistant should grasp the root of the tail with both hands and lift. Lifting on any other part of the tail may cause damage. Recently calved cows can be motivated to rise if they hear their own calf bawling with hunger. The calf is best restrained close to the cow but out of her sight. Some workers use electric goads and various anecdotal or traditional methods of inflicting pain to stimulate a cow to rise; these measures have a low success rate in inexperienced hands and are not recommended.

The value of hip clamps is controversial. Their proper use requires experience, skill, and a delicate touch. Continual use causes trauma and pain that is counterproductive. The forelimbs support 60% of a cow's weight and, therefore, the use of a canvas sling under the sternum is almost mandatory for consistent success. A chest band is required to prevent the sling from slipping backward. If the sling is suspended from the time at one end of a fork lift, and the hip clamps from a time at the other end, minimal trauma results. If a fork lift is not available, a T-bar suspended by a pulley from an overhead beam (or a tripod for animals at pasture) will serve. The jaws of the clamps must be well protected with synthetic foam or rubber secured in place with a wrap of duct tape.

Hip clamps should not be applied too tightly and should lift the cow slowly to allow time for the circulation of the limbs to

become reestablished. The device is lifted until the hindfeet just touch the ground. Often, the cow will hang with the limbs slightly flexed. This should not be confused with unilateral flexion, which indicates peroneal paralysis. Next, one assistant on each side of the cow presses a shoulder into the paralumbar fossa while facing the hindlimb. The device is slowly lowered as the assistants attempt to force each hindlimb into a weightbearing posture and to reduce the flexion by manipulating the stifle and hock. As soon as any weight is supported by the two limbs, the device should be lowered 1–2 in. This process may have to be repeated several times.

Even if the cow does not stand, the lifted position provides an opportunity to manipulate the limbs, auscultate for crepitation, and perform vaginal and rectal examinations.

Moving Recumbent Cows: The chances of resolution are considerably enhanced by moving the cow to a location with an earthen floor. In warm, relatively dry weather, the best location for a recumbent cow is grassy pasture, although this means that a method to lift the cow must be readily available. Otherwise, the location selected should have a roof and some protection from the elements. These conditions often exist in a hay barn or implement shed, which may have the added benefit of allowing installation of a pulley system to lift the cow.

Moving the cow requires rolling her into lateral recumbency. The cow can then be slid over dry straw for a short distance by pulling on a rope attached to a lower forelimb and a halter rope. Transportation over longer distances can be accomplished using a suitably prepared farm gate hauled by tractor. The longest dimension of the farm gate is closely applied to the back of the cow still in lateral recumbency. A tarpaulin is placed on the gate to protect the cow from contact with the ground. Dry straw is spread on the tarpaulin, and the cow is rolled over onto the makeshift stretcher. The halter should be tied to the gate to minimize struggling, and a sack placed over the eyes to minimize alarm while the cow is being moved. The tail is best tied to the hock of the upper limb. Once moved, the cow should be restored to sternal recumbency. A few cows, particularly if <12 hr postpartum, will rise immediately after being moved to a location with good footing.

Recumbent cattle should be examined daily to determine any change in ability to rise or bear weight. The chance of improve-

ment is very low if the cow does not show any improvement within 5 days of moving to a location with good footing and correction of any serum electrolyte abnormalities.

Supportive Care of Recumbent Cows:

It is vital that recumbent cows be provided with clean water at all times. A shallow rubber feed bowl prevents spillage. If the cow does not drink, she must be given fluid therapy either by drench or parenterally. Every effort must be made to roll the cow from one side onto the other at least three times a day, with more frequent movement being desired. If this is not done, the weight of the cow results in continued ischemia of the muscles of the hindlimb and exacerbation of compartment syndrome.

Protection from the elements is essential. Rain and wind can reduce body temperature considerably and worsen shock if present. A windbreak of straw bales is vital. Straw bedding should be provided to help insulate the cow from the ground. A recumbent cow does not require a warm environment; however, in a cold environment, an inactive animal can gradually succumb to hypothermia.

The downer cows most difficult to treat are those that do not try to eat. A cow that salivates on its feed will not eat it later. Rather than being offered large amounts of feed, the cow should be tempted with sweet hay. This should be cleared away every 30 min if not accepted. Placing bitter-tasting weeds such as ivy or dandelion in the mouth may provoke salivation and an interest in eating. Lettuce and cabbage leaves are accepted by some cows. In extreme cases, the cow can be drenched with rumen contents.

Prevention: Effective strategies to prevent milk fever are important to decrease downer cow syndrome. All dairy cows should be

monitored closely around calving for early signs of parturient paresis (*see* p 988). Prophylactic administration of calcium to all cows, beginning with cows entering their second or later lactation, is beneficial in herds with a high incidence of milk fever, especially in smaller farms that cannot implement feeding acidogenic salt diets.

The critical issue seems to be the length of time (several hours) from when clinical signs of milk fever begin until treatment. Every cow that has been successfully treated for hypocalcemia should, if necessary, be moved to a location with a good footing and remain there for 48 hr. Straw over sand provides good insulation and good footing.

Animal Welfare Considerations:

Although a cow may rise after being recumbent for >14 days, this does not imply that a cow should be unmonitored for this period. So long as the cow looks bright, occasionally struggles to rise, and continues to eat and drink, recovery is a possibility. However, if the cow becomes listless, shows no interest in feed, or has decubital lesions or starts to lose condition, euthanasia on humane grounds must be considered irrespective of how long she has been recumbent. A cow that has decubital lesions, a poor appetite, or shows signs of wasting is unsuitable for salvage slaughter. Attempting to send animals in this condition to the slaughterhouse is considered an act of cruelty in many countries.

"Dragging" recumbent cows is illegal in some countries. Both veterinarians and producers must be aware of the legal interpretation of the word "dragging." Access to some locations may be so restricted that rolling the animal onto an improvised sled may be impossible. At all times, even when using a sled, great care must be taken to avoid injury to dependent parts of the animal such as the udder, ears, and tail.

LAMENESS IN SMALL ANIMALS

Signs of musculoskeletal disorders include weakness, lameness, limb swelling, and joint dysfunction. Motor or sensory neurologic impairment may develop secondary to neuromuscular lesions. Abnormalities of the musculoskeletal system may also affect other organs of the

endocrine, urinary, digestive, hemolymphatic, and cardiopulmonary systems. Evaluation of musculoskeletal disease is aimed at localizing and defining the lesion(s). Diagnosis requires accurate review of the signalment, history, and physical status of the animal. A lameness

examination is critical to determine a diagnosis. Useful ancillary tests include radiography, ultrasonography, arthrocentesis, arthroscopy, arthrography, electromyography, and tissue biopsy and histopathology. For subtle lesions, advanced imaging techniques, including bone scans, CT, and MRI, are being used with greater frequency in specialty clinics and university hospitals.

THE LAMENESS EXAMINATION

The lameness examination is a key feature to identify musculoskeletal lesions. Evaluation is performed with the animal at rest, rising, and during locomotion on flat or inclined surfaces. Single- or multiple-limb lameness is noted, with the severity related to the type of activity. With a forelimb lameness, the head is elevated during weight bearing on the unsound limb. The stride is also shortened on the affected side. For hindlimb lameness, the head is dropped during weight bearing on the affected limb. Limbs should be assessed from a distal to proximal manner, and bones, joints, and soft tissue should be palpated. Abnormalities to note include swelling, pain, instability, crepitation, reduced range of motion, and muscle atrophy. In evaluation of a subtle or obscure lameness, serial examinations before and after exercise may be necessary. For fractious animals, sedation may be required; palpation, radiography, and arthrocentesis can often be performed while an animal is sedated with IV butorphanol and acepromazine; propofol; medetomidine (alone or combined with butorphanol or hydromorphone); or a combination of ketamine, diazepam, and acepromazine.

Imaging Techniques: Helpful imaging procedures to diagnose lameness include survey and contrast radiography, ultrasonography, nuclear scintigraphy, CT, and MRI. Animals undergoing these evaluations should be mildly sedated or anesthetized. Survey radiography of affected limbs or the spine requires multiple, orthogonal views. Subtle lesions are often identified after comparison with the contralateral normal limb. The most frequent contrast studies used to evaluate lame animals are arthrograms for joint diseases and myelography for spinal canal disorders. Ultrasonography is useful to evaluate musculotendinous injuries such as bicipital tenosynovitis, Achilles tendon rupture, and muscle contracture. Nuclear scintigraphy, CT, and MRI studies are usually available at private or academic

referral centers. Nuclear scintigraphy involves IV injection of a radioactive compound that localizes and highlights periosteous soft tissue and bone lesions. CT imaging permits high contrast and resolution of osseous structures, whereas MRI is helpful to delineate soft tissue and joint injuries. Both can also be used to assess the spinal column, although MRI is a better standard to evaluate nervous tissues.

Arthroscopy: Arthroscopy is a minimally invasive tool used for diagnosis and therapy of lame animals. Advantages of the technique include improved visualization and diagnosis of joint pathology, ability to treat injuries by removal of damaged cartilage or ligament, and reduced surgical dissection. Disadvantages are costs of equipment and development of expertise in its use. Common conditions that can be diagnosed or treated by arthroscopy include osteochondrosis, bicipital tenosynovitis, joint fractures, and cranial cruciate ligament and medial meniscal injuries.

PAIN MANAGEMENT

Control of pain in lame or operative animals involves broad classes of compounds such as NSAIDs and opioids (*see also* PAIN ASSESSMENT AND MANAGEMENT, p 2104). Analgesic agents can be administered via oral, parenteral (including constant-rate infusions), epidural, local, or transdermal routes. Nonpharmacologic pain management strategies include acupuncture therapy, massage, physical therapy, and diet.

Commonly used NSAIDs include deracoxib (4 mg/kg/day, PO), firocoxib (5 mg/kg/day, PO), meloxicam (dogs: 0.1 mg/kg/day, IV, SC, PO; cats: 0.1 mg/kg/day, IV, SC, PO, for 1–3 days), carprofen (2.2 mg/kg, PO, bid), ketoprofen (1 mg/kg/day, PO, IV, SC, IM), etodolac (12.5 mg/kg/day, PO), tepoxalin (10 mg/kg/day, PO), and aspirin (dogs: 22 mg/kg, PO, bid; cats: 10 mg/kg, PO, every 48 hr). The use of NSAIDs is contraindicated in animals with hepatic or renal insufficiency, gastroenteritis, or coagulopathy, and in animals receiving concurrent corticosteroid therapy.

Opioid analgesics bind to μ , κ , and δ receptors in the CNS to provide pain relief. Commonly used opioids include morphine (0.1 mg/kg, IV, IM, SC, every 3–4 hr), oxymorphone (0.05 mg/kg, IV, IM, SC, every 3–4 hr), hydromorphone (0.1 mg/kg, IV, IM, SC, every 2–4 hr), butorphanol (0.1 mg/kg, IV, IM, SC, every 2–4 hr in dogs and cats), and buprenorphine (0.01 mg/kg, IV, IM, SC,

tid in dogs and cats, also transmucosal in cats). Opioid narcotics can be given with sedatives such as acepromazine (0.5 mg/kg, IV, IM, SC, every 4–6 hr) for enhanced efficacy of analgesia and sedation. Oxymorphone, hydromorphone, and butorphanol are more potent than morphine. Buprenorphine has the longest duration of action. Another opioid, fentanyl, is most frequently administered via transdermal patches applied for 3 days on shaved areas. Oral opioids used for pain relief include tramadol (5 mg/kg, tid), butorphanol (1 mg/kg, tid), hydromorphone (0.5 mg/kg, tid), codeine (1 mg/kg, tid), and oxycodone (0.3 mg/kg, tid).

Local administration of analgesics involves joint injections with morphine (1 mg diluted in 5 mL of saline), bupivacaine (1 mL/20 kg body wt), or lidocaine (1 mL/20 kg body wt) before joint surgery as a preemptive block of intracapsular pain receptors. Epidural morphine (0.1 mg/kg) in the lumbosacral space is also a useful adjunct for postoperative pain relief in the hindlimbs and for reduced anesthetic requirements. Corticosteroids are considered weak analgesic adjuncts, because they indirectly reduce pain by their

primary action as local anti-inflammatory agents at the site of injury. Drugs used include prednisone or prednisolone (1–2 mg/kg/day, PO) or dexamethasone (1–2 mg/kg/day, IV). Their use is contraindicated during concurrent NSAID treatment.

Gabapentin (10 mg/kg, PO, bid) is a calcium channel blocker used to inhibit neurons stimulated by pain; it is useful for treatment of animals with chronic or neuropathic pain. Dexmedetomidine (5 mcg/kg/day, IM) and medetomidine (10 mcg/kg/day, IM) are newer analgesic-sedative, α_2 -receptor blocking agents useful to facilitate examinations or diagnostic evaluations.

Joint fluid modifiers (glucosamine, chondroitin sulfate, hyaluronan, pentosan polysulfate, omega-3 fatty acids) have received extensive attention in treating degenerative joint disease and alleviating discomfort. While contraindications and adverse effects are few, scientifically proven efficacy of these compounds is limited and most reports are regarded as anecdotal evidence. Stem cell therapy to alleviate pain and discomfort of diseased joints is also a newer modality for which scientific validity is pending.

ARTHROPATHIES AND RELATED DISORDERS IN SMALL ANIMALS

Many arthropathies are developmental, including aseptic necrosis of the femoral head, patellar luxation, osteochondrosis, elbow dysplasia, and hip dysplasia. Other arthropathies are degenerative, infectious or septic, immune-mediated, neoplastic, or traumatic.

ASEPTIC NECROSIS OF THE FEMORAL HEAD

(Legg-Calvé-Perthes disease)

This deterioration of the femoral head seen in young miniature and small breeds of dogs is associated with ischemia and avascular necrosis of the bone. The exact cause is unknown, although there may be a hereditary component in Manchester Terriers. Infarction of the bone leads to collapse of the femoral head and neck,

followed by revascularization, resorption, and remodeling. The lesion is often bilateral.

Clinical signs include hindlimb lameness, atrophy of the thigh muscles, and pain during manipulation of the hip joint. Radiography reveals irregular bone density of the femoral head and neck, collapse, and fragmentation of the bone. Chronic cases have evidence of degenerative joint disease.

Treatment involves surgical excision of the affected femoral head and neck and early postoperative physical therapy to stimulate limb usage. Prognosis for recovery is excellent.

PATELLAR LUXATION

This hereditary disorder in dogs and cats is characterized by ectopic development of

the patella medial or lateral to the trochlear groove of the femur. Patellar luxation can be associated with multiple deformities of the hindlimb, involving the hip joint, femur, and tibia. Medial patellar luxations can be involved with a reduced coxofemoral angle (coxa vara), lateral bowing of the femur, internal rotation of the tibia, shallow trochlear groove, and hypoplasia of the medial femoral condyle; lateral luxations cause the reverse changes.

Clinical signs are variable and based on the severity of luxation. Animals of any age may be affected. In general, cats and small and miniature breeds of dogs have a medial luxation, and large dogs have a lateral luxation. Affected animals are lame or ambulate with a skipping gait. Palpation of the stifle joint reveals displacement of the patella. In Grade I, clinical signs are mild and infrequent, and the patella can be manually luxated but easily returns to the trochlear groove. In Grade II, the patella luxates during flexion of the joint and is repositioned during extension, causing animals to have a resolvable skipping lameness. In Grade III, the dislocated patella is more frequently out of, instead of in, the trochlear groove, and lameness is consistent. Bone deformities are evident in these animals. In Grade IV, lameness and limb deformations are most severe. Radiography of affected animals reveals various degrees of limb changes based on the grade of the luxation.

The type of surgery is based on the severity of the luxation and can include both orthopedic and soft-tissue procedures. Useful procedures involve fascial releasing incisions (on the side of the luxation), joint capsule and retinaculum imbrications (on the side opposite the luxation), deepening of the trochlear groove, tibial crest transposition, and fabella to tibial tuberosity derotation sutures. Severe deformations may require femoral or tibial osteotomies, stifle joint arthrodesis, or limb amputation.

Prognosis for recovery is good in mild or moderately affected animals. Concurrent cranial cruciate ligament and medial meniscal injuries should be identified and treated. Cats are less severely affected than dogs and have an excellent prognosis.

OSTEOCHONDROSIS

Osteochondrosis is a developmental disorder of medium and large rapidly growing dogs that is characterized by

abnormal endochondral ossification of epiphyseal cartilage in the shoulder, elbow, stifle, and hock joints. Although the exact cause is unknown, excessive nutrition, rapid growth, trauma, and a hereditary component are suspected to be contributing factors. As a result of abnormal maturation and vascularity, basal cartilage cells thicken and weaken, thus leading to cartilage cracks, fissures, and flap formation (osteochondritis dissecans) after minor trauma or normal pressure to the joint. Abnormal cartilage congruency and joint debris lead to a synovitis and subsequent arthritis and continued cartilage breakdown. Cartilage flaps can break loose and attach to the joint capsule or migrate and deleteriously affect joint motion.

Clinical signs are lameness, joint effusion, and reduced range of motion in affected joints or limbs. Locations of the lesions include the head of the humerus (shoulder joint), the medial aspect of the humeral condyle (elbow joint), the femoral condyles (stifle joint), and the trochlear ridges of the talus (hock joint). Additionally, fragmented medial coronoid process and ununited anconeal process in the elbow joint may be related conditions. Radiography is useful in identifying joint lesions; changes may include flattening of joint surfaces, subchondral bone lucency or sclerosis, osteophytosis, joint effusion, and "joint mice." Arthrography can be used to delineate cartilage flaps, and arthroscopy can also be performed to identify and treat cartilage or joint lesions. CT imaging also helps identify subchondral bone changes.

Treatment involves surgical excision of cartilage flaps or free-floating fragments and curettage of subchondral bone to stimulate fibrocartilage formation. Animals with degenerative joint disease may benefit from NSAIDs, eg, aspirin (10 mg/kg, PO, bid), carprofen (2.2 mg/kg, PO, bid), deracoxib (4 mg/kg/day, PO), firocoxib (5 mg/kg/day, PO), meloxicam (0.1 mg/kg/day, PO), tepoxalin (10 mg/kg/day, PO), or etodolac (12.5 mg/kg/day, PO). Joint fluid modifiers such as polysulfated glycosaminoglycan (4.4 mg/kg, IM, twice a week for 4 wk) may also help prevent cartilage degeneration. Prognosis for recovery is excellent for the shoulders, good for the stifle joint, and fair for the elbow and tarsal joints. Concomitant signs of degenerative joint disease, other joint conditions, or instability (hock joint) deleteriously affect recovery.

ELBOW DYSPLASIA

(Ununited anconeal process, Fragmented medial coronoid process, Osteochondrosis of the humeral condyle)

Elbow dysplasia is a generalized incongruity of the elbow joint in young, large, rapidly growing dogs that is related to abnormal bone growth, joint stresses, or cartilage development. One or more of the following lesions may be present in the joint: an ununited anconeal process of the ulna, fragmentation of the medial coronoid process of the ulna, and osteochondrosis of the medial aspect of the humeral condyle. Radiographic grading of dysplastic elbow joints is performed by the Orthopedic Foundation for Animals in the USA and in Scandinavian and European kennel clubs.

Ununited Anconeal Process: This results when there is separation of the ossification center of the anconeal process from the proximal ulnar metaphysis. Fusion should be completed by 5–6 mo of age. The fracture is postulated to result from a biomechanical imbalance of force and movement in the rapidly growing elbow. Initially, the anconeal process is connected to the ulna by a bridge of fibrous tissue, which fragments to form a pseudoarthrosis, and the elbow becomes unstable. This joint laxity continues to damage the articular cartilage, and secondary osteoarthritis results. A hereditary basis has been implicated but not proved.

Lameness develops insidiously between 4 and 8 mo of age; however, some bilateral cases may not be diagnosed until dogs are >1 yr old. Affected elbows may deviate laterally, and the range of motion is restricted. Advanced cases have osteoarthritis, joint effusion, and crepitus. Clinical signs are suggestive, and the diagnosis is confirmed by radiography. A lateral radiograph of the elbow in the flexed position allows visualization of the ununited process. Both elbows should be examined because the condition can be bilateral.

Fragmentation of the Medial Coronoid Process: In this condition of the medial compartment of the canine elbow, the coronoid process fails to unite, either partially or totally, with the ulnar diaphysis and, thus, does not become a part of the articular surface of the trochlear notch. Joint laxity, irritation, and finally osteoarthritis result. This condition and osteochondrosis of the medial humeral condyle are considered to be the most common causes of osteoarthritis of the

canine elbow. Bone fragments can be seen by radiography, arthroscopy, or CT.

Osteochondrosis of the Medial Humeral Condyle: This results from a disturbed endochondral fusion of the epiphysis of the medial epicondyle with the distal end of the humerus. The exact cause is unknown, but because the carpal and digital flexors originate from the ventral aspect of this structure, it may represent an epiphyseal avulsion. It results in pain on flexion of the elbow or deep digital palpation and is accompanied by soft-tissue swelling. Radiographically, radiodense structures have been seen caudal and distal to the area of the medial epicondyle.

Treatment: Early surgical treatment is recommended before degenerative joint disease develops. For fragmentation of the medial coronoid process, a medial arthrotomy or arthroscopy is performed and the fragmented process removed. For ununited anconeal process, either a lateral arthrotomy is performed and the ununited process removed, or a midshaft ulnar osteotomy is performed to relieve asynchronous growth and result in union of the process. Reattachment of the process by screw fixation is also an option. For osteochondrosis, the subchondral bone lesion is curetted to stimulate fibrocartilage formation. Prognosis after surgery is good if degenerative joint disease has not developed in the joint. Aspirin or NSAIDs (eg, carprofen, deracoxib, firocoxib, etodolac, meloxicam, tepoxalin) can be used to reduce pain and inflammation. Joint-fluid modifiers (glycosaminoglycans, hyaluronic acid) may be useful.

HIP DYSPLASIA

Hip dysplasia is a multifactorial abnormal development of the coxofemoral joint in dogs that is characterized by joint laxity and subsequent degenerative joint disease. It is most common in large breeds. Excessive growth, exercise, nutrition, and hereditary factors affect the occurrence of hip dysplasia. The pathophysiologic basis for hip dysplasia is a disparity between hip joint muscle mass and rapid bone development. As a result, coxofemoral joint laxity or instability develops and subsequently leads to degenerative joint changes, eg, acetabular bone sclerosis, osteophytosis, thickened femoral neck, joint capsule fibrosis, and subluxation or luxation of the femoral head.

Clinical signs are variable and do not always correlate with radiographic

abnormalities. Lameness may be mild, moderate, or severe and is pronounced after exercise. A "bunny-hopping" gait is sometimes evident. Joint laxity (Ortolani sign), reduced range of motion, and crepitation and pain during full extension and flexion may be present. Radiography is useful in delineating the degree of arthritis and planning of medical and surgical treatments. Standard ventrodorsal views of sedated or anesthetized animals can be graded by the Orthopedic Foundation for Animals, or stress radiographs performed and joint laxity measured (Penn Hip). A dorsal acetabular rim view is used by some surgeons to evaluate the acetabulum before reconstructive surgery. Modified ventrodorsal and dorsoventral projections have also been proposed in an effort to mimic the normal standing posture of dogs. Recent reviews of American and international radiographic screening programs have failed to identify a "gold standard." An evaluation shift toward genome screening may yield more promising results in the future.

Treatments are both medical and surgical. Mild cases or nonsurgical candidates (because of health or owner constraints) may benefit from weight reduction, restriction of exercise on hard surfaces, controlled physical therapy to strengthen and maintain muscle tone, anti-inflammatory drugs (eg, aspirin, corticosteroids, NSAIDs), and possibly joint fluid modifiers. Surgical treatments include pectineal myotectomy to reduce pain, triple pelvic osteotomy to prevent subluxation, pubic fusion to prevent subluxation, joint capsule denervation to reduce pain, dorsal acetabulum reinforcement to reduce subluxation, femoral head and neck resection to reduce arthritis, and total hip replacement for optimal restoration of joint and limb functions. Additionally, femoral corrective osteotomies can be performed to reduce femoral head subluxation, although degenerative arthritis may persist.

Prognosis is highly variable and depends on the overall health and environment of the animal. In general, if surgery is indicated and performed correctly, it is beneficial. Animals on which surgery is not performed may require a change in lifestyle to live comfortably.

DEGENERATIVE ARTHRITIS

(Degenerative joint disease, Osteoarthritis)

Progressive deterioration of articular cartilage in diarthrodial joints is characterized by hyaline cartilage thinning, joint effusion, and periarticular osteophyte

formation. Joint degeneration can be caused by trauma, infection, immune-mediated diseases, or developmental malformations. The inciting cause initiates chondrocyte necrosis, release of degradative enzymes, synovitis, and continued cartilage destruction and inflammation. Abnormal cartilage congruency and joint capsule anatomy can further lead to alteration in normal joint biomechanical function. Pain and lameness develop secondary to joint dysfunction or muscle atrophy and to limb disuse. Although more common in dogs, joint degeneration may also be seen in cats.

Clinical signs of degenerative joint disease include lameness, joint swelling, muscle atrophy, pericapsular fibrosis, and crepitation. Radiographic changes in the joint include joint effusion, periarticular soft tissue swelling, osteophytosis, subchondral bone sclerosis, and possibly narrowed joint space. Arthrocentesis may be unremarkable or yield minor changes in color, turbidity, or cell counts of synovial fluid.

Treatments can be medical or surgical. Nonsurgical therapies include weight reduction, controlled exercise on soft surfaces, and therapeutic application of warm compresses to affected joints. NSAIDs (eg, aspirin, etodolac, carprofen, deracoxib, meloxicam, firocoxib, tepoxalin) reduce pain and inflammation. Caution is advised with long-term NSAID usage in dogs. The most frequently cited adverse effects include GI problems such as inappetence, vomiting, and hemorrhagic gastroenteritis. A carprofen-associated hepatopathy in Labrador Retrievers has also been reported. Corticosteroids also suppress prostaglandin synthesis and subsequent inflammation, but short-term use is advised to prevent iatrogenic hyperadrenocorticism, cartilage degeneration, and intestinal perforation. Joint-fluid modifiers such as glycosaminoglycans or sodium hyaluronate may prevent cartilage degradation. Surgical options include joint fusion (arthrodesis), most frequently performed on the carpus and tarsus; joint replacement, such as total hip replacement; joint excision, such as femoral head and neck osteotomy; and amputation. Prognosis is variable and depends on the location and severity of the arthropathy.

SEPTIC ARTHRITIS

Infectious arthritis is most frequently associated with bacterial agents such as staphylococci, streptococci, and coliforms. Causes include hematogenous spread or penetrating trauma, including surgery.

Other agents producing a septic arthritis include rickettsia (Rocky Mountain spotted fever, ehrlichiosis) and spirochetes (borreliosis).

Clinical signs of septic arthritis include lameness, swelling, pain of affected joint(s), and systemic signs of fever, malaise, anorexia, and stiffness. Radiography may reveal joint effusion in early cases and degenerative joint disease in chronic conditions. Arthrocentesis reveals increased levels of WBCs, especially neutrophils. The synovial fluid may be grossly purulent. Bacterial culture and antimicrobial sensitivity testing may confirm the diagnosis. Serologic testing is used for nonbacterial agents. Treatment is with appropriate IV and oral antibiotics, joint lavage, and surgical debridement in severe cases.

IMMUNE-MEDIATED ARTHRITIS

Inflammatory polyarthritis secondary to deposition of immune complexes can produce erosive (destruction of articular cartilage and subchondral bone) or nonerosive (periarticular inflammation) forms of joint diseases. Rheumatoid arthritis, Greyhound polyarthritis, and feline progressive polyarthritis are examples of erosive arthritides. Systemic lupus erythematosus (SLE) is the most common form of nonerosive arthritis.

Clinical signs are lameness, multiple joint pain, joint swelling, fever, malaise, and anorexia. Clinical signs commonly wax and wane.

Diagnosis is aided by radiography, biopsy, arthrocentesis, and serologic testing. Radiography reveals periarticular swelling, effusion, and joint collapse plus subchondral bone destruction in erosive conditions. Arthrocentesis reveals synovial fluid with reduced viscosity and increased inflammatory cell counts. Biopsy of synovial tissue reveals mild to severe inflammation and cellular infiltrates. Serologic testing is performed for rheumatoid factor and antinuclear antibodies.

Treatment involves anti-inflammatory medications (eg, corticosteroids) and chemotherapeutic agents (eg, cyclophosphamide, azathioprine, or methotrexate). Prognosis is guarded because of relapses and inability to determine the inciting cause of the autoimmune reactions.

NEOPLASTIC ARTHRITIS

Synovial cell sarcoma is the most common malignant tumor involving the joints. The

tumor arises from primitive mesenchymal cells outside the synovial membrane. Clinical signs include lameness and joint swelling. Radiography reveals soft-tissue swelling and a periosteal reaction. Pulmonary metastasis is detected in ~25% of animals at initial examination. Biopsy reveals evidence of a soft-tissue tumor. Limb amputation is the treatment of choice, although palliative radiation may be considered for cases with a low tumor burden not involving bone.

POLYARTHRITIS

Polyarthritis involves inflammation of multiple joints and is classified as infectious (septic arthritis, *see* p 1197) or noninfectious (erosive or nonerosive [immune-mediated]). Nonerosive can be idiopathic or breed (Akita) associated, while erosive is characteristic of feline progressive arthritis and rheumatoid arthritis. Clinical signs of a polyarthritis include fever, lameness, swollen joints, lethargy, and inappetence. Diagnosis is by radiography (joint effusion, possible erosive bone destruction) and abnormal (increased cell counts) joint fluid analyses. Treatments involve longterm glucocorticoid therapy or other immunosuppressive medications such as azathioprine or cyclophosphamide. Prognosis in most cases is guarded or poor, with relapses common.

JOINT TRAUMA

Cranial Cruciate Ligament Rupture

Rupture of the cranial cruciate ligament is most frequently due to excessive trauma and a possibly weakened ligament secondary to degeneration, immune-mediated diseases, or conformational defects (straight-legged dogs). Plasmacytic-lymphocytic synovitis is sometimes diagnosed concurrently with ligament injury, but it remains unclear whether it is a cause or effect of the joint instability. Stable (nonsurgical) joints with an early or mild condition can be treated with steroids or an NSAID. Most injuries involve a midsubstance tear (mature dog), although bone avulsion (immature dog) at the origin of the ligament is possible. Instability of the stifle joint after rupture of the cranial cruciate ligament can lead to medial meniscal injury, joint effusion, osteophytosis, and joint capsule fibrosis.

Clinical signs involve lameness, pain, medial joint swelling, effusion, crepitation, excessive cranial laxity of the proximal tibia relative to the distal femur (drawer sign, or

positive compression test), and increased internal tibial rotation. Partial cranial crucial ligament tears are characterized by a reduced cranial laxity, usually more pronounced in flexion. Medial meniscal injury may be identified by a clicking sound during locomotion or flexion and extension. A tibial compression test (flexion of the hock and cranial displacement of the tibial tuberosity) can also be used to demonstrate laxity of the cranial cruciate ligament. Radiography reveals joint effusion and signs of degenerative joint disease in chronic injuries. Arthrocentesis may reveal mild cellular increases and hemarthrosis. Arthroscopy can confirm the diagnosis but requires specialized equipment.

Treatments include medical and surgical therapies. Weight reduction, controlled physical therapy, and NSAIDs alleviate pain and discomfort from inflammation and degenerative joint disease. Surgical stabilization of the stifle joint is recommended for active dogs. Extracapsular techniques include fascial suturing, fabella to tibial tuberosity imbrication sutures, cranial transposition of the fibular head, leveling of the tibial plateau, tibial tuberosity advancement, and synthetic grafts. Intracapsular techniques include fascia lata or patellar tendon grafts sutured over the top of the lateral femoral condyle. Medial meniscal injury requires removal of damaged avascular tissue. Postoperative physical therapy is critical for clinical recovery. Prognosis after surgery is good.

Joint Fractures

Traumatic fractures frequently involve the shoulder, elbow, carpal, hip, stifle, and tarsal joints. In immature animals, the weakness of the physis compared with adjacent bones, ligaments, and joint capsule predisposes this area to injury. A Salter-Harris classification scheme (I-V) is often used to describe the location of the fracture relative to the

physis and joint. Specific common sites of injury include the greater tubercle and condyle of the humerus, distal ulnar physis, and the head and condyles of the femur. The humeral condyle is also frequently injured in mature Spaniel breeds and characterized by Y or T fracture configurations. This may be related to incomplete ossification and vascularity of the bone.

Clinical signs of joint fractures include lameness, pain, and joint swelling. Chronic injuries may be characterized by angular limb deformities if the injury affected an open growth plate. Radiography and CT are useful in delineating the fracture.

The goal of joint fracture treatment is stable anatomic reconstruction to maintain joint congruency and joint and limb functions. Internal fixation with pins, wires, or screws is performed to achieve stable fixation. Prognosis for recovery is good if proper surgical technique has been used and joint trauma has not been excessive.

Palmar Carpal Breakdown

This hyperextension injury secondary to falls or jumps produces excessive force on the carpus, which leads to collapse of the proximal, middle, and/or distal joints secondary to tearing of the palmar carpal ligaments and fibrocartilage. Clinical signs include lameness, carpal swelling, and a characteristic plantigrade stance. External splints or casts may be attempted in mild cases, although surgical treatment is usually required to restore limb function. Surgery involves fusion (arthrodesis) of the affected joints using a bone plate and screws, pins and wires, or external skeletal fixation. A cancellous bone graft is used to enhance bone union, and postoperative support is necessary. Prognosis for recovery is good.

Hip Luxation

Traumatic dislocation of the hip is most frequently a craniodorsal displacement of the femoral head relative to the acetabulum. Clinical signs include lameness, pain during manipulation of the hip joint, and a shortened limb due to dorsal displacement of the femur. Radiography is useful in confirming the luxation and delineating the presence of other fractures in the femoral head or acetabulum. Treatment involves either closed manipulation and postoperative slings to maintain the reduction or open surgical stabilization using sutures or toggle pins. Femoral head and neck resection or total hip replacement can be performed after failed reductions. Prognosis for recovery is usually excellent.

Capital physeal fracture. Courtesy of Dr. Ronald Greeff.

MYOPATHIES IN SMALL ANIMALS

Myopathies can be congenital, hereditary, idiopathic, inflammatory, metabolic, neoplastic, traumatic, or due to nutritional imbalances.

YELLOW FAT DISEASE

(Nutritional steatitis, Nutritional panniculitis)

Yellow fat disease is characterized by a marked inflammation of adipose tissue and deposition of "ceroid" pigment in fat cells. It may be seen alone in cats or with accompanying myopathy in rats, mink, foals, and pigs.

It is believed that an overabundance of unsaturated fatty acids in the ration, together with a deficiency of vitamin E or other antioxidants, results in lipid peroxidation and deposition of "ceroid" pigment in the adipose tissue. Most naturally occurring and experimentally induced cases have been in animals that have had fish or fish by-products as all or part of the diet. The specific cause is believed to be related jointly to the high unsaturation of the fish oil fatty acids and their lack of protection with vitamin E or other antioxidants.

Affected cats are frequently obese, usually young, and of either sex. They lose agility, are unwilling to move, and resent palpation of the back or abdomen. In advanced disease, even a light touch causes pain. Fever is a constant finding, and anorexia may be present.

In mink, kits may be affected with steatitis shortly after weaning and, if untreated, losses may continue until pelting time. Signs appear suddenly; the kits may refuse a night feeding and be dead by morning. Affected mink may refuse their feed and show a peculiar, unsteady hop, followed by complete impairment of locomotion and coma. At pelting, survivors show yellow fat deposits and hemoglobinuria.

The typical laboratory finding is an increased WBC count, with neutrophilia and sometimes eosinophilia. Biopsy of the subcutaneous fat shows it to be yellowish brown and firm. Histologic examination reveals severe inflammatory changes and associated ceroid pigment.

The offending excessive fat source must be removed from the diet. Administration of vitamin E, in the form of α -tocopherol, at

least 30 mg daily for cats, or 15 mg daily for mink, is necessary. Antibiotics are of doubtful value, despite the fever and leukocytosis. Parenteral use of fluids is not advisable unless dehydration exists. Because of associated pain, affected animals should be handled as little as possible.

LABRADOR RETRIEVER MYOPATHY

(Centronuclear myopathy)

This inherited (autosomal recessive) condition is characterized by a type 2 muscle fiber deficiency and is now called centronuclear myopathy. Clinical signs are seen at <5 mo of age and include skeletal muscle atrophy, stunted growth, ataxia, and weakness. Signs are progressive until the animal reaches maturity, when they stabilize. Animals may have a normal life span. Diagnosis is by creatinuria, muscle biopsy, and electromyography. Histology reveals increased connective tissue around muscle fibers and staining deficiency of type II fibers. Myotonic discharges are seen with electromyography. There is no effective treatment, although warm housing and L-carnitine supplementation may make affected dogs more comfortable. This condition has different clinical features than exercised-induced collapse in Labrador Retrievers.

GREAT DANE MYOPATHY

Inherited myopathy of Great Danes is a noninflammatory condition of young Great Danes. Affected dogs have been identified in England, Australia, and Canada. An autosomal recessive mode of inheritance is suspected. Clinical signs include exercise-induced tremors, weakness, and muscle wasting. CK activity is usually increased, fibrillation potentials are detected in skeletal muscles, and histopathology reveals a central core myopathy. Treatment is supportive, at best.

FIBROTIC MYOPATHY

Fibrotic myopathy is a chronic, progressive, idiopathic, degenerative disorder affecting the semitendinosus, gracilis, quadriceps,

infraspinatus, and supraspinatus muscles, primarily in dogs. The cause is unknown. Affected muscles are characterized by contracture and fibrosis. Normal tissues are replaced by dense collagenous connective tissue. Clinical signs include a nonpainful, mechanical lameness. Neurologic function is normal. Surgical release of affected tissues via tenotomy, myotenyotomy, Z-plasty, or complete resection produces inconsistent results. Prognosis is guarded because of recurrence.

MYOSITIS OSSIFICANS

Myositis ossificans is an idiopathic non-neoplastic form of heterotopic ossification of fibrous connective tissue and muscle that frequently affects tissues near the hip joint in Doberman Pinschers. It may be related to a bleeding disorder (von Willebrand disease) in these dogs. Surgical resection of the mineralized mass is usually rewarding.

POLYMYOSITIS

Polymyositis is a systemic, noninfectious, possibly immune-mediated, inflammatory muscle disorder in adult dogs. It may be acute or chronic and progressive. Clinical signs include depression, lethargy, weakness, weight loss, lameness, myalgia, and muscle atrophy. CK may be increased, and electromyography reveals abnormal spontaneous muscle activity. Muscle biopsy reveals myonecrosis, lymphocytic-plasmacytic perimyscular infiltration, phagocytosis, and fiber regeneration. Polymyositis may be associated with megaesophagus and immune-mediated disorders (myasthenia gravis, lupus erythematosus, polyarthritis). Oral corticosteroids (1–2 mg/kg, bid for 3–4 wk) are the treatment of choice; other immunosuppressive agents such as azathioprine or cyclophosphamide can also be used. Prognosis is favorable, although relapses are not uncommon.

MASTICATORY MYOSITIS

(Eosinophilic myositis)

Masticatory myositis is an immune-mediated, inflammatory condition that affects the muscles of mastication. The exact cause is unknown. Specific autoantibodies directed against type II muscle fibers have been detected in affected animals. In acute cases, muscles are swollen, and there is difficulty in opening the jaw. In chronic cases, there is anorexia, weight loss,

difficulty in opening the jaw, and muscle atrophy. Diagnostic hematologic values include eosinophilia and increased levels of globulin and muscle enzymes. Electromyography reveals abnormal spontaneous electrical activity in affected muscles. A biopsy sample of the temporalis muscle is usually taken; histologic changes include lymphocytic-plasmacytic cellular infiltrates, muscle atrophy, and fibrosis. Although spontaneous regression can occur, prednisone treatment, on a decreasing dosage schedule (2 mg/kg/day for 2 wk, then 1 mg/kg/day for 2 wk, then 1 mg/kg/day for 1 mo) is usually effective. Relapses are common, and long-term (6–8 mo) medication may be required.

FELINE HYPOKALEMIC POLYMYOPATHY

Feline hypokalemic polymyopathy is a generalized metabolic muscle weakness disorder in cats secondary to hypokalemia associated with excessive urinary depletion or inadequate dietary intake. Extracellular hypokalemia causes muscle cell membrane hyperpolarization and secondary excessive permeability to sodium. This leads to hypopolarization of the muscle cell and subsequent weakness.

Clinical signs include generalized weakness, ventroflexion of the neck, abnormal gait, anorexia, and muscle pain. The neurologic examination is normal. Serum chemistries reveal hypokalemia (<3.5 mEq/L) and increased creatinine and CK. The urine has a low specific gravity, and potassium excretion is increased. Treatment is by potassium supplementation, given PO (5–8 mEq/day) or IV in cats with profound hypokalemia. Prognosis is excellent with early diagnosis and treatment.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (*see* p 1027) is a hypermetabolic disorder of skeletal muscle characterized by catabolism and contraction, usually secondary to inhalant anesthetic agents and stress. It is seen most frequently in heavily muscled dogs. Abnormal calcium regulation, glycogenolysis, and contractile protein activity result in production of heat, CO_2 , and lactic acid.

Clinical signs include tachycardia, tachypnea, pyrexia, muscle rigidity, and cardiopulmonary failure. Signs develop 5–30 min after exposure to the anesthetic agent. Treatment consists of immediate

cessation of anesthesia and hyperventilation with oxygen. IV fluid therapy, corticosteroids, and ice packs are also used. Dantrolene, a muscle relaxant, may be given at 2–5 mg/kg, IV. Prognosis is poor in severe cases. Urinary output, serum potassium levels, and cardiac function should be monitored.

EXERTIONAL MYOPATHY

(Rhabdomyolysis, Tying-up, Monday morning disease)

This acute exertional myopathy of racing Greyhounds and working dogs is characterized by muscle ischemia secondary to exercise or excitement. Avascularity and lactic acidosis cause muscular lysis, myoglobin release, and a nephropathy.

Clinical signs include muscle pain and swelling 24–72 hr after racing. Severe cases are characterized by stiffness, hyperpnea, collapse, myoglobinemia, and acute renal failure. Urinalysis reveals myoglobinuria; serum potassium, phosphorus, and muscle enzymes are increased. Treatment includes supportive care such as IV fluids, bicarbonate, body cooling, rest, and muscle relaxants (eg, diazepam). Prognosis depends on severity. (See also EXERTIONAL MYOPATHIES IN HORSES, p 1178.)

MUSCULAR TRAUMA

Infraspinatus Contracture: Infraspinatus contracture is a uni- or bilateral fibrotic myopathy of the infraspinatus muscle that is usually secondary to trauma in hunting or working dogs. Clinical signs include an acute lameness, pain, and swelling in the shoulder region. The lameness subsides, but a gait abnormality develops 2–4 wk after injury as muscle fibrosis and contracture progress. Clinical signs include a characteristic adduction of the elbow, abduction of the foreleg, and external rotation of the carpus and paw. The limb is circumducted with each stride of the leg. Palpation of the shoulders reveals outward rotation of the humerus as the elbow is flexed. Treatment consists of resection of the fibrous musculotendinous portion of the muscle, including tenotomy of the tendon of insertion. Limb and joint functions are immediately improved, and prognosis for full recovery is excellent.

Tenosynovitis of the Biceps Brachii Tendon: This inflammation of the biceps brachii tendon of origin and associated synovial sheath can be uni- or bilateral. It usually affects mature, large dogs. The

mechanism of injury can be direct, indirect, overuse, or migration of osteochondral fragments (“joint mice”) from humeral osteochondrosis lesions.

Clinical signs include a progressive or chronic, intermittent lameness that worsens after exercise and improves with rest. The range of motion of the shoulder joint is reduced, and atrophy of the shoulder muscles may be apparent. Acute pain can be elicited by applying digital pressure to the biceps tendon during flexion and extension of the shoulder joint.

Diagnosis can be confirmed by ultrasonography or arthroscopy of the damaged tendon. Radiography can reveal dystrophic calcification of the tendon, osteophytes in the intertubercular groove, or mineralized fragments within the tendon sheath. Contrast arthrography may demonstrate filling defects and irregularities of the synovial sheath. Arthrocentesis may be inconclusive. Diagnosis can also be made by exploration of the tendon and associated sheath.

Acute, mild cases can be treated with rest and oral NSAID and opioids. Acute, severe cases can be treated with intralesional injections of methylprednisolone acetate (20–40 mg) and rest. Chronic cases refractory to multiple corticosteroid injections or cases involving identifiable tendon defects or tears, or “joint mice,” are treated by tenodesis (resection and attachment of the tendon to the proximal humerus) and osteochondral fragment removal. Arthroscopic-guided tendon resection has also been described. Prognosis for recovery is good.

Quadriceps Contracture (Quadriceps Tie-down, Stiff Stifle Disease): This serious fibrosis and contracture of the quadriceps muscles develops secondary to distal femoral fractures, inadequate surgical repair, and excessive dissection in young dogs. Adhesions develop between the bone, periosteal tissue, and quadriceps muscles, which lead to limb extension, disuse, osteoporosis, degenerative joint disease, and bone and joint deformations. Clinical signs include hyperextension and cranial displacement of the affected limb. Surgery is usually required to resect fibrous tissues and increase motion of the stifle joint. Bone and soft-tissue reconstructions along with postoperative flexion bandages and physical therapy are required to recover limb function. Prognosis is guarded. Prevention of the condition by accurate, biologic stable repairs of bone fractures is preferred.

Achilles Tendon Disruption (Dropped Hock):

This acute, traumatic injury to the common calcaneal tendon (gastrocnemius, superficial digital flexor, biceps femoris, semitendinosus, and gracilis muscle tendons) is seen primarily in mature working and athletic dogs. The common tendon can be ruptured or avulsed from the tuber calcanei of the talus. Ruptures may be partial or complete, and the gastrocnemius tendon component is most frequently affected. Clinical signs include a severe nonweight-bearing lameness, tarsal hyperflexion, and a plantigrade stance. Palpation reveals swelling, pain, and torn or fibrotic tendon ends. Radiography may reveal avulsed bone fragments. Treatment is by surgical repair of torn ends and reattachment of tendinous tissue to the tuber calcanei. External splints or fixators should be used to protect the repair for 4 wk. Prognosis is variable and based on chronicity of the injury, success of the surgery, and expected performance of the dog.

Iliopsoas Muscle Trauma: Trauma to the iliopsoas muscle or tendon of insertion can cause an acute or chronic lameness in

active dogs. Physical examination reveals focal pain at the proximal medial aspect of the thigh (attachment of tendon to the lesser trochanter), especially during simultaneous hip joint extension and internal rotation. Ultrasonography reveals disruption of muscle fibers, and radiography may reveal dystrophic calcifications at the region of tendon insertion. Treatment with rest and NSAIDs is helpful.

MUSCLE TUMORS

Primary skeletal muscle tumors can be benign (rhabdomyoma) or malignant (rhabdomyosarcoma). Secondary tumors involved with metastatic spread include lymphosarcoma, hemangiosarcoma, and adenocarcinomas. Local tumors (fibrosarcoma, osteosarcoma, mast cell tumors) can invade adjacent muscle. Lipomas can also invade intermuscular tissue spaces.

Clinical signs include localized swelling and lameness. Diagnosis is confirmed by biopsy and histologic evaluation of the samples. Treatment is by surgical excision or limb amputation; chemotherapy and radiation may be used depending on the tumor type.

OSTEOPATHIES IN SMALL ANIMALS

Osteopathies can be developmental, infectious (osteomyelitis), idiopathic (eg, hypertrophic osteopathy), nutritional, neoplastic, or traumatic.

DEVELOPMENTAL OSTEOPATHIES

Angular Deformity of the Forelimb

(Radial and ulnar dysplasia)

Abnormal development of the radius and ulna can occur secondary to distal (radial, ulnar) or proximal (radial) physeal injury or hereditary breed characteristics (Bulldogs, Pugs, Boston Terriers, Basset Hounds, Dachshunds). Asynchronous growth of the two bones leads to shortened limbs, cranial bowing of the bones, elbow joint subluxation, and valgus or varus deformities in the carpus.

Clinical signs include lameness and reduced painful motion in the elbow or

carpal joints. Radiography reveals the bone deformations and closed physes.

Treatment is based on correcting angulation and length of the limb and reestablishing joint congruity. Surgical procedures include corrective osteotomy and stabilization with internal or external implants and tension-releasing osteotomies. Prognosis is good for animals without severe limb deformations.

Cranio-mandibular Osteopathy

Cranio-mandibular osteopathy is a non-neoplastic, proliferative bone disorder of growing dogs that affects the mandible and tympanic bullae of Terrier breeds. The cause is unknown, but a genetic basis is suspected. The bone lesion is characterized by cyclical resorption of normal bone and replacement by immature bone along endosteal and periosteal surfaces.

Clinical signs vary in severity and include oral discomfort, weight loss, fever, and painful palpable enlargement of the mandible. Radiography reveals bilateral bone proliferation in the mandibles and tympanic bullae.

Therapy is symptomatic and consists of NSAIDs, opioids, or corticosteroids to reduce inflammation and discomfort, along with a soft-food diet. Prognosis is good with mild bone proliferation and animal maturation.

Hypertrophic Osteodystrophy

(Metaphyseal osteopathy)

Hypertrophic osteodystrophy is a developmental disorder of the metaphyses in long bones of young, growing dogs, usually of a large or giant breed. The exact etiology is unknown. The pathophysiology is based on metaphyseal vascular impairment, leading to a failure in ossification and to trabecular necrosis and inflammation.

Clinical signs include bilateral metaphyseal pain and swelling in the distal radius and ulna, fever, anorexia, and depression. Clinical signs may be periodic. Angular limb deformities may develop in severely affected dogs. Radiography reveals metaphyseal bone lucencies and circumferential periosteal bone formation.

Therapy is symptomatic and aimed at relieving pain (eg, NSAIDs, opioids), reducing dietary supplementation, and providing supportive fluid care. Treatment with corticosteroids (prednisone 0.5 mg/lb, PO, bid for 5 days, then tapered as needed) may be superior to treatment with NSAIDs in Weimaraners.

Multiple Cartilaginous Exostoses

(Osteochondromatosis)

Multiple cartilaginous exostoses is a proliferative disease of young dogs and cats characterized by multiple ossified protuberances arising from metaphyseal cortical surfaces of the long bones, vertebrae, and ribs. The exact etiology is unknown, but hereditary (in dogs) and viral (in cats) causes are suspected. Animals may be asymptomatic, and diagnosis is confirmed by palpation and radiography. Surgical excision of the masses is recommended if clinical signs such as lameness or pain develop.

Panosteitis

Panosteitis is a spontaneous, self-limiting disease of young, rapidly growing large and

giant dogs that primarily affects the diaphyses and metaphyses of long bone. The exact etiology is unknown, although genetics (in German Shepherds), stress, infection, and metabolic or autoimmune causes have been suspected. The pathophysiology of the disease is characterized by intramedullary fat necrosis, excessive osteoid production, and vascular congestion. Endosteal and periosteal bone reactions occur.

Clinical signs are acute and cyclical and involve single or multiple bone(s) in dogs 6–16 mo old. Animals are lame, febrile, inappetent, and have palpable long bone pain. Radiography reveals increased multifocal intramedullary densities and irregular endosteal surfaces along long bones. Therapy is aimed at relieving pain and discomfort; oral NSAIDs and opioids can be used during periods of illness. Excessive dietary supplementation in young, growing dogs should be avoided.

Retained Ulnar Cartilage Cores

Retained ulnar cartilage cores is a developmental disorder of the distal ulnar physis in young, large, and giant dogs characterized by abnormal endochondral ossification. As a result, progressive physal calcification ceases, and forelimb bone growth is restrained. The exact etiology is unknown, although dietary causes are suspected.

Clinical signs include lameness and angular limb deformities. Radiography reveals a radiolucent cartilage core in the center of the distal ulnar physis. Treatments include cessation of dietary supplements and osteotomy or osteotomies of the bone to reduce limb deformation. Prognosis is based on severity of the condition.

Scottish Fold Osteodystrophy

This heritable condition of Scottish Fold cats is characterized by skeletal deformations of the vertebrae, metacarpal and metatarsal bones, and phalanges secondary to abnormal endochondral ossification. Affected cats are lame, and affected bones are deformed and swollen. Treatment is by removal of exostoses. Prognosis is guarded.

OSTEOMYELITIS

Inflammation and infection of the medullary cavity, cortex, and periosteum of bone are most frequently associated with bacteria such as *Staphylococcus* spp, *Streptococcus* spp, *Escherichia coli*, *Proteus* spp,

Pasteurella spp, *Pseudomonas* spp, and *Brucella canis*. Anaerobic bacteria are less frequently isolated and may be part of a polymicrobial infection. Fungal diseases are based on geographic distributions and include *Coccidioides immitis* (southwestern USA), *Blastomyces dermatitidis* (southeastern USA), *Histoplasma capsulatum* (central USA), *Cryptococcus neoformans*, and *Aspergillus* spp (worldwide). Factors contributing to infection include ischemia, trauma, focal inflammation, bone necrosis, and hematogenous spread.

Clinical signs may be acute or chronic. Animals may have lameness, pain, abscessation at the wound site, fever, anorexia, and depression. Radiography can reveal bone lysis, sequestration, irregular periosteal reaction, loosening of implants, and fistulous tracts. Deep fine-needle aspiration, cytology, and blood cultures may also reveal evidence of infection.

Treatment includes both medical and surgical therapies. Long-term oral or injectable antibiotics such as clavulanic acid/amoxicillin (15 mg/kg, bid), cefazolin (30 mg/kg, bid), clindamycin (11 mg/kg, bid), enrofloxacin (15 mg/kg, bid), amikacin (15 mg/kg, bid), or oxacillin (22 mg/kg, tid) are used. Additionally, wound debridement, lavage, and removal of loose implants are recommended. Open or closed wound drainage and delayed autogenous, cancellous bone grafting can also be performed. In chronic, refractory cases, limb amputation may be warranted. Prognosis is variable and based on the severity and chronicity of the infection. Appropriate antimicrobial therapy based on bacterial culture and antibiotic sensitivity testing is mandatory for successful results.

HYPERTROPHIC OSTEOPATHY

Hypertrophic osteopathy is a diffuse periosteal proliferative condition of long bones in dogs secondary to neoplastic or infectious masses in the thoracic or abdominal cavity. The exact pathogenic mechanism is unknown, but periosteal vascularity is reduced.

Clinical signs include lameness, long-bone pain, and signs secondary to body cavity masses. Radiography reveals the primary masses and peripheral bone reactions.

Treatment includes thoracic or abdominal surgery to remove masses and unilateral vagotomy to block the neurovascular reflex associated with bone changes.

NUTRITIONAL OSTEOPATHIES

See also DYSTROPHIES ASSOCIATED WITH CALCIUM, PHOSPHORUS, AND VITAMIN D, p 1050.

Reduced bone mass, bone deformities, exostoses, pathologic fractures, and loose teeth (rubber jaw) are skeletal manifestations of nutritional derangements that affect parathyroid hormone function and calcium and vitamin metabolism. Specific causes such as secondary nutritional or renal hyperparathyroidism, hypovitaminosis D, and hypervitaminosis A can produce lameness. Diagnosis is by serum chemistry analyses, radiography, and identification of underlying nutritional deficiencies. Treatment is aimed at reversing the specific etiology. Surgery is rarely indicated.

BONE TUMORS

Skeletal tumors can be benign or malignant and primary or secondary to metastases or adjacent soft-tissue structures. The most common primary bone tumor is osteosarcoma that affects the distal radius, proximal humerus, distal femur, or proximal tibia.

Clinical signs include lameness, bone swelling, and an acute, nontraumatic pathologic fracture of the bone. Radiography reveals osteolysis, proliferation, and soft-tissue swelling; thoracic radiographs should be performed to delineate metastatic masses. Bone biopsy using a Michelle bone trephine or Jamshidi biopsy needle is imperative in confirming the diagnosis. Less frequently identified tumors include chondrosarcoma, fibrosarcoma, and hemangiosarcoma. Treatment includes limb amputation and chemotherapy with carboplatin, cisplatin, or doxorubicin. Palliative care to reduce pain and discomfort can be provided with oral NSAIDs, opioids, transdermal patches, or radiation therapy. Prognosis is guarded. Untreated animals rarely live more than several months. Amputation and chemotherapy may double the survival times. Median survival times after amputation are 5 mo in dogs and 4 yr in cats. Advanced procedures such as limb sparing and excision of metastases can also (infrequently) be performed.

BONE TRAUMA

Bone fractures are frequently caused by vehicular accidents, firearms, fights, or falls. Fractures can be open or closed and involve single or multiple bones. Characteristics of the fracture—such as simple, comminuted, oblique, transverse, or

spiral—are based on disruptive trauma forces (bending, compression, tension, and rotation).

Clinical signs invariably include lameness, pain, and swelling. Radiography is useful in delineating the fracture pattern. Treatments are based on the type of fracture, age and health of the animal, technical expertise of the surgeon, and owner finances.

Young, healthy dogs with incomplete fractures can be treated with external splints or casts. Other injuries are treated with external (fixators) or internal devices, such as bone plates, screws, orthopedic wires, interlocking nails, and pins. Frequently, cancellous bone grafts are used to augment fracture healing in ill or aged patients.

Antibiotics are given for open fractures or prolonged repairs. Perioperative analgesics (eg, epidural morphine, narcotic skin patches, systemic narcotics [including constant-rate infusion], oral NSAIDs) are used to alleviate discomfort. Physical therapy or rehabilitation is critical to restore limb function and overall well-being.

Prognosis for recovery is usually good, depending on the nature of the injury and success of repairs; successful wound therapy and monitoring of cardiopulmonary and urologic functions are essential. Followup care includes radiographic and clinical assessments of fracture healing. Internal implants may not need to be removed unless complications such as stress protection, infection, or soft-tissue irritation develop.

NERVOUS SYSTEM INTRODUCTION

The nervous system is composed of billions of neurons with long, interconnecting processes that form complex integrated electrochemical circuits. It is through these neuronal circuits that animals experience sensations and respond appropriately.

Neuronal processes that transmit electrical alterations to the neuron cell body are called **dendrites**. Dendrites have receptor sites that receive stimulation or inhibition from outside sources. If electrical stimulation of the cell body reaches a critical threshold, an electrical discharge called an **action potential** develops. The action potential spontaneously travels away from the cell body along an outgoing process called an **axon**. When the action potential reaches the terminal branches of the axon, chemicals called **neurotransmitters** are released. Neurotransmitters either stimulate or inhibit receptor sites on other neurons, muscles, or glands. Although neurons may have a variety of shapes, each one has dendrites, a cell body, and an axon and releases neurotransmitters.

Basic Sensory and Motor Functions

The peripheral nervous system (PNS) is formed by neurons of the cranial and spinal nerves. The central nervous system (CNS) is formed by neurons of the spinal cord, brain stem, cerebellum, and cerebrum.

Groups of neuronal cell bodies in the PNS are called ganglia, whereas those in the CNS are called nuclei. Nuclei form the CNS gray matter. Groups of axons in the CNS form the

white matter and are arranged into tracts. The tracts are usually named after their site of origin and termination (eg, the spinocerebellar tract begins in the spinal cord and ends in the cerebellum).

PNS sensory or afferent neurons carry information such as nociception, proprioception, touch, temperature, taste, hearing, equilibrium, vision, and olfaction to the spinal cord or brain stem. CNS sensory neurons carry information to the cerebellum, brain stem, and cerebrum for further interpretation. Important spinal cord and brain-stem sensory tracts include several spinocerebellar, spinothalamic, and spinoreticular tract systems. The spinoreticular tracts begin in the spinal cord and terminate in the reticular formation of the medulla. The dorsal fasciculi gracilis and cuneatus of the spinal cord and the medial and lateral lemniscus of the brain stem are also important sensory tracts. In animals, these sensory tracts may carry fibers from many sensory modalities such as proprioception, nociception (pain), and touch. An alteration in sensation may be due to either CNS or PNS disease.

Reactions to sensory inputs are initiated by efferent or motor neurons in the cerebrum and brain stem called **upper motor neurons** (UMNs). The UMN axons descend to brain-stem and spinal cord segments in tracts named after their site of origination and termination.

The UMNs of the reticulospinal tracts (from midbrain, pons, and medulla oblongata reticular formation) and the

rubrospinal tract (from midbrain) are important for voluntary movements of skeletal muscles in domestic animals. The rubrospinal tract mainly functions to facilitate flexors of the limbs, whereas the pontine and medullary reticulospinal tracts have either a facilitative (pontine) or inhibitory (medullary) effect on the extensors. The corticospinal tracts (cell bodies in the cerebral cortex) are most important for voluntary movement in primates. Domestic animals with severe cerebrocortical disease may suffer only transient loss of voluntary movements, because their corticospinal tract has limited influence.

The pontine reticulospinal (from the pons) and vestibulospinal (from vestibular nuclei of the medulla oblongata) tracts facilitate extensor skeletal muscle activity used to support the body. Knowledge of location and function of sensory and motor brain-stem and spinal tracts is essential to localize nervous system lesions and determine their severity. Mild spinal cord compression affects the superficial spinal cord tracts (fasciculus gracilis, cuneatus, spinocerebellar, and vestibulospinal tracts), so initial signs include ataxia and extensor weakness. Important voluntary motor tracts are located in the lateral portions of the spinal cord deep to the spinocerebellar tracts, and paresis or paralysis develops with moderate spinal cord compression. Because many tracts are involved, loss of nociception from the periosteum of the toes and tail (deep pain) occurs when spinal cord lesions are bilateral and severe. This loss of nociception is also an indicator of severe cord injury because those fibers that transmit deep pain are typically nonmyelinated, slow-transmitting C type fibers, which are very resistant to pressure.*

Motor neurons with cell bodies in the brain stem, and spinal cord gray matter and axons that travel in the PNS cranial and spinal nerves, respectively, are referred to as **lower motor neurons (LMNs)**. Injury to either the UMNs or LMNs results in paresis or paralysis. Brain-stem and spinal cord reflexes are the phylogenetically oldest responses of the nervous system. When the eyelid is touched, it closes; when the toe is pinched, the limb withdraws even before conscious perception intervenes. Only a sensory neuron in the PNS, a connector (internuncial) neuron in the CNS, and an LMN are necessary for a reflex to be present. In a monosynaptic reflex (eg, patellar reflex), only a sensory neuron and LMN are present. During the neurologic examination (see p 1213), testing brain-stem and spinal reflexes is helpful to localize CNS

and PNS lesions to specific areas. If a reflex is depressed or absent, a lesion must involve the sensory nerve, internuncial neuron, LMN, or muscle at that particular site.

The autonomic nervous system is divided into sympathetic and parasympathetic portions and controls activity in smooth and cardiac muscles and glands. Visceral afferent (sensory) neurons travel in cranial and spinal nerves and sensory spinal cord tracts to the thalamic and hypothalamic regions of the brain stem. UMNs in the hypothalamus descend to LMN cell bodies of the brain-stem nuclei and sacral segments for parasympathetic control and to the intermediolateral gray matter of the spinal cord for sympathetic control.

LMNs of the sympathetic nervous system exit through thoracolumbar spinal nerves (T1 to L4) to affect smooth muscles associated with the pupils, eyelids, orbits, hair follicles, blood vessels, and thoracic and abdominal viscera. **Horner syndrome** (ptosis, miosis, and enophthalmos) is a common finding associated with loss of sympathetic innervation to the eye.

LMNs of the parasympathetic nervous system exit via cranial nerve (CN) III to innervate smooth muscle of the pupils and eyelids, CN VII to the lacrimal and salivary glands, CN IX to salivary glands, and CN X to cardiac muscles and glands and to smooth muscles of all the thoracic and abdominal viscera to the level of the transverse colon. LMNs of the parasympathetic nervous system also exit through the sacral segments to all the viscera in the caudal abdomen, including the bladder and colon. Sacral lesions commonly result in loss of the urinary bladder (detrusor) reflex.

Divisions and Effects of Lesions

See also THE NEUROLOGIC EVALUATION, p 1213. The PNS consists of 26 or more pairs of spinal nerves that correspond to each spinal cord segment and 12 pairs of cranial nerves that correspond to specific brain and brain-stem segments.

The PNS spinal nerves form the brachial plexus to the thoracic limb; the lumbosacral plexus to the pelvic limb; and the cauda equina to the bladder, anus, and tail. Brachial or lumbosacral plexus lesions cause paresis or paralysis of a thoracic or pelvic limb, respectively, with reduced or absent spinal reflexes and reduced or absent sensation of the limb. (See also LIMB PARALYSIS, p 1259.) Cauda equina lesions result in an atonic bladder; a dilated, unresponsive anus; and a flaccid, paralyzed tail.

Lesions of all spinal nerves (eg, acute polyradiculoneuritis) result in paresis or paralysis of all four limbs (quadriparesis or quadriplegia, respectively) with depressed or absent spinal reflexes and altered sensation of the limbs. Lesions restricted to PNS cranial nerves result in deficits associated with dysfunction of that particular nerve and no signs of dysfunction in the limbs or other parts of the nervous system.

The spinal cord of dogs and cats is divided into 8 cervical, 13 thoracic, 7 lumbar, 3 sacral, and 5 or more caudal segments. Horses and cows have 6 lumbar and 5 sacral segments, and pigs have 6–7 lumbar and 4 sacral segments. Spinal cord lesions from L4 to S2 cause pelvic limb ataxia, conscious proprioceptive deficits, and paresis or paralysis with depressed or absent spinal reflexes and muscle tone (LMN signs). Sensation may also be depressed or absent below the lesion. Lesions from T3 to L3 cause pelvic limb ataxia, conscious proprioceptive deficits, and paresis and paralysis with normal or exaggerated spinal reflexes (UMN signs). Pelvic limb sensation caudal to the lesion may also be depressed or absent. With spinal cord lesions extending from C6 to T2, thoracic limb spinal reflexes may be depressed or absent, and severe lesions may cause quadriplegia. The spinal reflexes remain intact in the pelvic limbs, but sensation may be affected.

Spinal cord lesions from C1 to C5 cause hemiparesis or hemiplegia (paresis or paralysis of the limbs on one side), or quadriparesis. Spinal reflexes in all four limbs are often preserved. Severe lesions may cause respiratory distress or arrest due to involvement of the UMNs to respiratory muscles in the C5 area.

The brain stem is divided from caudal to rostral into four segments: the medulla oblongata (myelencephalon), the pons (metencephalon), the midbrain (mesencephalon), and the thalamus and hypothalamus (diencephalon).

Similar to lesions of the cervical spinal cord, lesions of the medulla oblongata cause conscious proprioceptive deficits and weakness on the same side (ipsilateral) or both sides with normal or hyperactive limb reflexes. However, involvement of CN nuclei IX, X, XI, or XII localizes the lesion to the caudal medulla oblongata. Involvement of CN nuclei VI, VII, or VIII localizes the lesion to the rostral medulla oblongata. It is rare to have a lesion of the medulla oblongata that does not affect one or more of the cranial nerves as well as sensory and motor tracts.

Pontine lesions cause ipsilateral conscious proprioceptive deficits,

hemiparesis or quadriparesis with normal or hyperactive limb reflexes, mental depression from involvement of the ascending reticular activating system (ARAS), and CN V and IV deficits.

The cerebellum is part of the metencephalon and is attached to the dorsal surface of the pons and medulla by rostral, middle, and caudal cerebellar peduncles. The cerebellum coordinates all muscle activity and establishes muscle tone. The flocculonodular lobe of the cerebellum has equilibrium functions and is considered part of the vestibular system. Unilateral lesions of the cerebellum cause ipsilateral dysmetria (hypermetria or hypometria) and a contralateral (paradoxical) head tilt. Bilateral lesions of the cerebellum cause generalized incoordination of the head and limbs, head tremors (intention tremors), and generalized dysequilibrium.

Midbrain (mesencephalon) lesions cause contralateral conscious proprioceptive deficits and hemiparesis. CN III nucleus involvement is present on the ipsilateral side and localizes the lesion to the midbrain. In large, midbrain lesions, the ARAS is affected, and the animal will be stuporous or comatose. If the sympathetic UMNs and parasympathetic LMNs are both affected in the midbrain, the pupils will be midrange size and unresponsive to light.

Diencephalic lesions can be difficult to differentiate from cerebral cortical lesions, because many tracts going to and from the cerebrum pass through the diencephalon by way of the internal capsule. The thalamus, hypothalamus, and subthalamus of the diencephalon have many important structures that alter feeding, drinking, breeding, sleeping, and other behaviors, as well as regulate body temperature. The pituitary gland, which controls many hormonal functions of the body, is connected to the hypothalamus. The ARAS projects through the subthalamus area, in which lesions also produce stupor or coma.

The telencephalon, also called the cerebral cortex, is divided into the neocortex, paleocortex, and archicortex. The paleocortex and archicortex include the olfactory and limbic regions, which provide smell and emotional reactions to all stimuli. The neocortex is divided into the frontal, parietal, occipital, and temporal lobes. The frontal cortex functions include intelligence and fine motor skills (corticospinal tract). Lesions in this area cause dementia, lack of recognition of the owner, difficulty in training, compulsive pacing, circling toward the side of the lesion (adversion syndrome), and motor seizures with contralateral

involuntary muscle twitching. Contralateral hopping and placing deficits are also found with frontal lobe lesions. Ascending and descending tracts to and from the frontal lobe form the internal capsule through the region of the basal nuclei and diencephalon. Lesions of the internal capsule can produce the same signs as frontal lobe lesions. The parietal lobe (somesthetic cortex) is for interpretation of general perception, nociception, temperature, and pressure; lesions result in proprioceptive deficits on the contralateral side of the body.

● Occipital lobe and optic radiation lesions result in blindness with pupils that respond normally to light. Unilateral occipital lobe and optic radiation lesions result in some degree of visual loss in the contralateral eye, depending on the percentage of crossover of the optic nerve fibers in the optic chiasm of the species (65% in cats; 75% in dogs; 80%–90% in cattle, horses, pigs, and sheep). The pupils still respond normally to light. Blindness with pupils that do not respond to light is associated with lesions of the retina, optic nerve, optic chiasm, or rostral optic tract.

Difficulty in localizing sound is hard to evaluate clinically. It may occur with temporal lobe lesions, as may psychomotor seizures characterized by hysterical running. “Fly-biting” or “star gazing” hallucinations are suspected to occur with lesions in the temporal-occipital region. Aggression occurs when the pyriform area (paleocortex) of the temporal lobe and the underlying amygdaloid nucleus are affected. Aggression can also occur with hypothalamic lesions.

Lesions of the olfactory region may alter feeding or breeding behavior. Slow-growing lesions of the cerebrum and diencephalon often result in few clinical signs because of the adaptability of functions in these areas in animals.

Mechanisms of Disease

Disease processes affecting the nervous system may be congenital or familial, infectious or inflammatory, toxic, metabolic, nutritional, traumatic, vascular, degenerative, neoplastic, or idiopathic.

Congenital disorders may be obvious at birth or shortly after (eg, an enlarged head from hydrocephalus or an uncoordinated gait from an underdeveloped cerebellum). Some familial disorders (eg, lysosomal storage diseases) cause a progressive degeneration of neurons in the first year of life, whereas others (eg, inherited epilepsy) may not manifest for 2–3 yr. (See also

CONGENITAL AND INHERITED ANOMALIES OF THE NERVOUS SYSTEM, p 1222.)

Infections of the nervous system are due to specific viruses, fungi, protozoa, bacteria, rickettsia, prions, and algae. Noninfectious inflammations such as steroid-responsive meningoencephalomyelitis and meningoencephalomyelitis of unknown etiology (MUE), formerly called granulomatous meningoencephalomyelitis, Pug dog encephalitis, and other CNS inflammatory diseases, may be immune-mediated. Until there is a histologic diagnosis, the term MUE is used.

Toxicity of the nervous system is most frequently caused by organophosphates (see p 3064), pyrethrins (see p 3063), carbamates (see p 3059), bromethalin (see p 3167), metaldehyde (see p 3070), ethylene glycol (see p 3046), metronidazole (see p 2696), theobromines (see p 2966), sedatives, and anticonvulsants (eg, phenobarbital, bromide). Botulinum, tetanus, and tick toxins, as well as coral and certain other snake venom intoxications, cause neurologic signs.

Metabolic alterations of nervous system function most commonly result from hypoglycemia, hypoxia or anoxia, hepatic dysfunction, hypocalcemia, hypomagnesemia, hypernatremia, hypokalemia, and uremia. Hypothyroidism, hyperthyroidism, hypoadrenocorticism, and hyperadrenocorticism are endocrine disorders that can cause neurologic dysfunction.

Thiamine deficiency results in ataxia, stupor, and coma or seizures in dogs, cats, and cattle. Deficiency of vitamin B₆ may cause seizures.

Trauma to the PNS and CNS causes focal and multifocal neurologic signs from physical damage, hemorrhage, edema, and progressive formation of oxygen-containing free radicals and nervous system destruction that is usually complete in 24–48 hr but lasts as long as 4 days because of the slow influx of inflammatory cells.

Vascular lesions of animals are usually due to septicemia and bacterial embolization of the CNS. Fibrocartilaginous embolization of the spinal cord is common in dogs. Arteriovenous malformations occur occasionally and cause spontaneous hemorrhages. Cerebrovascular disease from arteriosclerosis is rare in domestic animals but has been associated with hypothyroidism caused by hyperlipidemia. Cerebrovascular disease from hypertension is rare but may be seen as multiple cerebral microbleeds with MRI.

Familial degeneration of neurons occurs in lysosomal storage disorders. Degeneration of intervertebral discs that subsequently herniate into the vertebral canal

often produces paresis and paralysis in dogs.

Neoplasms of the CNS and PNS are most common in dogs and cats. Astrocytes, oligodendrocytes, and microglia can all become neoplastic and form astrocytomas, oligodendrogliomas, and gliomas. Ependymal cells and the choroid plexus, which line the internal cavities of the CNS and produce CSF, also can become neoplastic and form ependymomas and choroid plexus papillomas. Meningeal cells of the dura, arachnoid, and pial membranes form meningiomas, which are common in dogs and cats. Neurofibrosarcomas are common tumors of the nerve sheaths of peripheral nerves in dogs. Lymphosarcoma is a common metastatic tumor of the PNS and CNS in dogs, cats, and cattle. Hemangiosarcoma is the most common metastatic tumor of the CNS in dogs. (*See also*

NEOPLASIA • OF THE NERVOUS SYSTEM, p 1267.)

The idiopathic mechanism of disease is reserved for described syndromes with characteristic clinical signs, predictable outcomes, and no known necropsy findings.

THE NEUROLOGIC EVALUATION

An accurate history and thorough physical and neurologic examinations are necessary to evaluate a problem involving the nervous system. An understanding of functional neuroanatomy, neurophysiologic concepts, and mechanisms of disease is a prerequisite for accurate interpretation of clinical findings. Based on the initial clinical assessment, 1) the anatomic location(s) of disease can be determined, and 2) the problem may be defined as diffuse, multifocal, or focal; symmetric or asymmetric; painful or nonpainful; progressive, regressive, waxing and waning, or static; and mild, moderate, or severe. The potential mechanisms of disease must also be considered to determine differential diagnoses. Further diagnostic tests include clinicopathologic tests (on serum, blood, urine, feces, and CSF), diagnostic imaging (including plain and contrast radiography, CT, and MRI), and electrodiagnostic testing.

HISTORY

Neurologic diseases tend to have a species, age, breed, and occasionally a sex predilection. The primary complaints for neurologic problems often include behavioral changes, seizures, tremors, cranial nerve deficits, ataxia, and paresis or paralysis of one or

more limbs. Information about the onset, course, and duration of the primary complaint can be used to determine the most probable disease mechanisms. Congenital and familial disorders are most common in purebred animals at birth or within the first few years of life. Inflammatory, infectious, metabolic, toxic, and nutritional disorders can be seen in any species, breed, or age; tend to have an acute or subacute onset; and are usually progressive. Vascular and traumatic disorders have an acute onset and rarely progress after 24 hr. Most degenerative and neoplastic disorders tend to be seen in older animals (except for familial neuronal degeneration) and have a chronic onset and progressive course. Many idiopathic disorders begin acutely and improve throughout a short time. Information about similar familial problems, concurrent or recent systemic disease, vaccination status, other affected animals, diet, possible exposure to toxins or trauma, and past neoplastic disorders may be useful to further support certain mechanisms of disease.

PHYSICAL AND NEUROLOGIC EXAMINATIONS

Evidence of disease in other body systems may be associated with inflammatory, metabolic, toxic, or metastatic neoplastic disorders of the nervous system. Infections of the CNS may not have any signs other than neurologic. External signs of trauma or toxic exposure may support these mechanisms of disease.

The neurologic examination consists of evaluation of the following: 1) the head, 2) the gait, 3) the neck and thoracic limbs, and 4) the trunk, pelvic limbs, anus, and tail. Initially, an attempt should be made to relate all deficits to one focal anatomic lesion.

If abnormalities are found on evaluation of the head, then an initial attempt should be made to explain all limb abnormalities by a lesion above the foramen magnum. If no abnormalities are found on evaluation of the head, but thoracic limb abnormalities are present, then an attempt should be made to explain the abnormalities by a cervical lesion (C1 to T2). Paralysis or paresis of all four limbs with loss of all spinal reflexes (with or without cranial nerve deficits) is often associated with diffuse peripheral nerve or neuromuscular junction disease (*see* p 1238).

Knowledge of specific diseases within a certain mechanism for a given species, age, breed, and sex of animal enables an accurate list of differential diagnoses and

a diagnostic plan to be formulated after the history and physical and neurologic examinations are completed. Toxic, metabolic, and nutritional mechanisms rarely produce asymmetric neurologic deficits. The other mechanisms of disease may result in symmetric or asymmetric deficits.

Evaluation of the Head

Mentation, head posture and coordination, and cranial nerve functions are observed during evaluation of the head. Abnormal findings are due to lesions above the level of the foramen magnum in the cerebrum, the brain stem (diencephalon, midbrain, pons, or medulla oblongata), or the cerebellum. Dementia, compulsive pacing, or other behavioral abnormalities and seizures are frequently due to lesions in the cerebrum or diencephalon. Stupor, obtundation, semicoma, or coma may be due to lesions of the cerebrum, diencephalon, or midbrain. A head turn or compulsive circling without a head tilt is also associated with a cerebral or diencephalic lesion on the side toward which the animal turns. A head tilt is due to vestibular system disease (CN VIII, rostral medulla oblongata, or cerebellum). Abnormal head coordination, bobbing, and tremors result from cerebellar dysfunction.

The **cranial nerves** consist of 12 pairs located in specific brain-stem segments;

they are simple to test, and test results can help localize disease to that segment. Abnormal findings are produced by lesions of the peripheral cranial nerve or cranial nerve nuclei. If a brain-stem lesion is present, abnormalities are seen in the gait, thoracic or pelvic limbs, and at times mental status. If only a peripheral cranial nerve is affected, there are no changes in gait, the thoracic or pelvic limbs, or mentation. Cranial nerve lesions of one side produce ipsilateral deficits except for lesions of the trochlear nerve (CN IV), which crosses in the midbrain.

I. Olfactory: The olfactory nerves transmit smell.

Tests: The animal's ability to find food or the reaction to chemicals (eg, cloves, benzene, or xylene) should be observed. Substances that irritate the nasal mucosa and the trigeminal nerve endings (eg, alcohol or phenol) should not be used.

Signs of Dysfunction: Inability to find food or respond to nonirritating chemicals is found with disease of the cribriform plate, olfactory bulbs, and olfactory region.

II. Optic: The optic nerves are necessary for vision and also carry the afferent fibers of the pupillary light reflex to the midbrain.

Cranial nerves accessible for nerve block in an equine head. Illustration by Dr. Gheorghe Constantinescu.

Visual Tests: Cotton balls can be dropped and the animal observed watching them fall to the floor. The menace response is tested by making a threatening gesture toward each eye, causing the animal to blink. The animal sees the menacing motion (CN II) and blinks the eye (CN VII). In foals and calves this reflex will be evident by 7–10 days of age, whereas in puppies and kittens it may not be present until 10–12 wk. Excessive air currents or touching the eyelashes should be avoided, because this will test response to touch (CN V) rather than vision. ●stacle testing may be necessary when visual acuity is in doubt. It is useful to blindfold one eye at a time to detect blindness of either eye.

Pupillary Light Reflex: A bright focal light is directed into each pupil toward the temporal retina, and the pupil is observed for immediate constriction. The opposite pupil should constrict consensually (a consensual or indirect response) (CN II afferent and CN III efferent).

Ophthalmoscopic Examination: This detects local eye diseases. Chorioretinitis or papilledema may be associated with central or peripheral nervous system diseases. Papilledema is often seen with increased intracranial pressure.

Signs of Dysfunction: Unilateral optic nerve dysfunction results in a decrease or loss of vision and decreased pupillary light reflexes on the affected side. Consensual pupillary constriction of the affected eye should still occur when the other eye is

stimulated with light. Unilateral lesions of the optic tract, lateral geniculate nucleus, optic radiation, thalamus, or occipital cortex usually produce a contralateral visual deficit with normal pupillary light reflexes (see above).

III. Oculomotor: These nerves carry efferent parasympathetic fibers from the pupillary light reflex center of the midbrain to the fibers of the ciliary ganglion, which innervate the constrictor muscle of the pupils. They are also efferent to the levator palpebrae muscles; the dorsal, medial, and ventral rectus muscles; and the ventral oblique muscles of the eye.

Tests: The pupillary light reflex test should be performed as described for the optic nerves, and constriction of the pupils to light should be observed. The presence or absence of ptosis of the upper eyelid as well as ventrolateral strabismus should be noted.

IV. Trochlear: These are the motor nerves to the dorsal oblique muscles of the eye.

Test: The eyeballs should be observed for a vertical misalignment (easiest to see in species with a horizontal- or vertical-shaped pupil).

Signs of Dysfunction: Trochlear nerve or midbrain lesions may result in the dorsal aspect of the globe rotating laterally.

V. Trigeminal: These nerves have three branches. The mandibular branch is the motor nerve to the muscles of mastication

and the sensory nerve to the floor of the oral cavity, ventral dental arcade, and the skin of the ventrolateral head. The ophthalmic and maxillary branches are sensory to the skin of the dorsolateral head; mucous membranes of the roof of the oral cavity, the dorsal arcade, and the nasal cavity; and the eyeball, including the cornea (pain).

Tests: Jaw tone and masticatory movements should be evaluated, and the masseter and temporalis muscles should be palpated for atrophy to evaluate the motor component of the trigeminal nerve. The sensory function can be evaluated by touching the medial and lateral canthi of the eyelid, which elicits the **palpebral reflex** and closure of the eyelids (CN V afferent and CN VII efferent). Stimulation of the cornea results in globe retraction (CN V afferent and CN VII efferent). In stoic animals, sensation is tested by a pinprick to the nasal mucosa (an avoidance response, turning the head away, will be seen).

Signs of Dysfunction: Lesions of the trigeminal nerves or pons produce temporal and masseter muscle atrophy and/or loss of sensation to the face, cornea, and nasal mucosa. A bilateral lesion of the trigeminal motor nerves produces a dropped jaw.

VI. Abducent: These are the motor nerves to the lateral rectus and retractor bulbi muscles of the eye.

Tests: The eyeballs should be observed for medial strabismus. The corneal reflex should be elicited with the eyelids held open, with the eyeball observed for retraction and the third eyelid observed for prolapse.

Signs of Dysfunction: Lesions of the abducent nerves or rostral medulla oblongata result in medial strabismus and lack of globe retraction.

VII. Facial: These are the motor nerves to the muscles of facial expression (ear, eyelids, nose, and mouth). The sensory part of CN VII is for taste on the rostral third of the tongue. The parasympathetic portion of CN VII innervates the tear glands.

Tests: The menace and palpebral reflexes should be elicited to test orbicularis oculi muscle function. The nose should be examined for deviation (with unilateral lesions). The lip should be pinched to see whether it retracts. The ear should be tickled to see whether it moves. Atropine or another bitter substance may be placed on the distal tongue to test taste. A Schirmer tear test should be performed to evaluate parasympathetic innervation of tear glands.

Signs of Dysfunction: A facial nerve lesion results in an inability to blink the eyelid or move the lips or nose; acutely it produces a droopy face, and food accumulates in the affected cheek. Tear and saliva production may be reduced on the side of the lesion. Later, facial muscle contractures are observed.

VIII. Vestibulocochlear: There are two main divisions of these nerves. The first division, the cochlear nerve, transmits auditory stimuli. The second division, the vestibular nerve, functions to maintain posture, muscle tone, and equilibrium.

Tests: Deafness is detected when loud noises do not evoke a response from an awake or sleeping animal. Unilateral deafness is best detected with electrodiagnostics, ie, a brain-stem auditory evoked response (BAER) test. (In puppies, this evaluation should not be performed before 6 wk of age, because results may be erroneous.) Head tilt, dysequilibrium, and a tendency to circle, fall, or roll to one side develop with unilateral or asymmetric vestibular lesions. The animal should be examined for the presence of spontaneous nystagmus with the head held in a normal position and in a deviated position (positional nystagmus), as well as for abnormal eye position (ventral strabismus) on the affected side when the nose is elevated. Normal vestibular nystagmus (physiologic nystagmus) is seen as a few beats to the left as the head is turned to the left, and to the right as the head is turned to the right.

Signs of Dysfunction: Unilateral lesions of the vestibulocochlear nerves produce dysequilibrium with a head tilt toward the side of the lesion. A spontaneous positional, horizontal, or rotary nystagmus is often present. A positional nystagmus (one in which the character of the nystagmus changes with changes in the animal's position) or a vertical nystagmus are almost always seen with central vestibular disease. A bilateral vestibular lesion results in dysequilibrium on both sides, wide side-to-side excursions of the head (often with no head tilt), loss of normal vestibular nystagmus, and possible deafness. Occasionally, a cerebellar or cerebellar peduncle lesion will result in a head tilt away from the lesion (paradoxical head tilt), but conscious proprioceptive deficits and hemiparesis will be ipsilateral with hypermetria of limbs on the ipsilateral side.

IX. Glossopharyngeal and X. Vagus: The glossopharyngeal and vagus nerves provide sensory and motor control of the

pharynx and larynx, and the vagus nerves provide sensory and motor control of the viscera.

Tests: The hyoid bones should be pinched to elicit a gag reflex. The animal should be observed for normal phonation and respiratory sounds.

Signs of Dysfunction: Lesions of the glossopharyngeal and vagus nerves or caudal medulla oblongata result in dysphagia, megaesophagus, or laryngeal paresis or paralysis. A change in phonation also occurs with vagus nerve and nucleus lesions.

XI. Spinal Accessory: These nerves innervate the trapezius, sternocephalic, and brachycephalic muscles.

Tests: The muscles should be palpated.

Signs of Dysfunction: Lesions of the cranial cervical spinal cord or caudal medulla oblongata may result in muscle atrophy. This may be accompanied by weakness when the examiner turns the head away from the side of the lesion.

XII. Hypoglossal: These are the motor nerves to the tongue and geniohyoid muscles.

Tests: The tongue should be observed for muscular control during licking and lapping of water. The tongue curls under to lap water in dogs and cats. In large animals, the tongue may be grasped and pulled side to side to assess its strength.

Signs of Dysfunction: Lesions of the hypoglossal nerves or caudal medulla oblongata may result in deviation or atrophy of the tongue. As with the facial nerve, this deviation of the tongue is at first away from the affected side, then with muscle contracture is toward the affected side.

Evaluation of the Gait

The gait is observed while the animal walks, trots, gallops, turns, sidesteps, and backs up. In large animals, ambulation up and down a grade, on and off a curb, and while blindfolded may accentuate subtle gait deficits. Evaluation of gait is especially important in ambulatory large animals because postural reactions are difficult to obtain because of size and because spinal reflexes usually are not tested unless the animals are recumbent. In small animals, subtle deficits may be detected by postural reaction testing of the limbs (*see below*) and by hemistanding and hemiwalking (standing or walking on one side). Animals with

chronic lesions in the cerebral cortex and diencephalon usually have a relatively normal gait but may circle compulsively. Animals with lesions of the midbrain, pons, and medulla oblongata have paresis or paralysis of the limbs, with deficits often more severe on the side of the lesion. Cerebellar lesions produce ataxia and dysmetria. Vestibular dysfunction causes ipsilateral falling, rolling, or circling. If no abnormalities are found on evaluation of the head, but the gait is abnormal, a lesion most likely is located in the spinal cord, peripheral nerves, or muscles.

Evaluation of the Neck and Thoracic Limbs

The neck is examined for pain and, in large animals, atrophy and desensitization to pinprick, which indicate a lesion of the cervical spinal cord. Wheelbarrowing, tonic neck and eye, conscious proprioceptive positioning, placing, hopping, and righting are postural reactions that detect subtle lesions.

Wheelbarrow: The pelvic limbs of small animals are lifted slightly off the ground while keeping body posture as normal as possible, and the animal is evaluated while walking on the thoracic limbs. This test is used to detect subtle deficits of the thoracic limbs. Normal animals should not stumble or knuckle over on the toes as they walk.

Tonic Neck and Eye: With the dog or cat standing, the nose is elevated and the eyes observed to see whether they coordinately adjust to the center of the palpebral fissures. In vestibular dysfunction, the eyeball on the affected side rotates downward (positional strabismus or eye drop). Simultaneously, the thoracic limbs should extend with no tendency to knuckle or collapse, and the pelvic limbs should flex.

Conscious Proprioceptive Positioning:

Each foot is displaced by turning it onto its dorsum or by abducting or adducting the limb widely. The animal should immediately replace the leg to a normal position. Lesions of the nervous system often affect conscious proprioception first.

Placing: Small animals may be carried toward a table top; on seeing the table, a normal animal anticipates placing its forepaws on the surface. If blindfolded, the animal should place the forepaws on the table only when the limbs contact the edge of the table. A loss of placing response may be present in subtle dysfunction even when the gait is normal.

Hopping: In small animals, three legs can be held off the ground with normal posture maintained, and the animal forced to move or hop (by being pushed laterally and forward) on the fourth limb. For large dogs and other large animals, one pelvic or thoracic limb opposite the side to be tested is held off the ground. When the animal is pushed toward the side to be tested, it should hop on the limb. Animals will not hop when pushed in a medial direction. Motor and proprioceptive loss, cerebellar incoordination, and cerebrocortical deficiency may be detected.

Righting: The animal is observed to see whether it can right itself from lateral recumbency. A small animal suspended upside down by the hips attempts to hold its head up when the trunk is rotated from side to side and extends its forelimbs to support weight when lowered to the ground. With vestibular dysfunction, the animal twists toward the side of the lesion or curls its head under (bilateral vestibular lesions).

Spinal Reflexes: The spinal reflexes are tested with the animal in lateral recumbency and the limbs relaxed. When the toes or skin of the distal thoracic limb are pinched, that limb should withdraw and the opposite limb usually does not move. This is the **flexor or withdrawal reflex**; it is present if spinal cord segments C6 to T2 and nerves of the brachial plexus are intact. Intramedullary spinal cord lesions at C6 to T2 usually depress or abolish the reflex, but mild extramedullary lesions may produce no change. With lesions cranial to C6, a simultaneous extension of the opposite limb (the **crossed extensor reflex**) may occur when the tested limb flexes. The crossed extensor is a normal reflex; however, an exaggerated response is interpreted as an upper motor neuron (UMN) sign indicating loss of inhibition from the UMN. The **Babinski reflex** is elicited by stroking the palmar surface of the paw in either a carpus to toe or toe to carpus direction. A positive (abnormal) response would be dorsiflexion of the toes, which is interpreted as a UMN sign.

Other tendons (biceps and triceps) and muscles (extensor carpi radialis) may be tapped with a percussion hammer and the response evaluated to test C6 to C7, the musculocutaneous nerve (biceps), and C7 to T2, the radial nerve (triceps, extensor carpi). These reflexes can be difficult to obtain in normal animals, so a reduced response should be interpreted with caution. All reflexes may be normal or exaggerated with lesions above C6.

Muscle Atrophy: Focal muscle atrophy of the limbs or neck localizes the lesion to the cell body in the spinal cord, ventral spinal nerve root, or peripheral axon of the nerve that innervates that muscle.

Sensation: Conscious perception of superficial (skin) or deep (osseous) pain is tested by applying forceps to the skin or bone, respectively, and observing a behavioral response. Such a response indicates that the peripheral sensory nerve and spinal cord, as well as the pathways through the brain stem to the cortex, are intact.

If the evaluation of the head is abnormal, an initial attempt should be made to explain any thoracic limb abnormalities by a lesion above the foramen magnum. If the thoracic limb abnormalities cannot be explained by a lesion in the head, then a multifocal or diffuse disease process (such as an inflammatory, toxic, metabolic, nutritional, traumatic, or metastatic neoplastic disorder) must be present.

If there are no abnormalities on evaluation of the head, and the thoracic limbs are abnormal, then a lesion of the cervical spinal cord or brachial plexus is present. In lesions of the cervical spinal cord, the gait of the thoracic and pelvic limbs is abnormal, and pelvic limb spinal reflexes are normal or exaggerated.

If no abnormalities are found on evaluation of the head and thoracic limbs, then a lesion must be below the T2 spinal cord segment.

Evaluation of the Trunk, Pelvic Limbs, Anus, and Tail

The trunk of the animal is observed for abnormal posture or deviation of the vertebral column, pain, desensitization or hyperesthesia to light pinpricking, and focal muscle atrophy.

Cutaneous Trunci and Panniculus Reflex:

Pinpricks applied to the skin of the thorax and abdomen result in contraction of the cutaneous trunci muscle. This reflex arc includes the afferent cutaneous branches of the lumbar and thoracic spinal nerves, a spinal cord tract that ascends to T2, and the LMNs in the lateral thoracic nerve to cutaneous trunci muscles. The reflex is used to localize spinal cord lesions between the site of stimulation and T2.

Postural Reactions: Wheelbarrowing, proprioceptive positioning, placing, and hopping are evaluated on the pelvic limbs in a manner similar to that used for the thoracic limbs. As with the thoracic limbs,

these tests require complete integrity of the brain, spinal cord, and peripheral nerves; thus, they are useful to localize lesions and to detect subtle deficits that support the presence of a neurologic lesion.

Spinal Reflexes: The pelvic limb spinal reflexes are more reliable to localize thoracolumbar lesions than are the thoracic limb reflexes. Spinal reflexes are normal or exaggerated with lesions above the reflex arc (UMN) and are depressed or absent with lesions at the level of the reflex (LMN). Percussion of the patellar tendon should cause the stifle to extend if L4 to L6 spinal cord segments and the femoral nerve are intact. Percussion of the gastrocnemius and cranial tibial muscles causes the hock to extend or flex, respectively, and tests the tibial and peroneal nerves, lumbosacral plexus, and L6 to S2 spinal cord segments. A crossed extensor reflex may be associated with lesions above L6 (UMN sign). When the anus is pinched or pricked with a pin, the sphincter tightens and the tail pulls down if S1 to S3 (anus) and caudal (Cd) tail segments and nerves are intact. An atonic (areflexic) bladder, anus, and tail are seen with lesions affecting S1 to Cd5 or the cauda equina. As an incidental finding, the femoral (patellar tendon) reflex may be absent in some geriatric dogs.

Muscle Atrophy: Focal muscle atrophy of the trunk or pelvic limb localizes a lesion to the nerve that innervates that muscle.

Sensation: In moderate to severe spinal cord lesions, superficial sensation may be absent from the cranial aspect of the lesion caudally. In severe spinal cord lesions, deep pain is absent from the periosteum of all toes and the tail.

Schiff-Sherrington Phenomenon: In some animals with acute, severe lesions of the spinal cord between T2 and L3, the pelvic limb paralysis is accompanied by an extensor rigidity of the thoracic limbs when the animal is in lateral recumbency. This occurs because of an interruption of an ascending spinal cord tract from the lumbar intumescence, which inhibits extensors of the forelimb. Although a severe lesion produces this syndrome, the prognosis is probably not hopeless if deep pain sensation can be elicited from the pelvic limbs.

CLINICAL PATHOLOGY

Abnormalities of serum glucose, liver enzymes, BUN, bile acids, ammonia, electrolytes, or blood gases can occur with

metabolic dysfunctions. Serum cholinesterase is decreased in acute organophosphate toxicity, and serum lead determinations are increased in lead toxicity. Serum thyroid and cortisol determinations and stimulation tests are useful to detect endocrinopathies. Serum titers or PCRs for viral, fungal, protozoal, and rickettsial organisms can be evaluated. Serum muscle enzymes, especially CK, may be increased in myopathies. Serum acetylcholine receptor antibodies can be detected in dogs and cats with myasthenia gravis, and type II M muscle antibody titers are used to confirm masticatory muscle myositis. Muscle and nerve biopsies are essential for diagnosis and characterization of many neuromuscular disorders. In some cases, brain biopsy is necessary to confirm and characterize an inflammatory or neoplastic process so that proper antimicrobial therapy, chemotherapy, or radiation therapy can be administered.

CEREBROSPINAL FLUID ANALYSIS

The analysis of CSF may further aid in determining the mechanism of a CNS disorder (especially inflammation). The technique of collection is simple and safe with practice. Analysis of CSF requires minimal special equipment. Cell counts and identification should be performed within 30 min after collection, because cells begin to degenerate after that time. Several techniques are available to concentrate or stabilize cells so that a differential cell count can be obtained at a later time.

CSF is collected from the cerebellomedullary cistern or the subarachnoid space in the lumbar region. An increase in protein is often associated with encephalitis, meningitis, neoplasia, or spinal cord compression. Cellular content increases most frequently with inflammation of the CNS. Neutrophils are indicative of bacterial infections, subarachnoid hemorrhage (RBCs are also present), brain abscess or a steroid-responsive suppurative meningoencephalitis, or in some cases, necrosis within a tumor. Increased numbers of lymphocytes, monocytes, and neutrophils are most common in steroid-responsive nonsuppurative meningoencephalitis, meningoencephalitis of unknown etiology (MUE), fungal infections, toxoplasmosis, and neosporosis. Cultures of CSF may demonstrate the causative agent in bacterial and fungal infections. Paired serum and CSF immunoassays for canine distemper virus, cryptococcosis, toxoplasmosis, neosporosis, Rocky Mountain spotted fever, ehrlichiosis, and borreliosis can assist in diagnosis of these infections.

IMAGING

Plain radiographs of the skull and vertebral column are useful to detect fractures, subluxation, infection, or neoplasia of osseous structures. In most infections or neoplastic processes of the brain and spinal cord, plain radiographs are normal. Myelography is used to detect compressive or expansive spinal cord lesions, including herniated or protruded intervertebral discs and spinal cord tumors. CT and MRI scans are useful to evaluate lesions of the brain and spinal cord in small animals. CT scans are helpful to detect changes in bone, acute hemorrhage, and CNS neoplasia. MRI scans are the best to demonstrate soft-tissue changes, eg, neoplasia, abscesses, inflammation, and hemorrhage. MRI is the gold standard for evaluation of lumbosacral disease in small animals. Magnetic resonance angiography can be used to evaluate vascular changes in the CNS.

ELECTRODIAGNOSIS

An electroencephalogram (EEG) is a recording of the electrical activity of the surface of the cerebral cortex, which is influenced by subcortical structures. The EEG is consistently abnormal in hydrocephalus, meningoencephalitis, head trauma, and cerebral neoplasia. An EEG may determine whether seizure discharges are focal or diffuse. The EEG is often normal in idiopathic epilepsy, unless seizures are not well controlled and interictal spikes are present.

An electromyogram (EMG) is a recording of the electrical activity of muscles and is used to evaluate the health of the motor unit. The motor unit consists of the LMN, the nerve root, the peripheral nerve, the neuromuscular junction, and skeletal muscle. The peripheral nerve can be stimulated, and motor and sensory nerve conduction velocities calculated and compared to known normal values to help define the neuropathy as an axonopathy or myelinopathy. Repetitive nerve stimulation may lead to a reduction of the evoked potential in myasthenia gravis. Abnormalities of late waves (F and H) may be associated with disorders of the nerve roots.

The brain-stem auditory evoked response (BAER) is a recording of electrical activity in the auditory pathway from the inner ear receptors through the brain stem to the cerebral cortex. The animal may or may not be awake for this test. No response or a diminished response is seen in auditory nerve disorders associated with hearing

loss. Brain-stem disorders may also alter the BAER; it may be abnormal in the Chiari malformation of Cavalier King Charles Spaniels and may also be used as an indicator in determining brain death.

Spinal cord evoked potentials can be used to evaluate spinal cord integrity. These are elicited by stimulating a peripheral nerve and recording the potential as it ascends the spinal cord.

PRINCIPLES OF THERAPY

See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE NERVOUS SYSTEM, p 2590.

Seizure Control: Status epilepticus (continuous or cluster seizures) in dogs and cats may be interrupted by diazepam, given at 0.5 mg/kg (not to exceed 10 mg at one time), IV. Sodium pentobarbital to effect, not to exceed 3–15 mg/kg, IV, may also be used, followed by phenobarbital at 2–4 mg/kg, IV, every 6 hr. A better alternative is to give propofol as a constant rate infusion at 0.1–0.6 mg/kg/min, followed by a loading dose of phenobarbital (if the animal is not already on phenobarbital) of 2–4 mg/kg, IV, every 6 hr for a total of four doses. Diazepam given at 0.5–1 mg/kg/hr as a constant-rate infusion may be used to control persistent status epilepticus. If the animal has a preexisting hepatic condition that precludes the use of phenobarbital, then levetiracetam 40–60 mg/kg may be given IV, SC, or rectally, resulting in a therapeutic blood level that will persist for 9 hr. Oral anticonvulsants should be resumed as soon as possible if currently being given.

Recommended maintenance anticonvulsant therapy in dogs and cats is phenobarbital at 2–4 mg/kg, PO, bid, as needed to control seizures or to maintain serum levels at 15–40 mcg/mL. Dogs can be treated with potassium bromide (KBr), 22–44 mg/kg given with food until the serum level is 1,500–3,000 mcg/mL. Because KBr has a long half-life, if started at maintenance levels, the steady state therapeutic level will not be reached until 3 mo after initiation of therapy. Phenobarbital may become clinically effective in 72 hr, whereas KBr may take several weeks. The longterm efficacy of phenobarbital and KBr is about the same. However, KBr bypasses the liver, so it is preferred in animals with liver disease. Animals taking phenobarbital often have increased liver enzymes and cholesterol levels but decreased thyroid levels; these should be expected and often do not require treatment. KBr has also been linked with megaesophagus and pancreatitis in dogs. Because KBr is not commercially available,

it may be prepared by a compounding pharmacist by mixing KBr crystals in water to give a concentration of 250 mg/mL or by packing the crystals in gelatin capsules. KBr serum levels are affected by the salt content of the diet, so the diet should be consistent; the higher the dietary salt content, the faster the bromide is excreted via the kidneys. KBr has proved more efficacious than phenobarbital in dogs with cluster seizures and for seizures that are difficult to control. Phenobarbital and KBr may be given in combination. Diazepam is not an effective longterm oral anticonvulsant in dogs because of its short half-life; however, a compounding pharmacist can prepare rectal suppositories containing diazepam 0.5–2 mg/kg for home use in dogs with cluster seizures, or the injectable form can be given rectally at 1 mg/kg to prevent trips to emergency clinics. The tertiary anticonvulsants, levetiracetam and zonisamide, are gaining greater favor. Zonisamide especially has shown good efficacy in controlling seizures in those animals with a poor response to phenobarbital and KBr.

KBr may cause asthma in cats, so its use in cats is no longer recommended. Diazepam at 0.5–1 mg/kg, PO, bid, may be used in cats with uncontrolled seizures because of its longer half-life in cats; however, in one report diazepam was associated with fatal hepatic necrosis in cats and thus warrants close monitoring throughout the first few weeks of therapy. Phenobarbital is the anticonvulsant of choice in cats; if seizures are not well controlled, then levetiracetam is added. Acupuncture may be useful to control seizures in all species.

Acute Spinal Cord Injury: Acute spinal cord injury from trauma, intervertebral disc herniation, or fibrocartilaginous embolization resulting in paraplegia must be treated aggressively in dogs to ensure the best chance for recovery. If the dog is seen within the first 8 hr after injury, methylprednisolone sodium succinate or prednisolone sodium succinate is given at 30 mg/kg, IV, followed by 15 mg/kg in 2 and 6 hr, or a constant IV infusion to give a total dose of 60 mg/kg. Steroid use is not advised if it has been longer than 8 hr since the trauma occurred, because there may be more deleterious effects than beneficial ones. Dexamethasone is not used. Oral famotidine at 0.5–1 mg/kg, once or twice daily; cimetidine at 5–10 mg/kg, bid; or misoprostol at 3 mcg/kg, bid, can be used to protect the GI tract. Polyethylene glycol (PEG) 30% solution may be given IV at 2.2 mL/kg, then repeated in 24 hr. PEG is a newer treatment that appears promising. If

the injury occurred more than 72 hr before treatment, the benefit of PEG is questionable. For maximal benefit, decompressive spinal surgery should be performed as soon as possible, usually within 24 hr, when indicated.

Anti-inflammatory Drugs: For control of CNS inflammation in dogs and cats unassociated with a virus or other agent, prednisone at 2 mg/kg/day may be given PO. Oral famotidine at 0.5–1 mg/kg, once or twice daily; cimetidine at 5–10 mg/kg, bid; or misoprostol at 3 mcg/kg, bid, is given to prevent GI irritation. If GI ulcers develop and melena is detected, sucralfate (500 mg for cats and dogs <20 kg; 1 g for dogs >20 kg), PO, tid-qid, is given 2 hr apart from other drugs. NSAIDs should never be given in conjunction with steroids, because GI ulceration is common. The dosages of all steroids given should be slowly tapered; abrupt withdrawal should be avoided. Prednisone can be used as longterm maintenance therapy on alternate days to avoid complete suppression of adrenal function. Other chemotherapeutics used for inflammatory CNS disease such as MUE are cytarabine (50 mg/m², SC, bid for 2 days, then repeated at 3–4 wk intervals), mycophenolate (10 mg/kg, PO, bid), and cyclosporine (5 mg/kg, PO, bid).

Antiedema Drugs: After cranial surgery and in animals with brain tumors or head injuries that cause a declining neurologic status, 20% mannitol, 0.5–1 g/kg, may be given slowly IV. Mannitol is not given in spinal cord injuries. Use of methylprednisolone sodium succinate as described above for acute spinal cord injury is no longer recommended for head injuries in people, and its use in the veterinary field is declining. For palliative treatment of brain tumors, oral prednisone may be used.

Muscle Relaxants: Diazepam at 0.5 mg/kg or methocarbamol at 40 mg/kg, PO, tid-qid, relieves muscle spasms from intervertebral disc protrusion and other sources of nerve root irritation.

Antimicrobial Therapy: Refer to discussions of specific infections for antimicrobial therapy recommendations.

Nursing Care: Animals with paraplegia and quadriplegia need intensive nursing care. The animal should be maintained on padding and turned every 4–6 hr to avoid decubital ulcers. The bladder must be expressed or catheterized every 6–8 hr.

In paraplegic animals, diazepam may be given to facilitate relaxation of the urinary sphincter, making manual expression of the bladder easier. Urine must be monitored for evidence of cystitis. The skin must be kept clean and free of urine and

feces to prevent dermatitis. Quadriplegic animals may need to be hand fed nutritious food and given plenty of water. Manual extension and flexion of joints and muscle massage will help delay contractures and muscle atrophy in paralyzed limbs.

CONGENITAL AND INHERITED ANOMALIES OF THE NERVOUS SYSTEM

Congenital defects of the CNS are, by definition, present at birth. Some congenital defects may be inherited, others may be caused by environmental factors (eg, toxic plants, nutritional deficiencies, viral infections); for many, the cause is unknown. In those animals born with a well-developed nervous system (foals, calves, lambs, pigs), the clinical signs of a congenital neurologic disorder may be recognizable at birth. Kittens and puppies are born with a less well-developed nervous system, and in those species, neurologic signs may not be apparent until they begin to walk. In some inherited neurologic diseases, clinical signs of the disorder are not seen until the animal is an adult (eg, caudal fossa malformation syndrome/syringomyelia, neuronal ceroid lipofuscinosis), even though the defect has obviously been present since birth.

Congenital lesions can be categorized according to the primary region of the CNS affected. **Forebrain disorders** (cerebrum and thalamus) primarily result in clinical signs such as visual disturbances, changes in mental status or behavior, abnormal movements or postures, and seizures. **Cerebellar disorders** usually result in an intention tremor, widebased stance, and incoordination (dysmetria) of the head, trunk, and limbs. **Brain stem disorders** may result in cranial nerve dysfunction, postural disturbances, or vestibular dysfunction. In some cases, brain stem disorders may also result in weakness and proprioceptive gait disturbances, with more severely affected animals exhibiting impaired consciousness. **Spinal cord disorders** do not affect cerebral function or coordination of head movement but may produce weakness, motor dysfunction, or proprioceptive deficits of the limbs, including either dysmetria or reduced proprioceptive placing in more than one

limb. (See also DISEASES OF THE SPINAL COLUMN AND CORD, p 1245.) **Neuromuscular disorders** include diseases of the peripheral nerves, neuromuscular junction, or muscles. Disorders of these systems can result in signs of weakness and ataxia similar to those seen in spinal cord disease. In addition, they often cause disturbance of reflex function, pain sensation, or marked muscle atrophy. In some cases, these deficits are markedly episodic. **Multifocal disorders** result in combinations of signs from more than one of these categories of neurologic deficits.

CEREBRAL DISORDERS

Large Animals

Anencephaly means that the brain is largely absent at birth. It is a rare disorder but is seen sporadically in calves; the cause is unknown. Because the pituitary gland may also be absent, prolonged gestation (see p 1377) of affected calves can occur. Signs include profound lethargy, head pressing, and blindness with normal pupillary reflexes. Cerebral aplasia in calves is usually associated with complete absence of both cerebral hemispheres, and CSF may leak out of a small opening on the midline between the frontal bones.

Exencephaly means that the brain is exposed through a large defect in the skull (cranium bifida). The brain (encephalocele), meninges (meningocele), or both (meningoencephalocele) may protrude through this opening. Encephalocele and meningocele are seen in many species and are known to be inherited in pigs. Defects may be closed or open in terms of communication with the environment through skin defects. Too little information exists to reliably predict outcome and resolution of

any deficits. Good surgical outcomes have been achieved in rare case reports of closed meningoencephaloceles; however, safety and quality-of-life issues must be considered, as with any ataxic, seizing, or mentally inappropriate large animal. When the defects openly communicate externally, CNS infection should be presumed unless proved otherwise.

In **hydranencephaly**, there is a marked loss of cerebral cortical tissue (primarily the neocortex) within a cranial vault of normal conformation. The resultant cavity communicates with the ventricular system, has an incomplete ependymal cell lining, and is filled with CSF. Clinical signs may include lethargy, propulsive circling, head pressing, and blindness. Hydranencephaly develops as a result of the destruction of developing neural tissues and is sometimes accompanied by cerebellar hypoplasia and arthrogryposis. Hydranencephaly is seen sporadically or as an epidemic in calves, lambs, and less commonly in piglets. Known causes include infection in utero with a number of viruses, including Akabane virus (see p 620) in ruminants in Australia, Japan, and Israel; bluetongue virus (see p 738) in sheep and cattle in North America; Rift Valley fever virus (see p 768) and the virus of Wesselsbron disease (see p 775) in sheep and cattle in Africa; the Cache Valley virus in sheep in the USA; and the Chuzan virus in calves in Japan. Rarely, bovine viral diarrhea (see p 1436) and border disease virus (see p 622) produce hydranencephaly in lambs and calves. Hydranencephaly and porencephaly (cystic cavities in the cerebrum) are seen sometimes in lambs with in utero copper deficiency (swayback). It also is seen in a syndrome of prolonged gestation in sheep in Scotland (cause unknown).

Hydrocephalus, an increase in volume of the CSF, can appear similar to hydranence-

cephaly, but in hydrocephalus the ventricles retain a complete ependymal lining. Clinical signs can vary from mild to severe and include seizures, lethargy, or other forebrain abnormalities. There may be extensive expansion of the lateral ventricles in the frontal lobes. Hydrocephalus is seen sporadically in all large animals, although it is relatively common in calves, in which inheritance and vitamin A deficiency have been implicated.

Cyclopia is characterized by a single orbital fossa. One cause in lambs is ingestion by the gestating dam of plant alkaloids from *Veratrum californicum*. This malformation also is seen in pigs.

Idiopathic or familial epilepsy has been described in many species. Benign epilepsy is seen in young foals, particularly Arabians, up to 12 mo of age. The foal may present for seizures, head injuries, or postictal blindness. Foals usually recover spontaneously within a few months, but anticonvulsant therapy (phenobarbital, 100–500 mg, PO, bid, for a 50-kg foal) is probably advisable for 1–3 mo, followed by withdrawal over 2 wk. Epilepsy beginning by 1 yr of age has been recorded in Brown Swiss and Swedish Red cattle. Seizures are also seen in young Aberdeen Angus calves; if these calves survive, they show cerebellar signs but become clinically normal by 2 yr of age.

Metabolic disorders and lysosomal storage disorders often cause signs of forebrain dysfunction, along with other neurologic deficits, and are discussed further under multifocal disorders (see p 1234). Cerebral signs seem to be most prominent in citrullinemia.

Citrullinemia is a fatal hereditary metabolic defect of Holstein-Friesian calves (mainly in Australia and New Zealand) associated with cerebral cortical edema. It is due to increased citrulline in plasma, caused by deficiency of the urea cycle enzyme argininosuccinate synthetase. Affected calves appear healthy at birth but die of acute neurologic disease in 1–4 days. Signs are sudden in onset and consist of depression, aimless wandering, blindness, seizures, opisthotonos, and recumbency.

Narcolepsy, a disorder of sleep-wake control (typically characterized by excessive sleepiness or sudden paroxysmal attacks of flaccid paralysis with conservation of consciousness), has been reported in several equine breeds, particularly Shetland ponies. The animal is otherwise healthy. During narcoleptic episodes, rapid eye movements occur, and at the same time, the animal may also show cataplexy or sudden loss of muscle tone with collapse.

Protrusion of tissue on the forehead of a foal with meningoencephalocele. Courtesy of Dr. Rebecca Packer and Dr. Paige Jackson, Purdue University.

Small Animals

The same structural anomalies of the brain as described for large animals (*see* p 1222) are also found in small animals.

Hydranencephaly has been described mainly in kittens after in utero exposure to feline panleukopenia virus/parvovirus (*see* p 796). Brain stem malformations and cerebellar hypoplasia may be seen concomitantly.

Hydrocephalus is most common in dogs, particularly in toy and brachycephalic breeds. It can be classified as communicating (nonobstructive), in which CSF can flow freely into the subarachnoid space, or noncommunicating (obstructive). Known causes of noncommunicating hydrocephalus include atresia of the mesencephalic aqueduct, perinatal encephalitis, or adhesions caused by intraventricular hemorrhage at birth. Clinical signs of hydrocephalus usually indicate cerebral dysfunction and often progress, although some animals may remain asymptomatic. The fontanelles are often patent, and affected animals may have ventrolateral strabismus. Blindness due to polymicrogyria (excessive number of smaller gyri) and asymmetric dilatations of the lateral ventricles have been described in Standard Poodles. Hydrocephalus has been observed in Saint Bernard puppies in association with aphakia (absence of the lens) and multiple ocular defects. Imaging by ultrasonography (through the fontanelle), CT, or MRI can provide the diagnosis, and CSF analysis should identify encephalitis. Treatment relies on omeprazole to reduce CSF production or, if necessary, corticosteroids, or surgery to shunt CSF into the peritoneum.

Lissencephaly, an absence or reduction of cerebral gyri, is a rare disorder seen in Lhasa Apsos. It is also seen in association with cerebellar hypoplasia in Irish Setters, Wirehaired Fox Terriers, and Samoyeds and in Korat cats with microencephaly. Clinical signs consist of mild behavioral abnormalities and seizures.

Pug encephalitis is an ultimately fatal disease that may have a familial basis. Affected Pugs show behavioral changes, seizures, and CSF pleocytosis. A similar nonsuppurative, necrotizing encephalitis has been reported in several other toy breed dogs, including Yorkshire Terriers, Chihuahuas, and Maltese Terriers.

Neonatal encephalopathy is an inherited genetic disorder that has been described in Standard Poodles.

appear stunted and weak from birth and begin seizing at 4–5 wk of age. The disease is fatal. A genetic test is available for diagnosis of this disease in Standard Poodles.

Polymicrogyria is an inherited disease identified in Standard Poodles that results in focal areas of the brain having smaller and more gyri than normal, resulting in disruption of function. The most common clinical signs are visual disturbances, but ataxia, behavioral problems, and hydrocephalus can also be seen. Clinical signs are attributable to the portion of the brain affected by the abnormal gyri.

Idiopathic epilepsy may be inherited in certain breeds, including Beagles, Keeshonden, Irish Setters, Belgian Tervurens, Siberian Huskies, Springer Spaniels, Labrador Retrievers, Golden Retrievers, and German Shepherds. A specific type of seizure known as temporal lobe epilepsy appears to be familial in Cavalier King Charles Spaniels and is characterized by behavioral manifestations such as “fly biting.” The diagnosis of idiopathic epilepsy depends on eliminating other causes of seizures, particularly structural brain abnormalities (such as hydrocephalus or juvenile tumors), encephalitis, or metabolic causes (such as hepatic encephalopathy).

Hepatic encephalopathy is usually caused by a congenital portosystemic shunt. The shunt may be a single large vessel, or there may be microscopic shunting of blood within the liver. Breeds often affected include Miniature Schnauzers, Yorkshire Terriers, Cairn Terriers, Australian Cattle Dogs, Old English Sheepdogs, and Maltese Terriers. The clinical signs are usually noticed before 6 mo of age and primarily reflect cerebral dysfunction, including staring into space, inappropriate vocalizing, aggression, and agitation. Advanced neurologic alterations can cause depression, blindness, myoclonus, stupor, coma, or seizures. In cats, these signs are often accompanied by excessive salivation. A rare cause of hepatic encephalopathy is a deficiency of hepatic urea cycle enzymes. Pre- and postprandial bile acid tests may support the diagnosis. Definitive diagnosis may be facilitated by use of radiographic imaging techniques, such as positive contrast portography, CT, transcolonic portal scintigraphy, or diagnostic grayscale ultrasonography. Blood tests such as the ammonia tolerance test (*see* p 436) should be used with caution in cases of suspected hepatic encephalopathy because of risk of causing an encephalopathic crisis. Resting

ammonia levels can be performed; however, ammonia levels have been poorly correlated with both the diagnosis and presence of clinical signs.

Lysosomal storage disorders that commonly cause cerebral signs include ceroid lipofuscinosis and fucosidosis, although there are many other forms of lysosomal storage disorders as well as other inborn errors of metabolism (*see* p 1234). Genetic and enzymatic testing is available for some of these disorders. When specific tests are not available, organic acid screens may support the general diagnosis of metabolic error.

Puppy hypoglycemia is an idiopathic syndrome in toy breeds of dogs that is seen in the first 6 mo of life. It seems to relate to a relative immaturity of the liver, which affects glycogenolysis and can usually be managed by providing frequent meals of a commercial puppy diet. The problem usually resolves as the puppy matures.

Narcolepsy or cataplexy is inherited in Doberman Pinschers, Labrador Retrievers, and Dachshunds and has been described in additional canine breeds. It is rare in cats. Attacks are often stimulated by excitement. It must be differentiated from various types of syncope. Physostigmine (0.025–0.1 mg/kg, IV) potentiates the frequency and severity of cataleptic attacks. Imipramine (0.5–1 mg/kg, PO, tid) can be used to control the severity of the cataplexy.

CEREBELLAR DISORDERS

Large Animals

Arnold–Chiari malformation is a complex malformation of the caudal brain stem and cerebellum and typically consists of herniation of cerebellar tissue through the foramen magnum into the cervical spinal canal. It may be associated with spina bifida, hydrocephalus, or meningocele. It is rare in domestic animals, and the cause is unknown. (A more common variation of this disease is recognized in dogs and appears to be inherited, but this has not yet been proved.) In calves, it may be seen with bilateral elongation and extension of the occipital lobes.

Cerebellar hypoplasia has been described in many species. In utero viral infection (bovine viral diarrhea [*see* p 1436], bluetongue virus [*see* p 738], and swine fever virus [*see* p 713]) during midgestation is the most common cause. Cerebellar lesions may also be seen with bovine fetuses infected with Akabane or Wesselsbron viruses. Clinical or subclinical hydran-

cephaly and arthrogryposis may accompany the cerebellar disease. The pathologic features include destruction or loss of one or more layers of the cerebellar cortex, particularly the granule and Purkinje cell layers. Prophylactic vaccination of the dam before breeding can prevent the problem. A hereditary cerebellar hypoplasia/dysplasia is seen in Hereford, Shorthorn, Ayrshire, and Angus calves. Cerebellar hypoplasia is present at birth and is nonprogressive, in distinction to the abiotrophies.

Cerebellar abiotrophies have been reported in many species. In abiotrophies, the cerebellar development proceeds normally, and the animal remains unaffected for a period of months or even years before cerebellar neurons begin to die off prematurely. This is in contrast to the cerebellar hypoplasias, in which developing cerebellar germinal cells and neurons are destroyed in utero. In Aberdeen-Angus calves, clinical signs of abiotrophy start early and are accompanied initially by seizures. In Arabian foals and Swedish Gottland ponies, the onset of signs is from birth to 9 mo; in Yorkshire and Large White piglets, 1–3 mo; in Holstein calves, 3–8 mo; and in Merino sheep, 3–6 yr. Most abiotrophies are probably inherited (eg, recessive inheritance for affected Hereford cattle and Welsh Mountain and Corriedale sheep), but toxic causes should also be considered. The latter include locoweed, methylmercury, and exposure to organophosphates in utero (*see* p 3064). Use of trichlorfon during pregnancy can cause a congenital tremor in piglets due to both cerebellar hypoplasia and hypomyelination.

Hypomyelination congenita, in which myelination is delayed throughout the CNS, can resemble cerebellar disease due to the severe head and body tremor that usually develops. In contrast to pure cerebellar disease, a persistent fine tremor at rest is usually present as well as a marked intention tremor. Newborn lambs, piglets, and occasionally calves are affected. The condition can be associated with in utero infection by viruses such as the virus of Border disease (*see* p 622) or swine fever virus (*see* p 713) or exposure to trichlorfon (*see* p 3067). Affected lambs are often called “hairy shakers.” The condition is inherited in Saddleback and Landrace pigs and in Jersey and Shorthorn cattle. Signs are usually nonprogressive or may resolve completely if myelination has only been delayed.

Swayback or enzootic ataxia is largely due to copper deficiency, although there may be a familial predisposition. Hypomy-

elinogenesis can occur in utero and cause obtundation, blindness/deafness, falling or lying prostrate, and head tremor in lambs. The condition can be prevented by treating affected ewes in pregnancy. Kids, piglets, and perhaps calves may also be affected.

Small Animals

Cerebellar hypoplasia is seen in kittens after in utero infection with feline panleukopenia virus (*see* p 796). The condition is nonprogressive, and affected cats may make suitable pets. Diagnosis can be obtained antemortem using MRI. Concomitant hydrocephalus or hydranencephaly may also be seen. Cerebellar hypoplasia has also been reported in Chow Chows and is seen in association with lissencephaly in Irish Setters and Wirehaired Fox Terriers.

A selective hypoplasia of the cerebellar vermis is also seen in dogs, and when combined with hydrocephalus and cyst-like dilatation of the fourth ventricle, the condition has been termed the Dandy-Walker syndrome, which may have a familial basis. The cerebellar vermis may be partially or completely absent. Clinical signs are typical of a cerebellar disorder and include tremors, ataxia, and hypermetria. Occasionally signs of head tilt and circling may also be present. Toy Fox Terrier dogs are predisposed to the Dandy-Walker form.

Cerebellar abiotrophies have been described in a number of breeds of dogs. In Samoyeds and Beagles, the signs are apparent at the onset of ambulation; in Australian Kelpies, Rough-coated Collies, and Kerry Blue Terriers, the clinical signs are seen in puppies from 4–16 wk of age; in Brittany Spaniels, Old English Sheepdogs, and Gordon Setters, the signs appear in young or mature adults. Clinical signs include progressive cerebellar ataxia, intention tremor, hypermetria, and possible loss of menace response due to cerebellar involvement. Postural reactions remain normal as with any pure cerebellar disease; however, affected animals may be incoordinated when placing paws. Clinical signs can be differentiated from cerebellar hypoplasia, above, by the onset. Hypoplasia is present since birth (apparent at time of ambulation) and nonprogressive, whereas animals with abiotrophies are born normal and progress after onset.

Bandera syndrome is seen in Coton de Tulear dogs and manifests as a cerebellar ataxia from the time of birth. The cerebellum is anatomically normal. A DNA test is

available for this disease in the Coton de Tulear.

Congenital hypomyelination is seen as a familial/inherited disorder in Springer Spaniels, Chow Chows, Weimaraners, and Bernese Mountain Dogs, usually with signs developing around 2–8 wk of age. In the latter three breeds, it is often termed dysmyelination because the clinical signs of whole body tremor usually resolve spontaneously with time. The disorder is rare in cats. The diagnosis can be confirmed using MRI. (*See also* DEMYELINATING DISORDERS, p 1236.)

Caudal occipital malformation syndrome and subsequent **syringomyelia** has been commonly reported in Cavalier King Charles Spaniels and less commonly in other small breed dogs. The malformation is comparable to the Chiari type I malformation described in people and includes a congenital malformation of the occipital bone, resulting in a crowded caudal fossa and cerebellar herniation at the foramen magnum. The subsequent disruption of CSF flow results in formation of syringomyelia. A large proportion of asymptomatic Cavalier King Charles Spaniels have the caudal fossa malformation. Although the malformation is present at birth, clinical signs often do not appear until later in life. Clinical signs vary but commonly include paresthesias (eg, face rubbing, phantom scratching of the back of the head), ataxia, and weakness from syringomyelia. Medical management is often not curative but can be attempted with gabapentin (10 mg/kg, PO, tid) for paresthesias, omeprazole (0.7 mg/kg/day, PO) for reduction of CSF production, and analgesics for pain management. Surgical decompression via caudal occipital craniectomy is preferred as definitive treatment; however, recurrence rates of 25%–47% have been reported.

BRAIN STEM DISORDERS

Small Animals

Congenital vestibular disease has been reported in German Shepherds, English Cocker Spaniels, Doberman Pinschers, and Siamese and Burmese cats. Signs are bilateral and may be accompanied by deafness. This is likely a peripheral syndrome affecting the vestibular apparatus, and labyrinthitis has been identified histologically in some pups. The disorder appears inherited. There is no treatment. Deafness is permanent, although the clinical signs of vestibular dysfunction may improve as the animal learns to compensate.

Canine multiple system degeneration has been identified in Kerry Blue Terriers and Chinese Crested dogs. Clinical signs reflect both cerebellar and brain stem dysfunction, including ataxia, dysmetria, and festination. The disorder is inherited as an autosomal recessive mutation. There is no treatment.

SPINAL CORD DISORDERS

See also DISEASES OF THE SPINAL COLUMN AND CORD, p 1245.

Large Animals

Spinal muscular atrophy is an inherited disorder of Brown Swiss calves. The first clinical sign of spinal muscular atrophy is weakness of the pelvic limbs at 2–6 wk of age; calves (most are female) have difficulty getting up and then become recumbent. The characteristic sign is severe muscle atrophy, especially of the pelvic limbs. Histopathologic examination reveals degeneration and loss of motor neurons in the ventral horns of the spinal cord. Neurogenic atrophy of muscles is a consistent lesion. A similar disorder is seen in red Danish calves of American Brown Swiss lines. It is possible that spinal muscular atrophy and bovine progressive degenerative myeloencephalopathy (BPDME) are in some way related because they can be seen in the same blood lines, but the onset of BPDME occurs after 5 mo of age, and it causes ataxia and dysmetria rather than weakness and muscle atrophy. A motor neuron disease with neurofilament accumulation is seen in horned Hereford cattle in Canada with signs appearing soon after birth that are characterized by general tremors, incoordination, difficulty standing, and hyperesthesia to tactile stimulation. A suspected hereditary lower motor neuron disease with accumulation of neurofilaments also is seen in Yorkshire pigs around 5 wk of age, characterized by pelvic limb paresis progressing to recumbency. There is degeneration and loss of motor neurons throughout the spinal cord and brain stem. A similar condition is seen in young Hampshire pigs.

Bovine progressive degenerative myeloencephalopathy (BPDME, weaver syndrome) is a neurodegenerative disorder of Brown Swiss cattle that is seen in the USA, Canada, and Europe. Four basic criteria are required to establish a clinical diagnosis: 1) onset of bilateral pelvic limb ataxia and dysmetria at 5–8 mo of age; 2) deficient proprioceptive responses, ataxia

in all four limbs, and progressive paraparesis; 3) normal spinal reflexes and cranial nerve function and absence of dramatic muscle atrophy; and 4) a familial relationship. The disease was initially described as “weaver” because of the peculiar weaving gait. The histopathologic changes are primarily in the sensory nervous system, in contrast to those of spinal muscular atrophy (see above). Spinal dysmyelination causes congenital lateral recumbency and opisthotonos, but spinal reflexes and alertness are normal.

Simmental encephalomyelopathy, which is seen in association with behavioral change (eg, aggression or dullness), has an onset in Simmental and Simmental-cross calves at 5–12 mo of age. The gait abnormality progresses from pelvic limb ataxia to recumbency with opisthotonos, and death occurs within 6 mo. It has been reported in the USA, UK, Australia, and New Zealand. Characteristic lesions consist of symmetric necrosis in the caudate nuclei and in other areas of the brain and spinal cord. Similar multifocal lesions are seen in 1- to 4-mo-old Limousin and Limousin-cross calves (with additional signs of blindness) in Australia and England and in Angus calves in Australia and the USA.

Progressive myelopathy of Murray

Grey cattle in Australia is inherited (autosomal recessive), and calves usually show spastic paraparesis and ataxia at birth. Neuronal degeneration is widespread in the brain and spinal cord; primary demyelination also develops in the cord.

Progressive ataxia of Charolais cattle has been reported in the UK and North America. It causes clinical signs that are first noticed between 6 and 36 mo of age and progresses throughout 1–2 yr from slight ataxia involving all four limbs to recumbency. Female cattle typically manifest a rhythmic pulsatile pattern of urination. Histologic lesions consist of eosinophilic plaques and myelin breakdown in the white matter of the cerebellum and spinal cord.

Neuraxonal dystrophy (NAD) appears to be inherited in sheep and causes an unsteady, stiff, and swaying gait that progresses to paraparesis and finally tetraparesis. Suffolk and New Zealand Coopworth sheep are affected as lambs 1–6 mo old; Romney sheep are affected at 6–18 mo of age. Merinos develop a very similar disease at 1–4 yr of age. NAD has also been seen in 4- to 7-mo-old Merino lambs. Axonal swellings (spheroids) are typically found in gray matter of brain stem and spinal cord, although in the older Merino sheep, axonal spheroids mainly develop in large white

matter tracts of the CNS. NAD of Morgan horses affecting the lateral (accessory) cuneate nucleus usually develops at 6–12 mo of age and causes spastic paraparesis and pelvic limb ataxia. It is presumed to be inherited. NAD affecting several brain-stem nuclei and causing mild pelvic limb ataxia has also been reported in 4-mo-old Hafflinger horses in Germany.

Equine degenerative encephalomyelopathy has been mainly associated with vitamin E deficiency, but it may have a familial basis in Appaloosa horses and other breeds, based on occurrence of clusters of cases. Degeneration of the spinocerebellar tracts results in a slowly progressive, symmetric ataxia and paresis of all four limbs that starts as early as 7 mo of age. (See also DEGENERATIVE DISEASES OF THE SPINAL COLUMN AND CORD, p 1245.)

Progressive paresis in Angora goats has been reported in Australia and may have a heritable basis. Clinical signs of spastic paresis and ataxia appear from birth to 4 mo of age and progress to recumbency within a few weeks. Widespread (multisystem) neuronal degeneration is seen at necropsy.

Generalized glycogenosis in Shorthorn (type II) and Brahman (type IIb) cattle and in Corriedale sheep (resembling type II) is a lysosomal storage disease that causes ill thrift, respiratory signs, paraparesis, ataxia, and muscle weakness at 3–9 mo of age.

Cervical stenotic myelopathy (wobbler syndrome) is a compressive cervical spinal cord syndrome caused by vertebral canal stenosis, articular process osteophyte proliferation, and vertebral body tipping that occurs in young, rapidly growing horses. Thoroughbreds, Tennessee Walking Horses, and Warmbloods appear to be predisposed, with males being more commonly affected than females. Overnutrition is an important contributory factor, and the clinical signs often can be reversed in horses <9 mo old by reducing caloric intake and restricting exercise. Clinical signs typically become apparent from <6 mo up to 4 yr of age and include cervical myelopathy, with the pelvic limbs usually affected more severely. Imaging (eg, survey radiography, myelography, CT, MRI) can be used to identify stenotic or proliferative lesions, causing spinal cord compression in the midcervical spine. Treatment usually requires surgical decompression of the spinal cord and, in some cases, vertebral stabilization. Interbody fusion with titanium baskets (“Seattle Slew” implants) has shown more success; however, the prognosis remains guarded. In one study, 77% of horses showed neurologic improve-

ment, with 46% regaining athletic function. Early treatment appears to be associated with improved surgical outcome.

Occipitoatlantoaxial malformation is an inherited disorder (autosomal recessive) in Arabian foals and may also be seen in Miniature horse foals, Holstein calves, and lambs. Clinical signs are progressive ataxia, tetraparesis, and an extended neck posture. Affected foals are usually tetraparetic at birth, although neurologic deficits may not develop for several years. Diagnosis is by radiography. Laminectomy has been reported to be successful in some cases.

Spina bifida is seen in most species and usually results in dysfunction of the tail and anus, incontinence, and sometimes pelvic limb weakness (see p 1230).

Small Animals

Spinal muscular atrophy is an inherited lower motor neuron (LMN) disorder in Brittany Spaniels that can have an early (by 1 mo), intermediate (by 4–6 mo), or delayed (>1 yr old) onset. Rottweilers can also develop an early form of spinal muscular atrophy that is referred to as a motor neuron disease. Swedish Lapland puppies are affected at 5–7 wk of age, Stockard paralysis (seen in Great Danes crossed with Bloodhounds or Saint Bernards) has an onset at 11–14 wk, and English Pointers are affected when ~5 mo old. LMN disease also is seen in puppies of other breeds, including Doberman Pinschers and Briquet Griffon Vendéens; a focal form involving the thoracic limb(s) is seen in German Shepherds. Paraparesis or tetraparesis with neurogenic muscle atrophy are the main clinical features. The severe, generalized LMN disease in spinal muscular atrophy closely resembles the signs of a peripheral neuropathy. Loss of motor neurons in the spinal cord is the most striking feature on necropsy. There is no treatment.

Demyelination of Miniature Poodles is presumed to be an inherited disorder involving primarily the spinal cord. This rare condition causes paraparesis at 2–4 mo of age that rapidly progresses to tetraplegia. There is no treatment.

Ataxia of Parson Russell and Smooth-haired Fox Terriers can be confusing, because several forms of disease exist. In general, the diseases affecting these breeds are a spinocerebellar ataxia. The predominant clinical signs are cerebellar (cerebellar ataxia, intention tremor, hypermetria), but histopathologically at necropsy, spinal cord demyelination can be seen. Clinical signs begin to appear

at ~2–6 mo of age. In one form of the disease, seizures and myokymia (in which the muscles appear to show verminous movement) can occur. The disease is progressive, although in some cases signs may stabilize but not regress, and some affected animals are able to live a relatively normal life, despite the abnormal movements.

Afghan Hound myelopathy is an inherited disorder that causes both demyelination and necrosis of the spinal cord. Paraparesis develops some time during the first year of life and progresses to paraplegia within 1 wk. The thoracic limbs become involved over the next 1–2 wk. A similar condition is seen in young Kooiker dogs (Dutch Decoy dogs) of either sex, with signs beginning at 3–12 mo of age. Prognosis is poor in both breeds.

Neuraxonal dystrophy is described in both cats and dogs but primarily in Rottweiler dogs (autosomal recessive inheritance). In Rottweilers, onset is between 3–24 mo of age, and the disorder progresses slowly over several years. Signs include cerebellar dysfunction and dysmetria in all four limbs, but with preservation of paw position sense, which should distinguish it from leukoencephalomyelopathy (*see below*) and from advanced motor neuron disease in the same breed. Collie dogs in Australia and New Zealand develop similar clinical signs at 2–4 mo of age. There is also early onset in Papillons and Chihuahuas and in cats (autosomal recessive in domestic tricolored cats). Axonal spheroids, often in specific regions of the brain and spinal cord, are the characteristic pathologic finding of these conditions.

Leukoencephalomyelopathy of Rottweilers has a later onset than neuraxonal dystrophy (*see above*), usually at ~2–3 yr of age. It is possible that the disorders have a similar basis, because animals occasionally may show histopathologic features of both conditions. In leukoencephalomyelopathy, there is no head tremor, and paw position sense is delayed. Bilaterally symmetric areas of spinal cord demyelination are the predominant findings on necropsy.

Calcium phosphate deposition in Great Danes causes mineralization of soft tissues and bone deformity, with dorsal displacement of C7. The resultant compressive myelopathy is seen in puppies 1–2 mo old. This condition is distinct from caudal cervical spondylomyelopathy (*see below*).

Degenerative myelopathy is a painless, slowly progressive myelopathy that occurs commonly in dogs. Clinical signs are typically consistent with a thoracolumbar spinal cord localization with pelvic limb paresis and ataxia, although progression may eventually involve the thoracic limbs. Histopathologic changes include a noninflammatory axonopathy and myelinopathy. German Shepherds, Pembroke Welsh Corgis, Boxers, Rhodesian Ridgebacks, and Chesapeake Bay Retrievers are predisposed. There is no treatment. Physical therapy slows the progression of clinical signs. A mutation has been identified that is associated with increased risk of developing degenerative myelopathy, and a genetic test is available to identify those dogs at higher risk of developing the disease.

Progressive axonopathy of Boxer dogs is an autosomal recessive disorder that causes patellar hyporeflexia, severe dysmetria, loss of paw position sense, and spastic paresis at 1–7 mo of age. Axonal spheroids are widespread in both the central and peripheral nervous system on necropsy. Although this condition causes loss of the patellar reflex, in general, the signs are more suggestive of spinal cord disease than of a peripheral neuropathy. There is no treatment, but affected dogs can live relatively comfortably for a considerable time.

Breed-associated aseptic meningitis (steroid-responsive meningitis-arteritis) has been reported in Beagles, Bernese Mountain Dogs, Boxers, German Short-haired Pointers, and sporadically in other breeds. The main signs are neck pain, pyrexia, and dramatic pleocytosis in the CSF in young dogs. Prognosis is guarded to favorable, especially in dogs with acute disease that are treated promptly using immunosuppressive doses of corticosteroids.

Congenital vertebral malformations include hemivertebrae (shortened or misshapen vertebrae), block (fused) vertebrae, and butterfly vertebrae (having a sagittal cleft). Hemivertebrae are most common in screw-tailed dog breeds and are inherited in German Shorthaired Pointers. Decompressive surgery can be very successful but sometimes needs to be combined with spinal stabilization.

Multiple cartilaginous exostosis is a benign proliferation of cartilage or bone that can affect the ribs, long bones, or vertebrae and may have a familial basis.

Transitional vertebrae are often clinically associated with lumbosacral stenosis. Myelography or specialized imaging techniques (eg, CT, MRI) are usually

required to confirm spinal cord compression in these congenital conditions. Treatment consists of surgical removal.

Caudal cervical spondylomyelopathy (wobbler syndrome) may have a heritable basis in Borzois (5–8 yr) and Basset Hounds (<8 mo) and probably also Doberman Pinschers (≥2 yr) and Great Danes (<2 yr). Neurologic deficits range from mild ataxia of the pelvic limbs to tetraplegia. Affected dogs often keep their neck flexed ventrally, and there may be caudal cervical pain. Spinal radiographs may show malalignment or remodeling of the vertebrae, narrowing of one or more disk spaces, or spondylosis deformans. CT/myelography or MRI usually reveals a marked stenosis at the cranial orifice of the midcervical or caudal cervical vertebrae. Several surgical techniques can provide stabilization of the vertebrae or decompression of the spinal cord.

Atlantoaxial subluxation is most commonly seen as a congenital disorder in young toy or miniature breeds of dogs and occasionally as a congenital disorder in several large breeds, including Rottweilers and Doberman Pinschers. Signs usually develop within the first few years of life and consist of an acute or slowly progressive onset of neck pain or gait dysfunction, ranging from ataxia to tetraplegia. Radiographic confirmation of diagnosis should be followed by stabilization using ventral fixation. The prognosis is guarded.

Arachnoid diverticuli (arachnoid cysts, arachnoid pseudocysts, meningeal cysts, leptomeningeal cysts, subarachnoid cysts) cause accumulations of CSF and a focal myelopathy in young dogs. The cause is unknown, but some cysts may have a congenital origin. Signs consist of progressive ataxia and weakness. Diagnosis is made by myelography and/or MRI.

Cervical spondylomyelopathy (wobbler syndrome) in a 6-yr-old Doberman Pinscher. Courtesy of Dr. Ronald Green.

Prognosis may be favorable after surgical excision, although recurrence is possible.

Spinal dysraphism or myelodysplasia includes anomalies of the skin, vertebrae, and spinal cord that are secondary to faulty closure of the neural tube. Spinal dysraphism is inherited in Weimaraners. Neurologic deficits are evident by 4–6 wk of age and include paraparesis and a symmetric “bunny-hopping” gait in the pelvic limbs. There is a bilateral flexor reflex; pinching one paw elicits flexion of both pelvic limbs. There may be scoliosis or abnormal hair streams on the dorsal aspect of the neck. Diagnosis is based on clinical signs and imaging techniques such as myelography or MRI. There is no treatment, but neurologic deficits usually do not progress. Similar malformations have been seen in other breeds of dogs and in calves, foals, and lambs.

Syringomyelia is the development of one or more fluid-filled cavities within the spinal cord. **Hydromyelia** is accumulation of fluid within an enlarged central canal of the spinal cord. It is often difficult to differentiate between syringomyelia and hydromyelia, so the term **syringohydromyelia** is often used. Syringohydromyelia causes progressive ataxia and paresis; scoliosis and spinal pain is possible. Causes include trauma, neoplasia, inflammatory conditions, and developmental malformations. The most common cause in dogs is caudal occipital malformation syndrome (*see p 1226*).

Spina bifida occulta is a failure of the neural arch to fuse; if the spinal cord is also involved, it is called **spina bifida manifesta**. The most likely clinical signs of spina bifida are LMN signs in the pelvic limbs and urinary or fecal incontinence. The prognosis for animals with substantial neurologic deficits is poor. Spina bifida can also accompany the **sacrocaudal dysgenesis** that is inherited as an autosomal dominant trait in Manx cats.

Pilonidal sinus (dermoid sinus, dermoid cyst) is another consequence of faulty neural tubulation that appears to be inherited (autosomal recessive) in Rhodesian Ridgeback dogs. The sinus is lined by skin and may communicate with the subarachnoid space, causing possible meningitis or myelitis. Treatment consists of antibiotics and surgical excision of the sinus.

Epidermoid cysts are rare lesions that arise from entrapment of epithelial cells during closure of the neural tube. Myelography or MRI will reveal an intramedullary lesion in a young dog with progressive neurologic deficits.

NEUROMUSCULAR DISORDERS

See also DISEASES OF THE PERIPHERAL NERVES AND NEUROMUSCULAR JUNCTION, p 1238.

Large Animals

Spastic paresis is seen in many breeds of cattle and has been referred to as "contraction of the Achilles tendon," "straight hock," and "Elso heel." (See also LAMENESS IN CATTLE, p 1066.) It can be divided into two syndromes, one that affects calves and one that affects adults. In calves, the condition appears to be familial and can be seen in many breeds, with signs beginning between 1 wk and 1 yr of age. It is characterized by extension of the stifle and tarsus and by spastic contracture of the muscles of one or both pelvic limbs. Spasticity primarily affects the gastrocnemius and superficial flexor muscles; in some cases, other muscles of the pelvic limb are involved. The leg is usually held in extension behind the calf and does not touch the ground during walking. The disease is progressive but usually responds to neurectomy of the tibial nerve. The cause is unknown. No lesions are seen in peripheral nerves, and the condition is thought to involve excessive activity of the neuromuscular spindle reflex arc. Adult cattle are affected at 3–7 yr of age. Extensor muscles of the back and pelvic limbs are affected, causing lumbar lordosis and caudal extension of the limbs. This condition is also thought to be familial and is usually progressive. Mephenesin (30–40 mg/kg, PO, for 2–3 days) may produce variable control of signs. Quadriceps muscle hypoplasia as a cause of congenital lameness has been described in Holstein calves. Reduced numbers of spinal cord motor neurons suggest that there is failure to innervate the muscle on the affected side.

Hyperkalemic periodic paralysis (see p 1047) is seen in Quarter horses 2–3 yr old and is due to an inherited mutation of the sodium channel. It causes episodes of muscle tremor and sometimes recumbency, both of which may be precipitated by exercise. Hyperkalemia is usually present during an attack, and electromyography can also be helpful for diagnosis. Acetazolamide (0.5–2.2 mg/kg, PO, bid) or hydrochlorothiazide (0.5 mg/kg, PO, bid) may lessen the frequency and severity of attacks.

Myotonia congenita is an inherited/familial disorder in goats and Shropshire lambs and is occasionally seen in horses. It causes muscle rigidity; marked dimpling on percussion of the muscle belly; and a stiff,

stilted gait. Electromyography is a useful aid to diagnosis. This disease results from a mutation in a chloride channel.

Muscular dystrophy is an inherited disease in Merino sheep. It results in a slowly progressive stiffness that affects the limbs and neck from 3–4 wk of age onward. Clinically affected sheep have high resting and postexercise concentrations of serum CK and lactate dehydrogenase.

Porcine stress syndrome or malignant hyperthermia (see p 1027) is a hypermetabolic and hypercontractile syndrome that, when triggered by anesthesia or stress, produces a sustained increase of intracellular calcium levels within skeletal muscle fibers. This in turn causes muscle stiffness, hyperventilation, hyperthermia, and pale exudative pork. It results from a mutation in a calcium-channel gene that is inherited as an autosomal dominant trait, usually in Landrace pigs.

Small Animals

Hypertrophic neuropathy of Tibetan Mastiffs is an autosomal recessive disease that has been recognized in the USA, Switzerland, and Australia. It causes paraparesis by 8 wk and may progress to tetraparesis. Hyporeflexia is marked, but sensory function is preserved. Demyelination and remyelination are seen on nerve biopsy. Prognosis is guarded. Some puppies regain the ability to walk but remain weak. There is no treatment.

Alaskan Malamute polyneuropathy affects Alaskan Malamutes 10–18 mo old. Clinical signs include exercise intolerance, paraparesis progressing to tetraparesis, muscle atrophy, hyporeflexia, and, in some cases, laryngeal paralysis. Electromyography shows diffuse fibrillation potentials and positive sharp waves. On nerve biopsy, there is axonal necrosis with demyelination. There is no effective treatment, although clinical signs stabilize in some dogs. In most affected dogs, however, progressive disability leads to euthanasia.

Congenital laryngeal paralysis is seen in Bouvier des Flandres (autosomal dominant) and Siberian Huskies, Rottweilers, and Bull Terriers <1 yr old. It results in exercise intolerance and inspiratory dyspnea. Diagnosis is confirmed by visualization on laryngoscopy. Congenital laryngeal paralysis with diffuse peripheral neuropathy is seen in several breeds, including Dalmatians, Rottweilers, and Pyrenean Mountain Dogs (Great Pyrenees). Prognosis is guarded to poor.

Primary hyperoxaluria (1-glyceric aciduria) is a rare, inherited (autosomal recessive) neurofilament disorder of domestic shorthaired cats that results in renal disease and also produces weakness due to a peripheral neuropathy. Signs develop at 5–9 mo of age. A plantigrade stance is the most prominent sign, and spinal reflexes are sometimes reduced. Urine contains increased oxalate and 1-glycerate levels. There is no treatment.

Neuropathy of hereditary hyperchylomicronemia (hyperlipidemia) is a suspected autosomal recessive disorder that causes a generalized peripheral neuropathy in cats. Clinical signs do not develop until at least 8 mo of age. The hyperlipidemia results in deposition of lipid granules within nerves, and there is evidence that the clinical signs can be controlled by a low-fat diet. Blood samples from affected cats have the appearance of “cream of tomato soup.”

Sensory neuropathy of longhaired Dachshunds (probably autosomal recessive) causes pelvic limb ataxia at 8–12 wk of age. Urinary and GI function may also be disturbed. Paw position sense, spinal reflexes, and pain sensation are depressed, and self-mutilation can occur. There is a loss of myelinated fibers in sensory nerves and in selected areas of the spinal cord. There is no treatment, but affected dogs may have a relatively normal quality of life, provided self-mutilation does not occur.

Sensory neuropathy of Border Collies manifests as ataxia, lack of proprioception, and abnormal sensory testing. Onset is usually at 5–7 mo of age and progresses relentlessly. Euthanasia is the common endpoint. The genetics of this disease are not yet known.

Sensory neuropathy in Pointers is seen in English Pointers (autosomal recessive) in the USA and Shorthaired Pointers in Europe. Self-mutilation of the digits is the main clinical sign, and disease onset is before 6 mo of age. Pain perception is absent in the pelvic limbs and depressed in the thoracic limbs. There is neuronal loss in dorsal root ganglia. Prognosis is poor. There is no treatment.

Inherited polyneuropathy of Leonberger dogs is a distal neuropathy, with an age of onset of 1–9 yr in this breed. Clinical signs include weakness, exercise intolerance, change in bark, and dyspnea. Pedigree analysis suggests an X-linked inheritance.

Musladin-Lueke syndrome is a connective tissue disorder affecting muscles, bone, heart, and skin. Clinical

signs most prominently reflect muscle fibrosis and contractures. The resulting posture is that of the animal walking on its “tip-toes.” This is an inherited recessive disorder, reported in Beagles, for which the genetic mutation has been identified. The abnormal posture is present shortly after birth. Other clinical signs include thickened cartilage of the ear and wide-set eyes. Seizures may occur concurrently. It is not yet known whether the seizures are related to the primary disorder or are a concurrent disorder. There is no treatment. The human counterpart to this disease is progressive and frequently fatal; however, the disease appears to stabilize in dogs.

Congenital myasthenia gravis (autosomal recessive) has been described in Parson Russell Terrier, Smooth-haired Fox Terrier, and Springer Spaniel puppies. It is due to either a deficiency or dysfunction of the acetylcholine receptor, and there is none of the circulating antireceptor antibody seen in the more common acquired form of the disease. Clinical signs usually start at 5–10 wk of age. The characteristic finding is an exercise-induced weakness, often associated with megaesophagus. The prognosis is more guarded than in acquired myasthenia gravis. The congenital disease has also been described in cats. A presynaptic form is seen in 12- to 16-wk-old Gammel Dansk Hønsehund dogs (autosomal recessive). Treatment consists of anticholinesterase drugs.

Scotty cramp (autosomal recessive) causes episodes of muscular hypertonicity in Scottish Terrier puppies. These episodes are exacerbated by excitement, exercise, stress, and poor health and are characterized by a hypermetric gait and arching of the spine, which can cause the dog to somersault when it runs. The disorder seems to be related to faulty serotonin metabolism. Diazepam and promazines help to relieve signs.

Congenital myoclonus of Labrador Retrievers (familial reflex myoclonus) causes muscle spasms/hypertonicity from an early age. Puppies may be unable to walk or even maintain a sternal position due to extensor rigidity. The prognosis is very poor.

Hypokalemic myopathy of Burmese cats (autosomal recessive) causes periodic paralysis or weakness with ventral flexion of the neck. Cats are affected at 3–4 mo of age. Serum CK is markedly increased. Dietary supplementation of oral potassium usually produces a favorable response (eg, potassium gluconate solution at 2–4 mEq or mmol/cat/day, PO, until serum potassium levels are stable).

Myotonia congenita is seen in Chow Chows, Staffordshire Terriers, Great Danes, and Miniature Schnauzers (autosomal recessive) and causes signs similar to those seen in myotonic goats. There is often a degree of muscle hypertrophy, and marked stiffness is seen when dogs first rise. Dimpling is seen on percussion of several muscles, including the tongue. Diagnosis can usually be confirmed by electromyography (characteristic "dive bomber" sound); muscle biopsy changes are mild and nonspecific. Prognosis is guarded, although membrane-stabilizing drugs (procainamide, mexiletine) result in significant improvement.

X-linked muscular dystrophies have been described in Irish Terriers, Golden Retrievers, Miniature Schnauzers, Rottweilers, Samoyeds, German Shorthaired Pointers, Groenendaaler Belgian Shepherds, Brittany Spaniels, Rat Terriers, Labrador Retrievers, Japanese Spitz dogs, and also in cats. All are due to mutations in the dystrophin gene. Males show muscle stiffness, dysphagia, and weakness at an early age, along with a plantigrade stance and muscle atrophy as the animal gets older. Initial muscle hypertrophy may be marked, particularly in cats. Diagnosis is facilitated by the initial massive increases in serum levels of CK and by demonstration of hyalinized and mineralized muscle fibers on biopsy. Prognosis is guarded to poor. Currently, there is no treatment. A novel congenital muscular dystrophy has been reported in cats associated with deficiency of merosin (laminin α_2), in which degenerative changes occur in both muscles and peripheral nerves.

Labrador Retriever myopathy (autosomal recessive) causes a stiff gait and marked muscle atrophy in puppies of both sexes. Signs worsen with cold, stress, or exercise, and affected dogs may be unable to keep their heads elevated in a normal position from as early as 3 mo of age. Tendon reflexes are usually absent. Signs stabilize by 6–8 mo of age, and the prognosis is favorable, so affected dogs can make good pets. There is preferential atrophy of type II muscle fibers.

Dermatomyositis of Collies and Shetland Sheepdogs (inherited as a dominant trait with variable expressivity) causes atrophy and weakness of the masticatory and distal limb muscles from a few months of age, sometimes associated with trismus and megaesophagus. These signs are combined with a dermatitis over the face and extremities. The clinical signs

may wax and wane and, in general, do not become severely debilitating. Polymyositis and dermatitis are evident on histopathologic examination. This disorder has also been seen in Beauceron Shepherds, Pembroke Welsh Corgis, Australian Cattle Dogs, Lakeland Terriers, Chow Chows, German Shepherds, and Kuvasz dogs.

Glycogen storage diseases can cause muscle weakness and exercise intolerance in young dogs and cats. Examples include glycogenosis types II (Lapland dogs), III (German Shepherds and Akitas), IV (autosomal recessive in Norwegian Forest cats), and VII (English Springer Spaniels).

Mitochondrial myopathy has been described in Clumber and Sussex Spaniels and in Old English Sheepdogs. Mitochondrial myopathies result in exercise intolerance and collapse, and blood lactate and pyruvate levels are often increased after exercise. Ragged red fibers, indicating increased numbers of mitochondria, may be seen on muscle biopsy. Inherited disorders of carnitine metabolism are another cause of mitochondrial myopathy; they may cause accumulation of lipid vacuoles within muscle fibers.

Nemaline rod myopathy (probable autosomal recessive) in cats causes weakness and later a hypermetric gait at 6–18 mo of age. Patellar reflexes are depressed, and muscle atrophy develops progressively. Large numbers of nemaline rods are found in skeletal muscle fibers. The prognosis is poor. A similar disorder is seen sporadically in young dogs.

Central core myopathy has been described as a cause of weakness, muscle atrophy, and exercise intolerance/collapse in young Great Danes in the UK. Signs begin at approximately 6 mo of age. Prognosis is poor.

Congenital megaesophagus is inherited in Wirehaired Fox Terriers and Miniature Schnauzers and possibly also in German Shepherds, Great Danes, Irish Setters, Newfoundlands, Chinese Shar-Pei, Greyhounds, and Siamese cats. Clinical signs include regurgitation and aspiration pneumonia. Prognosis is guarded.

Devon Rex cat hereditary myopathy (autosomal recessive) is seen in kittens around 4–7 wk old and is characterized by exercise intolerance and passive ventroflexion of the head and neck, which is especially noticeable during locomotion, urination, or defecation. Some cats assume a "dog-begging" position. Megaesophagus is present. Prognosis is guarded.

MULTIFOCAL DISORDERS

Large Animals

Hereditary neuraxial edema with inherited congenital myoclonus (probable autosomal recessive) was first reported in neonatal Polled Herefords and is the result of decreased and/or defective glycine receptors, which provide inhibitory neurotransmission. The calves are alert but unable to rise; they are incoordinated and have coarse, tonic muscular contractions. Sudden stimuli cause vigorous extension of the legs and neck.

Shaker calf syndrome is a neurodegenerative disorder that is seen in Hereford calves. Affected animals show a marked tremor within hours of birth, difficulty in rising, a stiff gait, and loss of voice; signs progress to spastic paraplegia. There is excessive accumulation of neurofilaments within neurons of the central, peripheral, and autonomic nervous systems.

Vitamin A deficiency of sows can cause incoordination, head tilt, pelvic limb paralysis, paddling, and ocular lesions in piglets. Similar signs are seen in congenitally affected calves born from deficient dams.

Generalized Metabolic and Lysosomal Storage Disorders: **Maple syrup urine disease** is a genetic amino aciduria (consistent with a branched-chain ketoacid decarboxylase deficiency) in Hereford calves. Affected calves are dull, become recumbent in 2–4 days, and terminally have opisthotonos. The histologic lesions are severe and consist of generalized status spongiosus in the CNS.

GM₁ gangliosidosis is seen in inbred Friesian calves. Clinical signs become evident during the first week of life and include depression, swaying of the hindquarters, reluctance to move, and stiffness. Death occurs in 6–8 mo.

GM₂ gangliosidosis causes hypermetria and weakness in Yorkshire piglets within the first 3 mo of life. Death occurs in 4–6 mo.

α -Mannosidosis (autosomal recessive) is seen in Angus, Murray Grey, and Galloway breeds. It produces ataxia, head tremor, aggression, and failure to thrive. There may also be abortions and neonatal death. Most affected calves die within the first year, sometimes shortly after birth. Affected (homozygous) calves have an absolute deficiency of α -mannosidase, and heterozygotes are partially deficient. Mannosidosis can be controlled by identifying and eliminating heterozygotes on the basis of biochemical testing.

β -Mannosidosis causes recumbency and cerebellar signs in newborn Nubian goats and Salet calves.

Ceroid lipofuscinosis is seen in sheep, cattle, and goats. Young Nubian goats show cerebellar signs. Rambouillet sheep show blindness and decreased mentation from 8 mo of age. South Hampshire lambs 9–12 mo old show blindness, depression, head and thoracic limb tremor, and facial twitching and die by 30 mo of age. Devon cattle become blind and weak by 14 mo and die by 4 yr of age. The genetic mutation has been identified in some of these species (Devon cattle, South Hampshire sheep).

Globoid cell leukodystrophy has been reported in polled Dorset sheep 4–18 mo old. Exaggerated tendon reflexes, ascending paralysis, and cerebellar signs may be seen.

Small Animals

Multisystemic chromatolytic neuronal degeneration in Cairn Terriers causes paraparesis in young puppies that progresses rapidly to produce cerebellar involvement with bouts of cataplectic collapse. Degeneration of neurons is widespread in the brain, spinal cord, and sensory ganglia.

Multisystemic neuronal degeneration has also been reported in red-haired Cocker Spaniels and causes abnormal behavior and cerebellar signs. Neuronal changes are found in various brain-stem nuclei. A similar condition is seen in Miniature Poodles (3–4 wk) with signs characterized by rolling from side to side, inability to stand or right into sternal position, periodic opisthotonos, intention tremors, and lack of a menace response associated with neuronal degeneration in the cerebral cortex and cerebellum.

Hydrocephalus in Bull Mastiffs is an inherited disorder that is also associated with abnormal myelin. It results in blindness, abnormal behavior, and cerebellar signs. Bilaterally symmetric spongiform lesions are found in the deep cerebellar nuclei.

Dalmatian leukodystrophy is a rare inherited condition that causes visual deficits with progressive ataxia and tetraparesis at 3–6 mo of age. There is dilatation of ventricles, cavitation of cerebral white matter, and widespread loss of myelin.

Fibrinoid leukodystrophy has been described in two 8-mo-old Labrador Retrievers, a 9-mo-old male Scottish Terrier, a 6-mo-old female Miniature Poodle, and a 13-wk-old Bernese Mountain Dog. It results in progressive ataxia and tetraparesis with

personality changes starting at 6 mo of age. Rosenthal fibers are found around blood vessels of the CNS, and the cause seems to be a disorder of astrocyte function. Prognosis is poor.

Spongiform degenerative conditions have been described in young dogs and cats (breeds include Labrador Retriever, Shetland Sheepdog, Samoyed, Silky Terrier, Bull Mastiff, Saluki, Cocker Spaniel, Malinois-Shepherd crosses, Rottweiler, and Egyptian Mau and Burmese kittens) and are often associated with signs of ataxia/hypermetria, head tremors, intermittent contractures, postural abnormalities, and behavioral changes. The underlying pathology relates to spongy degeneration of either white or gray matter. The pathogenesis of these disorders remains uncertain, although a genetic mutation has been identified for a family of Australian Cattle Dogs and Shetland Sheepdogs. Prognosis is poor.

Hereditary quadriplegia and amblyopia in Irish Setters produces signs of head tremor, visual impairment, nystagmus, inability to stand, and seizures beginning at birth.

Lysosomal Storage Disorders: This clinically rare group of conditions results from deficiency of an enzyme that is essential for the metabolism of a protein, carbohydrate, or lipid substrate, or results from buildup of a byproduct that can be toxic to cells. Clinical signs usually appear early in life, although occasionally the onset is delayed. Specific diseases have been associated with a particular breed, but in theory, any breed could develop any one of these disorders, and many have been described in more than one breed. Considerable phenotypic variation should be expected beyond the classic signs described below. Prognosis is poor for all of these disorders, although gene replacement therapies are being actively investigated. Diagnostic testing is limited except for those diseases in which the enzyme or mutation has been identified or the pattern or organic acids has been recognized. Testing often includes urine metabolic screening, lysosomal enzyme screening, histopathology for specific characteristics in tissue biopsy, or DNA testing for known mutations. Genetics laboratories should be checked for testing availability.

Sphingolipidoses: Globoid cell leukodystrophy (Krabbe disease) is seen mainly in Cairn and West Highland White Terriers. Several other breeds of dogs, as well as cats, may be affected.

Clinical signs are variable and multifocal, and either an ascending paralysis is seen by itself or combined with a cerebellar disturbance. Death occurs 2–3 mo after the onset of signs. Total protein content of CSF may be increased. Large globoid cells are distributed throughout the white matter of the spinal cord and brain.

GM₁ gangliosidosis is seen primarily in cats, particularly Oriental breeds, and in Beagles, Portuguese Water Dogs, English Springer Spaniels, Alaskan Huskies, and Shibas. Signs of cerebellar dysfunction predominate, and corneal clouding may develop.

GM₂ gangliosidosis or familial amaurotic idiocy (Derry disease) has been seen in German Shorthaired Pointers, Japanese Pointers, mixed-breed cats, and Korat cats. Clinical signs seen at 6 mo of age include behavioral change and visual disturbances. Progressive ataxia and dementia develop later. Clinical signs of ataxia, hypermetria, head tremor, and corneal opacity develop in kittens at ~3 mo of age.

Niemann-Pick disease affects cats and causes cerebellar dysfunction with an associated abdominal enlargement due to hepatosplenomegaly. The neurologic deficits tend to vary with the six subtypes of this disease, ranging from severe cerebellar-like signs (types A and C) to neuropathic signs (type A variant).

Glucocerebrosidosis (Gaucher disease) is a rare disorder of Australian Silky Terriers that produces mainly cerebellar signs at 4–6 mo of age.

Glycoproteinoses: Fucosidosis of English Springer Spaniels has been reported in Australia, New Zealand, the UK, and North America. It is characterized by clinical signs of ataxia, personality change, dysphonia, dysphagia, hearing/visual deficits, and seizures. Signs tend to progressively develop from 6 to >24 mo of age. A high proportion of peripheral lymphocytes may show cytoplasmic vacuolation. A DNA-based blood test is available for diagnosis. Prognosis is poor, and there is no effective treatment.

α -Mannosidosis has been seen mainly in cats and may cause retinal and skeletal abnormalities as well as neurologic deficits. Cerebellar signs are the most consistent feature of the otherwise somewhat variable neurologic deficits.

Mucopolysaccharidoses (Types I, II, III, VI, VII): Mucopolysaccharidosis is primarily a disorder of cats, although some subtypes affect dogs. This disorder is associated with a flattening of the face,

corneal clouding, and multiple bone dysplasias. Plott hounds can also be affected. Several types of this disease are reported; type VI is often associated with progressive paraparesis secondary to focal bony protrusions into the vertebral canal. The skeletal changes are nonprogressive after 9 mo of age, and decompressive surgery may improve the neurologic deficits.

Glycogen Storage Disorders:

Glycogenosis (types II, III, IV, VII) and mucopolipidosis II are not as well described. English Springer Spaniels, Lapland dogs, German Shepherds, Akitas, and Norweigan Forest cats are among those described. Clinical signs generally include neuromuscular weakness, exercise intolerance, muscle tremors, or dysphagia.

Mucopolipidosis II affects domestic shorthaired cats and generally causes skeletal malformations.

Other Storage Disorders: Ceroid

lipofuscinosis is characterized by reduced vision, personality change, ataxia, and seizures. Clinical signs typically appear when animals are 12–24 mo old, although some can be older. The condition is an autosomal recessive trait in English Setters, Tibetan Terriers, and Border Collies. It has been reported in many additional breeds of dogs, as well as in Siamese cats. The genetic mutation has been identified in some breeds of dogs. The phenotype and age of onset are variable, and signs tend to slowly evolve throughout several years.

La Forâ disease occurs most commonly in miniature Wirehaired Dachshunds but also can affect other breeds, such as Bassett

Hounds, Beagles, Poodles, and mixed-breed dogs. It is most well known and genetically understood in the miniature Wirehaired Dachshund, and a genetic test is available for diagnosis in this breed. Clinical signs can include late-in-life onset myoclonic seizures that can in some cases be triggered by visual or auditory stimuli. Other clinical examination findings are not commonly reported.

MISCELLANEOUS CONGENITAL DISORDERS

Large Animals

Pendular nystagmus is seen in various breeds of dairy cattle but appears to have little clinical significance.

Congenital deafness has been reported in horses.

Small Animals

Pendular nystagmus is seen in various breed of Asian cats but appears to have little clinical significance. Compared with pathologic forms of nystagmus, in pendular nystagmus there is no fast or slow phase, and the nystagmus arcs are similar to the pendulum movement of a clock.

Congenital deafness is primarily associated with Dalmatians but has also been recorded in a number of breeds, including Australian Blue Heelers and Shepherds, English Setters, Boston Terriers, and Old English Sheepdogs. It is linked to blue eye color in white cats. The brain stem auditory evoked response (BAER) is a useful diagnostic test primarily used to identify carriers in a litter of affected animals. (See also **DEAFNESS**, p 518.)

DEMYELINATING DISORDERS

Hypomyelination and dysmyelination are disorders of myelin development characterized by axons with thin myelin sheaths, or by axons that are nonmyelinated or have abnormal myelin. There are two possible pathologic classifications: 1) thinly myelinated axons with predominantly normal myelin and occasional nonmyelinated axons, or 2) thinly myelinated axons with predominantly abnormal myelin and mainly nonmyelinated axons. These categories have been called hypomyelinating and dysmyelinating

disease, respectively, and are characteristic of the congenital myelin disorders seen in young animals. These pathologic changes should not be confused with demyelination, in which there is a breakdown and loss of previously normal myelin. In general, these types of demyelinating diseases do not present clinically as congenital problems.

Etiology and Epidemiology: Demyelinating disorders have been reported worldwide in people, mice, pigs (British

saddleback, Landrace), cattle (Hereford, Holstein-Friesian, Jersey, Murray grey, Lurthorn), hamsters, rats, sheep, Siamese kittens, and a number of dog breeds, including Chow Chow, Springer Spaniel, Dalmatian, Samoyed, Golden Retriever, Lurcher, Bernese Mountain Dog, Weimaraner, Australian Silky Terrier, and mixed breeds. This problem has also been documented in a litter of Vizslas and Catahoula Cur dogs.

In utero infection and heredity are the general causes of hypomyelination. The viruses of classical swine fever, border disease, and bovine viral diarrhea have been incriminated, but mechanisms responsible for the hypomyelination have not been defined; these three pestiviruses are closely related members of the family *Togaviridae* and are transmitted both vertically and horizontally. The inflammatory neuraxial disorders in domestic animals in which demyelination is found are canine distemper, visna, and caprine arthritis encephalitis syndrome. In none, though, does CNS demyelination occur as the predominant central feature of the disorder as it does in human multiple sclerosis. Most toxins that affect myelin cause demyelination. One in particular, trichlorfon, is an organophosphate (*see* p 3064) with a unique toxicity that causes Type A-V porcine congenital tremor syndrome. Pregnant sows treated with trichlorfon during mid and late gestation (days 45–77) produce litters in which up to 90% of the piglets develop a marked tremor syndrome secondary to cerebellar hypoplasia and hypomyelination. The mortality rate is high.

Other disorders resulting in hypomyelination are hereditary. Almost all of these disorders result in CNS hypomyelination, except in Golden Retrievers, in which hypomyelination of the peripheral nervous system (PNS) has been reported. In CNS hypomyelination, the basic defect involves interference with the functional maturation of oligodendrocytes. The exact mechanisms for the defect are not known, but a point mutation on a critical gene has been found in Springer Spaniels. In PNS hypomyelination, the defect involves Schwann cells.

The genetic basis for the inherited hypomyelination syndromes is not fully defined, but in most instances, males are affected more often and more severely than females. This supports a sex-linked recessive trait or mode of inheritance.

Clinical Findings: Clinical signs from hypomyelination of the CNS can be seen as

early as 10–12 days of age and certainly by the time of weaning. Signs include, most notably, a gross whole body tremor that involves the limbs, trunk, head, and eyes. The tremor lessens or disappears when the animal is resting or sleeping but reappears on arousal and increases with excitement. The tremors are very noticeable when the animal is eating and are a severe form of intention tremor. In addition, some animals may have difficulty standing and ambulating and may have weakness in the limbs. Secondary to this, postural test reactions may be deficient. Affected animals appear to have vision and other cranial nerve function, but occasionally a pendular nystagmus or a jerk nystagmus is seen when the globes are voluntarily moved. These neurologic deficits may be so severe in some animals that euthanasia is warranted. In some breeds of dogs, such as Chow Chows and Catahoulas, the signs usually dissipate over the first year of life, and the dogs are normal by 12–18 mo of age. In some dogs, the signs may disappear as early as 12–16 wk of age.

In Golden Retrievers with PNS hypomyelination, the clinical signs include ataxia, paresis, muscle atrophy, and hyporeflexia to areflexia. There is no evidence of CNS hypomyelination in this breed, and tremors are not present.

Lesions: In CNS hypomyelination, gross pathology reveals pallor of the white matter of the brain and spinal cord and possibly a gelatinous appearance. In PNS hypomyelination, the gross changes are minimal and there is no evidence of CNS involvement. In CNS hypomyelination, the microscopic changes include lack of myelin (which is usually severe but not absolute), fewer oligodendrocytes, astrocytes outnumbering oligodendrocytes, oligodendrocytes that differ in appearance from those in healthy animals, and abnormal types of glial cells. In PNS hypomyelination, the microscopic changes consist of paucity of myelinated fibers, fibers with inappropriately thin myelin sheaths relative to the caliber of their enclosed axons, occasional fibers with poorly compacted myelin, Schwann cells with larger than normal cytoplasmic volume, and increased numbers of Schwann cell nuclei.

Diagnosis: The diagnosis of CNS hypomyelination is made primarily from the spectrum of neurologic deficits and signs and the early age of onset. Unfortunately, histopathology is the only definitive method to confirm a diagnosis. In cases with a

heritable basis, pedigree evaluation may be helpful. In cases with a viral cause, confirmation may involve immunofluorescent antibody-staining techniques or virus isolation from nervous tissue (or both). In cases of PNS hypomyelination, biopsy of peripheral nerves is beneficial.

Differential diagnoses include disorders that could cause tremors in young animals. The possibilities are numerous, but some of the more common include glycogen storage disease, lysosomal storage disease, cerebellar hypoplasia, encephalitis, hypocalcemia, hypoglycemia, hyperammonemia, toxins (eg, metaldehyde,

organophosphates, chlorinated hydrocarbons, fluoroacetate, strychnine, hexachlorophene, bromethalin), and mycotoxins (eg, penitrem-A).

Treatment, Control, and Prevention:

There is no specific treatment for hypomyelination. The only means of control and prevention is selective breeding (for heritable syndromes) and immunization (for viral-induced syndromes). If given time to develop normal or further myelin, some animals with congenital hypomyelination syndromes become normal by the age of 12 wk to 18 mo.

DISEASES OF THE PERIPHERAL NERVES AND NEUROMUSCULAR JUNCTION

Diseases of the peripheral nerve and neuromuscular junction include degenerative diseases, inflammatory diseases, metabolic disorders, neoplasia, nutritional disorders, toxic disorders, trauma, and vascular diseases. For a discussion of congenital disorders, see p 1222.

DEGENERATIVE DISORDERS

Acquired Laryngeal Paralysis: Laryngeal paralysis (see p 1420) is common in middle-aged and older dogs. Large breeds, such as Labrador Retrievers, Golden Retrievers, and Saint Bernards, are predisposed, but small-breed dogs and cats can be affected. In most cases, no underlying cause is identified and the laryngeal paralysis is a component of a generalized polyneuropathy, canine chronic axonal degeneration. A few cases are due to trauma or neoplasia affecting the neck or mediastinum. Hypothyroidism (see p 553) is also a potential cause. Clinical signs consist of voice change, laryngeal stridor, and a dry cough. In severe cases, exercise intolerance and episodes of respiratory—especially inspiratory—distress and cyanosis occur. Some affected animals have signs of a more generalized polyneuropathy, such as weakness and proprioceptive deficits.

Diagnosis is based on laryngoscopy with the animal lightly anesthetized. There is a unilateral or bilateral lack of abduction of the arytenoid cartilages and vocal folds during inspiration. Management consists of identifying and treating any underlying

disorder. Treatment of idiopathic laryngeal paralysis consists of surgery, such as laryngeal tie back. Surgery does not restore normal laryngeal function but is usually successful in diminishing severe inspiratory dyspnea. A potential complication of surgery is aspiration of food or liquid.

Canine Chronic Axonal Degeneration:

Canine chronic axonal degeneration, sometimes called geriatric-onset laryngeal paralysis polyneuropathy, affects middle-aged and older dogs and is characterized by axonal degeneration of peripheral nerves. The cause is unknown. Affected dogs have a wide-based, shuffling gait with ataxia, tetraparesis, and generalized muscle atrophy with decreased spinal reflexes. Laryngeal paralysis is often an early feature. Facial paralysis and dysphagia are also possible. Diagnosis is based on clinical features, electrodiagnostic evaluation showing denervation and slowed motor conduction velocity, and nerve and muscle biopsy showing loss of large-caliber nerve fibers with axonal degeneration and neurogenic muscle atrophy, respectively. It is important to exclude treatable metabolic causes such as hypothyroidism. The neurologic deficits progress slowly over months. There is no specific treatment.

Equine Laryngeal Paralysis: See p 1458.

Dancing Doberman Disease: Dancing Doberman disease is a neuromuscular disease that affects Doberman Pinschers

of either sex, 6 mo to 7 yr old, and is likely inherited in an autosomal recessive pattern. Initially, affected dogs intermittently flex the hip and stifle of one pelvic limb while standing. Within several months, most dogs alternately flex and extend both pelvic limbs in a dance-like fashion. They often prefer to sit rather than stand. The condition slowly progresses to mild paraparesis, decreased proprioception, and atrophy of the gastrocnemius muscles. The thoracic limbs are not affected. Pathologic changes have been reported in pelvic limb muscles as well as peripheral nerves, and whether this is a primary muscle or nerve disease remains to be clarified. There is no treatment, and signs do not resolve. However, the disease usually does not result in severe disability and does not appear to be painful.

Distal Denervating Disease: Distal denervating disease is a common polyneuropathy of dogs in the UK; it has not been reported elsewhere. The cause is unknown. Any age and breed of dog may be affected. The onset of signs varies from a few days to several weeks. There is progressive tetraparesis, hyporeflexia, and atrophy of proximal skeletal muscles. Sensory deficits are not apparent. Electrodiagnostic evaluation typically shows denervation of limb muscles, relatively normal nerve conduction velocity, and markedly reduced amplitude of M waves. Peripheral nerve biopsies are usually normal, but examination of intramuscular nerves may be diagnostic; distal intramuscular axons degenerate with collateral axonal sprouting. Treatment is supportive, and the prognosis is excellent, with recovery in 4–6 wk. Relapse has not been reported.

Distal Polyneuropathy of Rottweilers:

Distal polyneuropathy of Rottweilers is characterized by paraparesis that slowly progresses to tetraparesis, hyporeflexia, and muscle atrophy. The clinical course can be progressive or can wax and wane. Male and female Rottweilers 1–4 yr old have been affected. The cause is unknown. Electrodiagnostic testing shows denervation in distal muscles of the limbs and decreased motor nerve conduction velocity. Nerve biopsy changes consist of axonal necrosis and demyelination, often with infiltrates of macrophages, most severe in distal nerve fibers. Prognosis is poor, although some dogs may temporarily improve with corticosteroid treatment.

Idiopathic Facial Paralysis: Idiopathic facial paralysis is a common disorder that

results in unilateral or bilateral paresis or paralysis of the facial muscles in dogs and cats. Cocker Spaniels, Pembroke Welsh Corgis, Boxers, English Setters, and domestic longhaired cats are at increased risk. There is acute onset of unilateral or bilateral inability to blink, drooping ear, drooping upper lip, and drooping from the corner of the mouth. Facial sensation (mediated via the trigeminal nerve) remains intact. Diagnosis is based on clinical features and exclusion of other causes of facial paralysis, including ear disease, trauma, and brain-stem lesions. Pathologic findings consist of degeneration of myelinated axons in the facial nerve. There is no inflammation. The cause is unknown, and there is no specific treatment. Artificial tears often help prevent corneal damage. Partial improvement may occur in a few weeks, but persistent dysfunction is common.

Stringhalt: (See also p 1137.) Stringhalt in horses is characterized by brisk, involuntary flexion of one or both pelvic limbs during the protraction phase of the gait. Severity ranges from a mild jerk in the limb to flexion so severe that the affected horse can hardly walk. There may be atrophy of the muscles in the distal aspect of the affected limb(s). Stringhalt is seen in two forms. Ordinary or classic stringhalt is seen sporadically throughout the world, usually as a unilateral problem in individual horses. The cause is unknown. Some cases resolve spontaneously, whereas long digital extensor tenectomy is effective in others.

Australian stringhalt is seen in outbreaks that affect multiple horses in a region and often affects both pelvic limbs. Horses in Australia, New Zealand, and the USA have been affected, usually in late summer or autumn. Australian stringhalt is associated with ingestion of Australian dandelion, European dandelion, and mallow, perhaps due to mycotoxins affecting these plants. Pathologically, the distal aspect of axons in the peroneal and tibial nerves degenerates. Horses with Australian stringhalt usually recover spontaneously when removed from offending pastures.

INFLAMMATORY DISORDERS

Acquired Myasthenia Gravis: Acquired myasthenia gravis is characterized by failure of neuromuscular conduction due to reduction in the number of acetylcholine receptors at the neuromuscular junction. It is caused by the development of circulating

antibodies directed against the acetylcholine receptors at the neuromuscular junction. It is fairly common in mature dogs, especially German Shepherds, Golden Retrievers, and Labrador Retrievers, but is uncommon in cats. Three clinical forms exist in animals. The generalized form, which affects 57% of dogs with acquired myasthenia, is characterized by exercise-induced stiffness, tremors, and weakness that resolve with rest. However, weakness is not always associated with exercise. Megaesophagus is common in the generalized form. Focal myasthenia (43% of affected dogs) presents as facial, pharyngeal, or esophageal weakness without generalized weakness. Least common is fulminant myasthenia, which presents as acute, flaccid paralysis and megaesophagus, which rapidly progresses to respiratory paralysis and is usually fatal.

Generalized weakness often resolves quickly after IV administration of edrophonium chloride (0.1–0.2 mg/kg), which is often used as a diagnostic test. Definitive diagnosis is based on the detection of antibodies in serum. Treatment consists of anticholinesterase drugs, eg, pyridostigmine (1–3 mg/kg, PO, bid–tid) or neostigmine (0.04 mg/kg, SC, qid). Immunosuppressive dosages of prednisone and other immunomodulating drugs are recommended in animals that do not respond to anticholinesterase therapy. Megaesophagus is managed with upright feeding and in some cases gastrostomy tube placement for feeding and hydration. Aspiration pneumonia is a frequent complication of megaesophagus and leads to death or euthanasia in ~50% of affected dogs. The prognosis is generally good for animals without pneumonia, and ~85% of dogs will undergo spontaneous remission, evident by a decrease in antibody titer, usually within 6 mo.

Acute Idiopathic Polyradiculoneuritis:

Acute idiopathic polyradiculoneuritis primarily affects the ventral nerve roots and peripheral nerves. It is common in dogs and rare in cats. Clinical signs often develop 7–14 days after a raccoon bite or scratch (Coonhound paralysis); however, other affected animals have not been exposed to raccoons. A similar syndrome can develop in dogs and cats within 1–2 wk of vaccination. An immune-mediated reaction to raccoon saliva or other antigen is suspected. Initially, there is a short-strided gait in the pelvic limbs that progresses within 1–2 days to flaccid tetraparesis or tetraplegia and, in some cases, to facial and laryngeal weakness. Occasionally, the thoracic limbs

are initially affected. Death from respiratory paralysis can occur in severe cases. Spinal cord reflexes are weak to absent, and severe muscle atrophy is evident within 10–14 days. Pain perception is intact, and some dogs may appear hyperesthetic, showing signs of discomfort on palpation of the trunk or limbs. Mentation and appetite are not affected. Urination, defecation, and tail movement usually remain normal.

Analysis of CSF collected from the lumbar subarachnoid space shows increased protein with a normal cell count. Electromyography shows denervation, and nerve conduction studies show marked dispersion and prolonged latency of F-waves, indicative of slowed conduction in the ventral roots. There is no effective treatment other than nursing care, and corticosteroids are not helpful. Most affected animals begin to improve spontaneously within 3 wk, with complete recovery by 2–6 mo. Animals with severe signs and marked muscle atrophy may recover incompletely. Relapses can occur, especially in hunting dogs that frequently encounter raccoons. Histopathologically, there is inflammation, demyelination, and varying degrees of axonal degeneration in the ventral nerve roots and peripheral nerves.

Chronic Relapsing Idiopathic Polyradiculoneuritis:

Chronic relapsing idiopathic polyradiculoneuritis is a rare disease associated with inflammation of the nerves and nerve roots. It affects mature dogs and cats. Exercise intolerance, ataxia, and weakness develop slowly throughout several months. Some animals have spontaneous temporary remissions. Spinal cord reflexes are decreased, and cranial nerves may be affected. In severe cases, decreased sensation is evident. Diagnosis is based on nerve biopsy. There is nonsuppurative inflammation; axonal degeneration; and demyelination of nerves, nerve roots, and, in some cases, dorsal root ganglia. The cause is unknown, although immune-mediated mechanisms are suspected. Corticosteroids help in some cases, but the disease tends to slowly wax and wane, gradually becoming more severe throughout months to years.

Chronic Inflammatory Demyelinating Polyneuropathy:

Chronic inflammatory demyelinating polyneuropathy is a fairly common disorder in adult dogs and cats. The cause is unknown. Onset of tetraparesis with hyporeflexia is insidious and sometimes accompanied by cranial nerve dysfunction. Electromyography is usually normal, but nerve conduction velocities are slowed with

temporal dispersion. Nerve biopsy shows multifocal paranodal demyelination. Clinical signs usually improve with administration of corticosteroids (eg, prednisone 1–2 mg/kg/day), although signs may relapse when therapy is stopped.

Polyneuritis Equi: Neuritis of the cauda equina (polyneuritis equi) is characterized by inflammation of the sacrocaudal nerves and occasionally other nerves. It is seen in adult horses of all breeds in Europe and North America. The cause is unknown, although an immunologic reaction incited by a viral infection is possible. Affected horses have circulating antibodies against P2 myelin protein. The most consistent clinical signs reflect involvement of the sacrocaudal nerves and include urinary and fecal incontinence, tail paralysis, perineal paresthesia or analgesia, atrophy of the gluteal muscles, mild pelvic limb ataxia, and in male horses, penile paralysis. Affected horses may rub the tail. The thoracic limbs and cranial nerves may also be affected. Diagnosis can usually be based on clinical findings. CSF may be xanthochronic with increased protein content and mononuclear pleocytosis. Sacral fracture should be excluded by rectal examination and radiography. There is no treatment, and the prognosis for recovery is poor. Histopathologically, there is granulomatous inflammation primarily affecting the extradural portions of the sacrocaudal nerves.

Protozoal Polyradiculoneuritis: Protozoal polyradiculoneuritis occurs in dogs, especially puppies, and is caused by infection with *Toxoplasma gondii* (see p 685) or *Neospora caninum* (see p 663). Transplacental infection is most common, and multiple puppies in a litter can be affected. Affected puppies are normal at birth but by 3–8 wk develop paraparesis and a “bunny-hopping” gait with weak or absent spinal reflexes. Over a period of several weeks, the pelvic limbs develop severe extensor rigidity and muscle atrophy. Without treatment, the disease can progress to the thoracic limbs, eventually leading to dysphagia and fatal respiratory paralysis. Serum CK concentration is often increased. Analysis of CSF usually shows increased protein and leukocytes (neutrophils, mononuclear cells, and eosinophils). Serum or CSF antibodies or identification of the organism on muscle biopsy are helpful in diagnosis. Early treatment with clindamycin (15–20 mg/kg, IM, PO, bid) or trimethoprim/sulfadiazine (15 mg/kg, bid) and pyrimethamine (1 mg/kg/day) for 4–6 wk may be

effective. The prognosis is poor in dogs with pelvic limb rigidity.

Sensory Ganglioneuritis: Sensory ganglioneuritis affects dogs of any breed, although Siberian Huskies are at increased risk. At 1–6 yr of age, there is ataxia of all limbs with no paresis, dysphagia, regurgitation, and difficulty prehending food. Hyperesthesia and self-mutilation occur in some cases. There is decreased proprioceptive positioning, weak to absent patellar reflexes, and decreased to absent pain perception in the limbs and face. Diagnosis is based on clinical signs, electrodiagnostic testing that demonstrates slowed sensory nerve conduction, and biopsy of a mixed or sensory nerve that shows loss of myelinated axons and endoneurial fibrosis. The cause is unknown, but loss of neurons in dorsal root ganglia with infiltration of lymphocytes and macrophages is seen at necropsy. There is no effective treatment; the disease typically progresses and leads to euthanasia.

Trigeminal Neuritis: Idiopathic trigeminal neuropathy is common in dogs and uncommon in cats. It is characterized by acute onset of flaccid jaw paralysis. Affected animals cannot close the mouth and have difficulty eating and drinking. Horner syndrome, facial paresis, and decreased facial sensation are also possible. The cause is unknown. Histopathologically, there is bilateral nonsuppurative inflammation and demyelination in the motor branches of the trigeminal nerve. Affected animals usually recover spontaneously within 3–4 wk. Fluid and nutritional support may be necessary.

METABOLIC DISORDERS

Diabetic Neuropathy: This uncommon complication of diabetes mellitus (see p 579) is seen in cats and rarely dogs. Signs include weakness, ataxia, and muscle atrophy. Affected cats often have unilateral or bilateral tibial nerve dysfunction, evident as a plantigrade stance. There are several proposed pathophysiologic mechanisms, but prolonged hyperglycemia seems to be the important underlying factor. Pathologic findings in nerves consist of demyelination with remyelination, axonal degeneration, or both. Diagnosis is based on clinical findings, laboratory evidence of diabetes mellitus, and nerve biopsy. The prognosis is guarded, but partial or complete recovery can occur with insulin therapy.

Hypothyroid Neuropathy: This neuropathy is a potential complication of

hypothyroidism in dogs (*see* p 553). Mature dogs, especially large-breed dogs, are predisposed. Several syndromes have been reported, including tetraparesis with proprioceptive deficits and hyporeflexia, vestibular dysfunction, megaesophagus, and laryngeal paralysis. In some cases, classic signs of hypothyroidism (eg, obesity and dermatopathy) are absent, and neurologic dysfunction is the only sign of illness. Pathologic findings in peripheral nerves consist of demyelination or remyelination and axonal degeneration. The pathophysiology is poorly understood and, in some affected dogs with motor deficits, a myopathy may also be present. Diagnosis is based on clinical features, laboratory assessment of thyroid function, and response to thyroid supplementation. In some, but not all, cases, signs resolve within several months of starting thyroid replacement therapy.

NEOPLASIA

Nerve Sheath Tumors: Nerve sheath tumors include schwannomas, neurilemmomas, and neurofibromas. They are seen in most domestic animals but are most common in dogs and cattle. In dogs, tumors often arise in the nerves of the brachial plexus, initially causing unilateral thoracic limb lameness and pain that may be confused with musculoskeletal disease. Pain may be elicited on palpation of the axilla or abduction of the limb; large tumors can be palpated. Muscle atrophy and monoparesis eventually develop. The spinal cord may become compressed by the invasive tumor, causing neurologic deficits in other limbs. The trigeminal nerve is the most frequently affected cranial nerve. This results in unilateral atrophy of the temporalis and masseter muscles and facial dysesthesia or anesthesia. Eventually, brain-stem compression can develop.

Early surgical excision may be curative, although recurrence at the proximal stump of the resected nerve(s) is common. In cattle, nerve sheath tumors are often recognized incidentally in old animals at slaughter. Often, multiple nerves, especially autonomic nerves and cranial nerve VIII, are affected. Peripheral nerves may also be affected by other tumors, including lymphoma and leukemia. (*See also* NEOPLASIA OF THE NERVOUS SYSTEM, p 1267, and PERIPHERAL NERVE SHEATH TUMORS, p 126.)

Paraneoplastic Neuropathy: (*See also* p 1280.) Paraneoplastic neuropathy is associated with neoplasia unrelated to tumor infiltration of nerves. It is most common in dogs with insulinoma but has

been associated with a variety of tumors, including bronchogenic carcinoma, multiple myeloma, sarcoma, and adenocarcinoma. The pathogenesis is not well understood but may be related to an immune response directed against the tumor that cross-reacts with nerve components. Clinically, there is paraparesis or tetraparesis that progresses over several weeks with decreased spinal reflexes and muscle atrophy. Diagnosis is based on identifying the underlying tumor, clinical and electrodiagnostic findings of neuropathy, and in some cases, nerve biopsy. Signs may improve with successful treatment of the underlying tumor.

NUTRITIONAL DISORDERS

Pantothenic Acid Deficiency: Pantothenic acid deficiency may develop in animals (particularly pigs) on rations of corn. Clinical signs include pelvic limb ataxia and a “goose-stepping” gait in which the stifles remain extended and the hips flex to lift the limbs off the ground. Pathologic findings consist of degeneration of myelinated fibers in peripheral nerves and chromatolysis and loss of sensory neurons in spinal ganglia.

Riboflavin Deficiency in Chickens:

Riboflavin deficiency (curled toe paralysis, *see* p 2941) can develop if feed is not formulated properly. Affected chicks show poor growth, diarrhea, and weakness. There is inability to extend the hocks and progressive inward curling of the toes, so that chicks rest and walk on their hocks. Mortality is high by the third week. At necropsy the peripheral nerves, especially the sciatic nerves, are swollen. Histopathologically, there is hypertrophy of Schwann cells, demyelination, and minimal axonal degeneration. Chickens often recover with riboflavin supplementation unless the curled-toe deformity is longstanding.

TOXIC DISORDERS

Botulism: Botulism is intoxication with a neurotoxin produced by *Clostridium botulinum*. It is seen in horses, cattle, sheep, and birds worldwide. It is uncommon in dogs and pigs. (For a complete discussion, *see* p 605 and p 2889.)

Ionophore Toxicity: (*See also* IONOPHORES, p 1175.) Ionophore toxicity has been seen in cattle, sheep, pigs, dogs, cats, and poultry; horses are particularly susceptible. Lasalocid-contaminated food has caused flaccid tetraparesis with hyporeflexia in

dogs. In 1995, cat food contaminated with sialinomycin caused an outbreak of polyneuropathy in ~850 cats in the Netherlands and Switzerland. Affected cats had acute onset of tetraparesis, hyporeflexia, dysphagia, respiratory weakness, and eventual muscle atrophy. Histopathologic findings consisted of degeneration of distal sensory and motor axons. Affected animals usually recover with supportive care and removal of the offending food.

Organophosphate Poisoning: Poisoning involving organophosphates (see p 3064) can cause three syndromes. The **acute form** is due to irreversible inhibition of acetylcholinesterase, resulting in increased acetylcholine activation of the nicotinic and muscarinic receptors in the parasympathetic nervous system, nicotinic receptors at the neuromuscular junction, nicotinic receptors of the sympathetic nervous system, and cholinergic pathways within the CNS. Clinical signs of acute toxicity include muscarinic signs (eg, vomiting, diarrhea, salivation, bronchoconstriction, increased bronchial secretions), nicotinic signs (eg, muscle tremor and twitching), and CNS signs (eg, behavioral change, seizures).

The **intermediate form** is primarily manifest as generalized muscle weakness due to accumulation of acetylcholine at the nicotinic neuromuscular junction, causing a depolarizing block. Cats are especially prone to this form of toxicity, most commonly due to chlorpyrifos. Affected cats often do not have obvious signs of acute toxicity, instead developing tetraparesis and ventroflexion of the neck several days after exposure. Mydriasis is common. Diagnosis is based on a history of exposure and the presence of typical clinical signs. Decreased cholinesterase activity in whole blood is supportive. Treatment of acute or subacute toxicity should include administration of atropine (0.2 mg/kg, IM) if dyspnea due to bronchial secretions and bronchoconstriction is present. Atropine will not relieve the nicotinic signs of tremors and weakness, which should be treated with pralidoxime chloride (20 mg/kg, IM or SC, bid). Diphenhydramine (4 mg/kg, IM or PO, bid) may help alleviate muscle weakness. Treatment for several weeks may be necessary.

The **delayed form** of toxicity is associated with degeneration of distal axons in the peripheral and central nervous systems. It is unrelated to inhibition of acetylcholinesterase and is seen only with certain organophosphates. Signs develop several weeks after exposure and are characterized by weakness and ataxia of the pelvic limbs. In

horses, laryngeal paralysis has also been reported. There is no specific treatment.

Tick Paralysis: Rapidly progressive paralysis may be caused by several species of ticks (see p 1314). Some female ticks produce a salivary toxin that interferes with acetylcholine release at the neuromuscular junction. In North America, *Dermacentor variabilis* and *D. andersoni* may affect dogs, sheep, and cattle. In Australia, *Ixodes holocyclus* causes an especially severe form of tick paralysis in dogs, cats, cattle, sheep, pigs, llamas, horses, and occasionally people. In Africa, the major tick associated with paralysis is *I. rubicundus*, with cattle, sheep, goats, and rarely dogs affected. A wide variety of ticks affect animals in Europe and Asia.

Clinical signs consist of paraparesis that progresses within 24–72 hr to flaccid tetraplegia, with weak to absent spinal cord reflexes. Sensory perception and consciousness remain normal. Dysphagia, facial paralysis, masticatory muscle weakness, and respiratory paralysis may develop in severe cases. Treatment consists of removal of the tick and application of a topical acaricide to kill any hidden ticks. For all except *I. holocyclus* paralysis, prognosis is good, and recovery occurs within 1–2 days. Tick antiserum is available for treatment of *I. holocyclus* paralysis, but prognosis is guarded because death from respiratory paralysis may occur despite treatment.

TRAUMA

The immediate effect of injury of a peripheral nerve is a variable degree of dysfunction, depending on the severity of the injury. The mildest form of injury is neuropraxia, which temporarily disrupts function with minimal morphologic alterations in the nerve. Axonotmesis is disruption of axons without disruption of the surrounding connective tissue of the nerve. The most severe form of injury is neurotmesis, which is complete severance of the nerve. With both axonotmesis and neurotmesis, there is subsequent degeneration of the axons distal to the injury site and in a portion of the nerve proximal to the injury site.

Diagnosis of peripheral nerve injuries is based on the history and clinical assessment of the motor and sensory function of the affected nerve(s). Electromyography often helps identify denervated muscles 5–10 days after injury. Nerve conduction studies may also be useful in diagnosis.

Prognosis is guarded. With neuropraxia, complete recovery usually occurs within 3 wk. For function to return after axons are

disrupted (axonotmesis, neurotmesis), the nerve must regenerate from the point of injury all the way to the innervated muscle. The growth rate of regenerating axons in the distal stump is 1–3 mm/day. Recovery is unlikely if the severed axons are substantially separated or if scar tissue interferes with axonal growth. Although various anti-inflammatory drugs have been recommended for traumatic nerve injuries, there is little evidence of benefit. Surgery to appose the nerve stumps should be performed promptly in cases in which the nerve has been sharply transected. In instances of blunt trauma, surgical exploration and excision of scar tissue may help. Surgery is often successful in horses with fibrous compression of the suprascapular nerve. Longterm management consists of physical therapy to minimize muscle atrophy and decreased mobility of joints. Bandages or splints may be necessary to help protect the affected limb.

Brachial Plexus Avulsion: Traumatic injury to the C6 to T2 nerve roots that innervate the thoracic limb can lead to brachial plexus avulsion in dogs, cats, and birds. With severe extension or abduction of the limb, the nerve roots stretch or tear from their attachment to the spinal cord. Clinical signs vary with the extent of root involvement. Complete avulsion results in flaccid paralysis of the limb, anesthesia distal to the elbow, ipsilateral Horner syndrome, and ipsilateral loss of the cutaneous trunci (pariculus) reflex. The injured animal bears little or no weight on the limb and drags the dorsal surface of the paw on the ground. Sensation to the ventral surface of the paw is spared if only the cranial nerve roots are affected. Avulsion of the caudal nerve roots causes loss of sensation on the caudal surface of the limb with variable loss on the cranial surface.

There is no treatment, and with complete avulsion, the prognosis is poor. Amputation of the limb may be necessary because of damage from dragging or self-mutilation. Recovery is possible in mild cases in which the roots are contused rather than avulsed.

Peripheral Nerve Injuries: These injuries are some of the most common neuropathies in animals. The **sciatic nerve** or its branches may be injured by pelvic fractures, during or after retrograde placement of intramedullary pins in the femur, or by injections of irritating substances in or near the nerve. Damage to the proximal aspect of the sciatic nerve causes monoparesis with inability to flex the stifle. The hock and digits cannot flex or extend, and weight is supported on the

dorsal surface of the foot with the hock excessively flexed. There may be loss of sensation below the stifle except for the medial aspect, which is innervated by a branch of the femoral nerve.

Injury to the **tibial nerve** results in inability to extend the hock or flex the digits as well as reduced sensation over the plantar surface of the foot.

Injury to the **peroneal nerve** results in inability to flex the hock or extend the digits as well as decreased sensation over the craniodorsal surface of the foot, hock, and stifle.

The **femoral nerve** may be injured in calves and foals during dystocia if excessive traction stretches or otherwise damages it. This results in an inability to bear weight on the limb because of an inability to extend the stifle. The patellar reflex is weak or absent. Sensation is lost along the medial surface of the limb (saphenous nerve).

The **suprascapular nerve** is most commonly injured in large animals secondary to trauma of the shoulder region. This results in atrophy of the supraspinatus and infraspinatus muscles and instability of the shoulder joint (sweeney, *see* p 1129). In horses, the nerve may be entrapped by connective tissue that develops in the region of the supraspinous fossa.

Calving Paralysis: Calving paralysis is seen in heifers with oversized fetuses. It has previously been attributed to bilateral compression of the obturator nerve, but damage to the sixth lumbar nerve root, which contributes to the obturator and sciatic nerve, probably accounts for most of the paralysis. Ischemic necrosis of muscles secondary to compression, and ruptures of muscles during attempts to rise, also contribute to the paraparesis. Additionally, metabolic derangements, such as hypocalcemia, may complicate the syndrome. (*See also* BOVINE SECONDARY RECTUMBENCY, p 1188.)

Facial Nerve Trauma: Facial nerve trauma is most common in large animals that become recumbent with subsequent compression of the side of the face. It can be caused by pressure from a halter in horses during general anesthesia. There is ipsilateral lip paralysis, deviation of the muzzle to the contralateral side, and weak to absent palpebral reflex. A drooping ear can result from injuries to the proximal aspect of the nerve.

VASCULAR DISEASES

Ischemic Neuromyopathy: Ischemic neuromyopathy is most common in cats

with arterial thromboembolism secondary to myocardial disease. It also is seen in dogs with a variety of underlying disorders, including hyperadrenocorticism, hypothyroidism, renal disease, cancer, and heart disease. Occlusion occurs most commonly at the distal aortic trifurcation, resulting in ischemia of muscles and nerves in the pelvic limbs. There is acute, painful paraparesis and an inability to flex or extend the hock. The flexor reflex and, in some cases, the patellar reflex are lost. Sensation distal to the hock is decreased. The gastrocnemius and cranial tibial muscles are often firm and painful. The nails may be cyanotic, and the femoral pulses are weak or absent.

Diagnosis can usually be made based on clinical features. Serum CK is often increased. Doppler ultrasonography helps evaluate blood flow in the distal aorta and femoral arteries. Pathologic changes are present distal to the level of the middle to

lower thigh and are characterized as focal muscle necrosis and degeneration of the central portions of the sciatic nerve and its branches. Management consists of analgesics, nursing care, and treatment of any underlying disease (eg, cardiomyopathy). Thrombolytic therapy with streptokinase or tissue plasminogen activator does not improve survival. Anticoagulants, such as unfractionated heparin or low-molecular-weight heparin, are used to reduce continued thrombus formation. Neurologic deficits may improve within 2–3 wk, but 6 mo may be required for complete recovery. Permanent deficits are possible. Approximately 60% of affected cats die or are euthanized during the initial episode. In the cats that survive, the longterm prognosis is guarded (median 12 mo) because of the underlying heart disease and high risk of recurrence of thromboembolism.

DISEASES OF THE SPINAL COLUMN AND CORD

Diseases of the spinal column and cord include congenital disorders, degenerative diseases, inflammatory and infectious diseases, neoplasia, nutritional diseases, trauma, toxic disorders, and vascular diseases. Many of these diseases are discussed in full in other chapters and are only briefly described here. For a discussion of congenital disorders related to the spinal column and cord, see p 1222.

DEGENERATIVE DISEASES

Cervical Spondylomyelopathy: Cervical spondylomyelopathy, also called cervical vertebral malformation-malarticulation and wobbler syndrome, is compression of the spinal cord caused by abnormal development of the cervical vertebrae. Genetic factors and possibly nutrition may be involved.

In dogs, there are two forms of the disease, disc-associated wobbler syndrome (DAWS) and bony-associated cervical spondylomyelopathy. DAWS affects middle-aged (mean 7 yr), large-breed dogs, especially Doberman Pinschers. There is ventral compression of the spinal cord due to protrusion of one or more caudal cervical discs, in some cases complicated by

congenital stenosis of the vertebral canal or hypertrophy of the ligamentum flavum. Bony-associated compression affects young (several months to 4 yr), giant-breed dogs, including Great Danes, Mastiffs, and Rottweilers. Spinal cord compression is due to bony proliferation of the articular processes and pedicles, usually of the C4 to C7 vertebrae.

Clinical signs can be acute or slowly progressive. Mild cases are characterized by subtle ataxia of all limbs, often evident as a long, protracted stride in the pelvic limbs, with short-strided gait in the thoracic limbs. In severe cases, there is paresis or paralysis of all limbs. Neck pain is variable. Differential diagnoses include congenital anomalies, trauma, meningomyelitis, discospondylitis, and neoplasia. Survey radiographs cannot confirm a diagnosis of cervical spondylomyelopathy but are useful in excluding discospondylitis and bony neoplasia. Definitive diagnosis requires myelography, CT, or MRI.

Nonsurgical treatment is indicated for dogs with mild signs and consists of exercise restriction and prednisone (0.5 mg/kg/day). Signs improve in ~50% of dogs and remained unchanged in ~25% of

dogs with nonsurgical treatment. Surgery is indicated in animals with substantial neurologic deficits and in those that do not respond adequately to nonsurgical treatment. The specific technique is based on the changes evident on imaging and include ventral slot with partial discectomy, dorsal laminectomy, or distraction and fusion of affected vertebrae. Overall, ~80% of dogs do well with surgery.

In horses, cervical spondylomyelopathy is the most common noninfectious disease of the spinal cord and occurs in many breeds. Most horses present at <3 yr of age, although they can be affected at any age. The mid-cervical region is most commonly affected, and there is spinal ataxia and tetraparesis. Diagnosis is based on imaging and excluding other causes. Plain radiographs may show abnormal articular facets and stenosis of the vertebral canal. Myelography is necessary for definitive diagnosis and surgical planning. Nonsurgical treatment involves NSAIDs and dimethyl sulfoxide to reduce inflammation. In yearlings, diet modification can help. Surgery most commonly involves ventral fusion of the affected vertebrae. Approximately 80% of affected horses improve with surgery. Owner/rider safety is a major concern in horses with ataxia.

Degenerative Lumbosacral Stenosis:

Narrowing of the lumbosacral vertebral canal or intervertebral foramina results in compression of the cauda equina or nerve roots. It is most common in large breeds of dogs, especially German Shepherds, and is rare in cats. It results from degeneration and protrusion of the L7–S1 disc, hypertrophy of the ligamentum flavum, or rarely subluxation of the lumbosacral joint. The cause is unknown, although German Shepherds with congenital transitional vertebrae are at increased risk. Clinical signs typically begin at 3–7 yr of age and may include difficulty using the pelvic limbs, pelvic limb lameness, tail weakness, and incontinence. Pain on palpation or extension of the lumbosacral joint is the most consistent finding. There may be proprioceptive deficits, muscle atrophy, or a weak flexor reflex in the pelvic limbs. Plain radiographs may show degenerative changes, but definitive diagnosis requires MRI, CT, or epidurography. Dogs in which mild pain is the only sign may improve with 4–6 wk of rest. Epidural injection of methylprednisolone acetate (1 mg/kg on each of day 1, day 14, and day 42) is effective in ~80% of dogs with pain and minimal neurologic deficits. Surgery is indicated when pain is refractory to medical

therapy or there are neurologic deficits. The most common technique is dorsal laminectomy with partial discectomy, but foramenotomy or stabilization is indicated in certain cases. Approximately 70%–95% of dogs improve with surgery, although preexisting urinary incontinence may not resolve.

Degenerative Myelopathy of Dogs:

Degenerative myelopathy of dogs, also called chronic degenerative radiculomyelopathy, is a slowly progressive, noninflammatory degeneration of the axons and myelin primarily affecting the white matter of the spinal cord. It is most common in German Shepherds, Pembroke Welsh Corgis, Boxers, Rhodesian Ridgebacks, and Chesapeake Bay Retrievers, but is occasionally recognized in many other breeds. The cause is a mutation in the superoxide dismutase 1 (SOD1) gene, inherited in an autosomal recessive pattern with incomplete penetrance. It is similar to familial amyotrophic lateral sclerosis in human patients. Pathologically, there is noninflammatory degeneration of axons in the white matter of the spinal cord, which is most severe in the thoracic region.

Affected dogs are usually >8 yr old and develop an insidious onset of nonpainful ataxia and weakness of the pelvic limbs. Spinal reflexes are usually normal or exaggerated, but in advanced cases there is flaccid tetraparesis and hyporeflexia reflecting lower motor neuron involvement. Early cases may be confused with orthopedic disorders; however, proprioceptive deficits are an early feature of degenerative myelopathy and are not seen in orthopedic disease.

Myelography or MRI and CSF analysis are essential to exclude compressive and inflammatory diseases. A DNA test based on the SOD1 gene is available on the Orthopedic Foundation for Animals Web site. Dogs that are homozygous for the mutation are at risk of the disease and will pass one copy of the mutant allele to their offspring. Heterozygotes are at low risk of the disease but have a 50% chance of passing one copy of the mutant allele to each offspring. Homozygous normals are at low risk of the disease and will not pass the mutation to offspring.

There is no specific treatment and no evidence that glucocorticoids, other drugs, or supplements alter the course of the disease. Most dogs are euthanized because of disability within 1–3 yr of diagnosis.

Equine Degenerative Myeloencephalopathy: Equine degenerative myeloencephalopathy is a progressive neurologic

disorder of horses and zebras characterized by diffuse degeneration of axons, myelin, and neurons in the spinal cord and, to a lesser degree, the brain stem. It has been reported in many equine breeds in North America, Australia, and England. The cause is incompletely understood, but a vitamin E deficiency and genetic factors are suspected. Clinical signs usually become apparent during the first year of life and consist of ataxia and weakness in all four limbs, although the hindlimbs may be more severely affected. Clinical signs may stabilize or slowly progress. There is no definitive diagnostic test. Clinical diagnosis is based on clinical features and excluding other causes. Myelography and CSF analysis are normal. Supplementation of pregnant mares and newborn foals with vitamin E is preventive in predisposed families, and affected horses may improve with vitamin E supplementation.

Intervertebral Disc Disease: Degeneration and subsequent herniation of the intervertebral disc results in compression of the spinal cord, spinal nerve, and/or nerve root. It is a common cause of spinal cord disease in dogs, with a lifetime prevalence of ~3.5%. Clinical signs due to disc disease are rare in cats and horses. Chondrodystrophic breeds of dogs (eg, Dachshund, Beagle, Shih Tzu, Lhasa Apso, and Pekingese) are most commonly affected, with Miniature Dachshunds having a lifetime prevalence of ~20%. In these breeds, there is chondroid degeneration of the discs within the first few months of life. Disc extrusion can occur as early as 1–2 yr of age, and clinical signs are often acute and severe. In contrast, fibroid disk degeneration typically occurs in large breeds of dogs >5 yr old and causes slowly progressive clinical signs.

The most common sites of disc herniation are the cervical and thoracolumbar regions. The predominant sign of cervical disc herniation is neck pain, manifested as cervical rigidity and muscle spasms. There may be thoracic limb lameness or neuro-

logic deficits, ranging from mild tetraparesis to tetraplegia. In thoracolumbar disc herniation, there may be back pain, evident as kyphosis and reluctance to move. Neurologic deficits are usually more severe than those seen in cervical disc disease and range from pelvic limb ataxia to paraplegia and incontinence. In paraplegic animals, the most important prognostic finding is whether there is deep pain perception caudal to the lesion. This is assessed by pinching the toe or tail and observing whether there is a behavioral response, such as a bark or turn of the head. It is important to pinch the bone to stimulate deep pain receptors, not just the skin, which tests only superficial pain. Reflex flexion of the limb must not be mistaken for a behavioral response.

Definitive diagnosis of disc extrusion is based on imaging studies. Spinal radiographs may show narrowing of the affected disc space, intervertebral foramen or articular facets, or radiodense calcified disc material within the vertebral canal. However, radiographs are not sensitive or specific enough for definitive diagnosis, which requires myelography, MRI, or CT. Dogs with pain and minimal to moderate neurologic deficits often recover with 2–3 wk of cage rest. A short course of prednisone (0.5 mg/kg/day for 3 days) is often helpful in relieving pain. The use of anti-inflammatory or analgesic medication without concurrent cage rest is contraindicated, because an increase in the dog's activity may lead to further disc extrusion and worsening of spinal cord compression. Clinical signs recur after conservative therapy in 30%–40% of cases.

In animals with severe neurologic deficits, prompt surgery offers the best chance of recovery (see TABLE 1). Other indications for surgery are failure of conservative therapy and recurrent episodes. Hemilaminectomy with removal of the extruded disc material is the most common procedure. Prophylactic fenestration of commonly affected disc spaces (eg, T11 through L4) decreases recurrence in small-breed dogs. Progressive myelomalacia develops in 5%–10% of dogs with paraplegia and loss of deep pain perception. In this syndrome, affected dogs develop flaccid tetraplegia, the level of anesthesia ascends cranially, and respiratory paralysis develops.

Diffuse Idiopathic Skeletal Hyperostosis: Also known as Forestier disease in human patients, diffuse idiopathic skeletal hyperostosis (DISH) is

Intervertebral disc extrusion, L3-L4, in a dog.
Courtesy of Dr. William Thomas.

TABLE 1 RECOVERY RATES AFTER SURGERY FOR INTERVERTEBRAL DISC DISEASE IN DOGS

Patient Type	Recovery Rate
Nonambulatory small-breed dog with thoracolumbar extrusion and intact deep pain	85%–95%
Small-breed dog with thoracolumbar extrusion and loss of deep pain <24 hr	50%
Small-breed dog with thoracolumbar extrusion and loss of deep pain >24 hr	<50%
Nonambulatory large-breed dog with chronic thoracolumbar protrusion	25%–50%
Ambulatory dog with cervical disc disease	95%
Nonambulatory dog with cervical disc disease	65%–95%

characterized by ossification of entheses, the sites where a ligament, tendon, or joint capsule inserts into bone. Radiographic criteria for diagnosis are flowing ossification along the ventrolateral aspect of at least four contiguous vertebrae with relative preservation of disc width and absence of facet joint ankylosis. Approximately 4% of dogs >1 yr old are affected, and the prevalence increases with age. As with spondylosis deformans, Boxers are at increased risk, with a prevalence of ~40%. The thoracic and lumbar regions are most commonly affected. It is unclear how often DISH causes clinical signs, and in many cases the radiographic findings are incidental. However, spinal pain and stiffness is possible and, in those cases, treatment is analgesics as needed.

Equine Motor Neuron Disease:

Equine motor neuron disease is a progressive, noninflammatory degeneration of motor neurons in the spinal cord and brain stem of horses. It is most common in the northeastern USA but has been reported in several areas of North and South America, Europe, and Japan. The cause is uncertain, but vitamin E deficiency is a strong risk

factor. Adult horses of any age and breed can be affected, although Quarter horses are affected most commonly. Affected horses typically do not have access to pasture grass and are fed poor-quality grass hay.

Clinical signs consist of generalized symmetric weakness, trembling, and muscle atrophy. Affected horses often stand with their head held low and their feet camped under their body, frequently shifting their weight from one limb to another. Ataxia is not a feature of this disease, in contrast to most spinal cord diseases. Many affected horses have retinal abnormalities, including a distinct reticulated pigment pattern and areas of hyperreflectivity. Electromyography and biopsy of the spinal accessory nerve or the sacrodorsalis caudalis muscle are useful in diagnosis.

There is no specific treatment, but some horses improve partially after 2–3 mo of illness. Horses that lack access to green forage high in vitamin E for prolonged periods should be supplemented with vitamin E.

Degeneration of Motor Neurons:

Degeneration of motor neurons is an inherited or sporadic disease seen in Brittany Spaniels, Pointers, German Shepherds, Doberman Pinschers, and Rottweilers; cats; Hereford, Brown Swiss, and red Danish cattle; Yorkshire pigs; and goats. Also called spinal muscular atrophy, this disease is characterized by progressive paresis, tremor, muscle atrophy, and weak spinal reflexes. The age of onset is typically within the first 1–2 yr of life. Electromyography and muscle biopsy help document muscle denervation, but definitive diagnosis is based on loss of motor neurons in the

Diffuse idiopathic skeletal hyperostosis (DISH) in a dog. Courtesy of Dr. William Thomas.

Spondylosis deformans in a dog. Courtesy of Dr. William Thomas.

ventral horn of the spinal cord and brain-stem nuclei on necropsy.

Metabolic Storage Disorders: Rare, usually inherited, metabolic disorders can affect the CNS, including the spinal cord. (See also CONGENITAL AND INHERITED ANOMALIES OF THE NERVOUS SYSTEM, p 1222.)

Spondylosis Deformans: Spondylosis deformans is a noninflammatory condition characterized by formation of bony projections (enthesophytes) at the location where the annulus fibrosus is attached to the cortical surface of adjacent vertebrae. These bony growths vary from small spurs located several millimeters from the junction between the disc and vertebra to bony bridges that span the disc space, leaving at least part of the ventral surface of the vertebra unaffected. The enthesophytes typically expand laterally and ventrally but not dorsally and therefore rarely affect the spinal cord. The cause is breakdown of the outer fibers of the annulus fibrosis and stretching of the longitudinal ligament. The increased stress at the vertebral attachment of the longitudinal ligament incites bony production.

Spondylosis deformans is seen in dogs, cats, and bulls, and the incidence increases with age. It is uncommon in dogs <2 yr old; by 9 yr of age, 25%–70% of all dogs are affected. It is especially common in Boxers, and a genetic predisposition has been identified in this breed. It is typically an incidental radiographic finding, and there is no correlation between the presence of spondylosis and clinical signs. Rare cases cause spinal hyperesthesia, which should be treated with analgesics.

INFLAMMATORY AND INFECTIOUS DISEASES

Infectious and inflammatory diseases of the spinal column and spinal cord include bacterial, rickettsial, viral, fungal, protozoal, and parasitic infections and idiopathic inflammatory disease. Many of these diseases can also affect the brain (see p 1262).

Some of the more common infectious and inflammatory diseases in which involvement of the spinal column or cord is a prominent feature are discussed below.

Bacterial Diseases

Discospondylitis is inflammation of the intervertebral disc and adjacent vertebral bodies. **Vertebral osteomyelitis** is inflammation of the vertebra without concurrent disc infection. Both diseases are usually caused by hematogenous spread of bacterial or fungal infection. Immunosuppression may play a role in some infections. Discospondylitis is most common in dogs, especially larger breeds. Osteomyelitis of the lumbar vertebrae can develop in dogs secondary to migration of plant awns. In cats, it is rare and usually due to direct spread of infection from an adjacent wound. Discospondylitis and vertebral osteomyelitis have also been reported in horses, ruminants, and pigs, especially neonates. Infection may be seen at any disc space, and multiple lesions may be seen.

In canine discospondylitis, the most commonly isolated organisms are *Staphylococcus* spp. Other organisms include *Brucella canis*, *Streptococcus* spp, *Escherichia coli*, *Proteus* spp, *Corynebacterium diphtheroides*, *Nocardia* spp, and *Aspergillus* spp. Spinal pain is the most consistent clinical finding. Systemic signs, such as fever, depression, and weight loss, are less common. Neurologic deficits may develop due to spinal cord compression caused by proliferative tissue or, rarely, spread of infection to the spinal cord or pathologic fracture.

Spinal vertebral body abscess (cross-section). Courtesy of Dr. Sameeh M. Abutarbush.

Early radiographic findings consist of destruction of the adjacent vertebral end plates and collapse of the disc space. More advanced lesions also have variable degrees of osteophyte formation. Blood and urine cultures often identify the causative organism. Affected dogs should be tested for brucellosis (see p 1402).

Although clinical signs usually resolve within 5 days of treatment with an appropriate antibiotic, treatment should be continued for at least 8 wk. Amoxicillin/clavulanic acid for presumed *Staphylococcus* spp infection is a good choice if cultures are negative.

Rickettsial Diseases

Neurologic abnormalities, including signs of spinal cord dysfunction, are sometimes seen in dogs with rickettsial infection. Dogs with **Rocky Mountain spotted fever** (*Rickettsia rickettsii*, see p 806) often have thrombocytopenia, leukocytosis, and a neutrophilic pleocytosis and mildly increased protein on CSF analysis. Diagnosis is based on a 4-fold increase in serum antibody concentration. Dogs with **ehrlichiosis** (*Ehrlichia canis*, see p 803) often have thrombocytopenia, anemia, leukopenia, hyperglobulinemia, and mononuclear pleocytosis and marked increase in protein on CSF analysis. A single serum antibody titer is usually sufficient for diagnosis of *E. canis*. Treatment of rickettsial myelitis consists of doxycycline or chloramphenicol for 14–21 days. Prognosis is good with early treatment, although neurologic deficits occasionally progress despite treatment.

Viral Diseases

Canine distemper encephalomyelitis (see p 777), caused by a paramyxovirus, remains one of the most common CNS disorders in dogs worldwide. Onset of neurologic deficits may be acute or slowly progressive, reflecting the location of the lesion(s) within the CNS. The brain stem and spinal cord are the regions most commonly affected in mature dogs. Neurologic signs are usually not preceded by, nor coincident with, the systemic illness seen in young dogs.

Definitive antemortem diagnosis is difficult. There may be active or inactive chorioretinitis on funduscopy. A lymphocytic pleocytosis with increased protein concentration is the most common finding on CSF analysis. Reverse transcriptase-PCR on urine or CSF is useful in diagnosis. There is no specific treatment, and the prognosis is

poor for severely affected dogs. Vaccination is usually successful in preventing the systemic form of distemper, but previously vaccinated dogs can be affected by the neurologic form.

Caprine arthritis and encephalitis (see p 747) is caused by a lentivirus that can also cause pneumonitis and arthritis. CNS disease is most common in goats 2–4 mo old, although older animals may also be affected. There is an acute onset of slightly asymmetric spastic paraparesis that may progress to tetraplegia with exaggerated reflexes. A mononuclear pleocytosis and increased protein in the CSF are present in ~50% of the cases. Serologic testing is helpful in detecting infection, but false-negatives can be seen. Histologically, there is severe nonsuppurative inflammation with demyelination or necrosis, most prominent in the white matter of the spinal cord. There is no treatment, and recovery is unlikely.

A related lentivirus is a rare cause of chronic encephalomyelitis in sheep (**maedi**, see p 1475). Affected sheep are usually >2 yr old and suffer an insidious onset of progressive ataxia, paraparesis, or tetraparesis.

Equine infectious anemia (see p 699) occasionally produces encephalomyelitis in horses. Neurologic deficits are usually referable to spinal cord disease and include ataxia and weakness in the hindlimbs. The protein concentration of and the number of lymphocytes in the CSF are often increased. Diagnosis is by positive agar gel immunodiffusion testing. There is no treatment, and affected horses are usually euthanized to prevent spread of the disease.

Equine herpesvirus 1 (EHV-1) encephalomyelopathy is a neurologic disorder that affects horses worldwide. The EHV-1 virus infects vascular endothelial cells, particularly those within the CNS, and causes an immune-mediated vasculitis with secondary infarction and hemorrhage throughout the brain and spinal cord. The EHV-1 virus has also been associated with meningoencephalitis in alpacas and llamas. In horses, neurologic signs may be seen as the primary disease or follow rhinopneumonitis or abortion. Any age animal may be affected.

Neurologic deficits have an abrupt onset, vary from mild hindlimb ataxia to paraplegia, and usually do not progress after 24 hr. Urine dribbling, fecal retention, and sensory deficits in the perineum and tail are common. The CSF is often xanthochromic with increased protein content and normal numbers of cells. Diagnosis is based on

clinical findings and an increase in antibody concentration in paired serum samples, isolation of virus from nasal or pharyngeal secretions, or PCR testing. There is no specific treatment, but anti-inflammatory agents such as dimethyl sulfoxide, dexamethasone, and NSAIDs may help. Supportive care is important to prevent complications such as urine retention, cystitis, and decubitus. Mildly affected horses often recover with supportive care. Even recumbent horses can eventually recover with meticulous nursing care. Vaccination does not protect from the neurologic form of this disease. (See also EQUINE HERPESVIRUS INFECTION, p 1444.)

Feline infectious peritonitis (see p 780) is a disease of domestic cats caused by an immune-mediated response to a coronavirus. CNS involvement is common. There are pyogranulomatous lesions involving the neural parenchyma, choroid plexuses, ependyma, and leptomeninges. Clinical signs of spinal cord involvement include spinal hyperesthesia and paraparesis or tetraparesis. Hyperglobulinemia and involvement of other organs, especially the eyes, are common. Serum antibody tests currently available are insensitive and nonspecific. A mixed (neutrophilic and mononuclear) pleocytosis with increased protein concentration is the most common finding on CSF analysis. There is no effective treatment, and prognosis is poor.

Feline leukemia virus-associated myelopathy is seen in some cats infected with the feline leukemia virus (FeLV, see p 790) for ≥ 2 yr. Ataxia and weakness of the pelvic limbs progresses to paraplegia within 1 yr. Other signs include diffuse spinal pain and abnormal behavior. Diagnosis is based on clinical features, FeLV serology, and exclusion of other causes, such as spinal lymphoma and myelitis due to toxoplasmosis or fungal infection. There is no treatment; affected cats are eventually euthanized because of disability. Pathologic findings consist of white matter degeneration, swollen axons, and dilation of myelin sheaths in the spinal cord and brain stem. FeLV antigen is present in the nervous system, indicating that the lesions are due to viral infection.

Teschovirus encephalomyelitis (see p 1307), also called Teschen disease, Talfan disease, and porcine polioencephalomyelitis, is caused by a neurotropic teschovirus previously classified as an enterovirus. There is a peracute or subacute onset of hindlimb ataxia and paresis with hyporeflexia, depression, seizures, and death.

Older pigs may survive, but mortality is high in young pigs.

Porcine hemagglutinating encephalomyelitis virus is a coronavirus that causes both vomiting and wasting disease (see p 728) and an encephalomyelitis. It is most common in piglets <3 wk old, and there is some overlap of these syndromes. The CNS disease starts with several days of vomiting, which is followed by hyperesthesia, muscle tremors, ataxia, paresis, opisthotonos, coma, and death. Histopathologically, there is diffuse nonsuppurative encephalomyelitis, primarily involving gray matter. Diagnosis is based on necropsy or an increase in antibody titer in paired sera. There is no treatment.

Rabies (see p 1302) is caused by a neurotropic rhabdovirus that reaches the CNS via peripheral nerves. It produces multifocal, nonsuppurative polioencephalomyelitis in all domestic mammals. Signs of spinal cord involvement include ataxia and progressive paralysis, usually with absent reflexes. Affected animals typically, but not invariably, die with progressive neurologic signs within 2–7 days of illness.

Fungal Diseases

Cryptococcus neoformans is the most common fungus to involve the CNS in animals. Infection is most common in dogs and cats and occurs occasionally in horses. Other fungal organisms may invade the CNS, including *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidioides immitis*, *Aspergillus* spp, and phaeohyphomycoses. Affected animals often have involvement of other organs, such as the lungs, eyes, skin, or bones. Signs of spinal cord involvement include paresis or paralysis and spinal hyperesthesia. Diagnosis is based on serology, culture, or identifying the organism in CSF or extraneural tissue. Fluconazole is often effective for cryptococcosis and coccidioidomycosis. Itraconazole or amphotericin B is recommended for histoplasmosis and blastomycosis, but the prognosis is guarded to poor. (See also FUNGAL INFECTIONS, p 632.)

Protozoal Diseases

Equine protozoal myeloencephalitis (see p 1309) is a common disease of horses that produces a nonsuppurative, often necrotizing, meningoencephalomyelitis. Horses are likely an aberrant host for the causative organism, usually *Sarcocystis neurona*, but less commonly, other protozoa cause the disease. Neurologic

signs are extremely variable and often asymmetric, reflecting involvement anywhere in the CNS. Ataxia and paresis are common. Other potential signs include obscure lameness, focal muscle atrophy, and cranial nerve dysfunction. Approximately 75% of affected horses improve with treatment, but permanent neurologic deficits are possible and relapse is not rare.

Neosporosis (see p 663) is caused by *Neospora caninum*, a protozoan that can cause a nonsuppurative encephalomyelitis, most commonly in dogs. Infection in young puppies typically causes ascending paralysis with rigid contraction of the muscles of one or both pelvic limbs. Other organs, including muscle, liver, and lungs, can be affected. Diagnosis is based on detection of antibodies to the organism by immunohistochemistry or PCR. Early treatment with clindamycin or sulfadiazine and pyrimethamine may be effective, but the prognosis is poor.

Toxoplasmosis (see p 685) is caused by *Toxoplasma gondii* and can occasionally cause a nonsuppurative encephalomyelitis in puppies, kittens, and piglets. Diagnosis is based on identifying the organism in tissue or a 4-fold increase in IgG antibody in paired sera. In cats, a high concentration of IgM antibody in serum or CSF supports the diagnosis. Clindamycin or sulfadiazine and pyrimethamine are recommended for treatment.

Parasitic Diseases

Verminous myelitis is inflammation of the spinal cord caused by parasite migration. Organisms include *Parafilaria strongylus tenuis* in sheep, goats, and llamas; *Hypoderma bovis* in cattle; *Strongylus vulgaris*, *Halickephalobus delectrix*, and *Setaria* spp in horses; *Stephanurus dentatus* in pigs; *Cuterebra* spp in cats; and *Baylisascaris procyonis* in dogs. Signs of spinal cord involvement are usually acute, often asymmetric, and may be progressive. Antemortem diagnosis is difficult. Increased eosinophils in the CSF is suggestive, but CSF findings are variable. Treatment with fenbendazole, thiabendazole, or ivermectin is recommended, but the prognosis is guarded. (See also CNS DISEASES CAUSED BY HELMINTHS AND ARTHROPODS, p 1310.)

Idiopathic Inflammatory Diseases

Feline nonsuppurative meningoencephalomyelitis (feline polioencephalomyelitis, staggering disease) is a slowly progressive, inflammatory disease of the CNS in domestic cats. It has been reported in North

America, Europe, and Australia. The cause is unknown, but an infectious agent, probably a virus, is strongly suspected. The disease causes neuronal degeneration, axonal loss, and demyelination with mononuclear inflammation, most severe in the thoracic segments of the spinal cord. The clinical course is marked by progressive paraparesis of 1–2 mo duration, often with focal hyperesthesia, head tremor, and behavioral changes. Antemortem diagnosis is difficult. There is no treatment, and prognosis is poor.

Granulomatous meningoencephalomyelitis (GME) is an inflammatory disease of the CNS in dogs worldwide. The cause is unknown, although an infectious agent, most likely a virus, is suspected. In the disseminated form, previously called inflammatory reticulosis, there are perivascular accumulations of mononuclear cells and neutrophils. In the focal form, previously called neoplastic reticulosis, there are granulomatous lesions containing primarily reticulohistiocytic cells. Adult dogs of any breed can be affected, but female, small-breed dogs, especially Poodles, may be predisposed.

Clinical signs are variable and may indicate focal or multifocal brain or spinal cord dysfunction. Cervical pain and tetraparesis are the most common signs of spinal cord involvement. Signs are often acute, but the focal form of GME can cause neurologic deficits that slowly progress over the course of several months. The CSF usually has increased protein and pleocytosis, with either mononuclear cells or neutrophils predominating. MRI and CT often show a single or multiple enhancing masses. Tentative diagnosis is based on clinical findings, imaging, CSF analysis, and exclusion of other possible diseases. Dogs often improve with immunosuppressive doses of corticosteroids and other immunomodulating drugs such as cytarabine, cyclosporine, and procarbazine, but relapse is possible, and many dogs eventually become refractory to treatment.

NEOPLASIA

See also NEOPLASIA OF THE NERVOUS SYSTEM, p 1267.

In dogs, neoplasms commonly affecting the spinal cord include osteosarcoma, fibrosarcoma, meningioma, nerve sheath tumor, and metastatic neoplasia. A tumor resembling neuroblastoma is seen in young dogs (5–36 mo of age), with German Shepherds affected most commonly. This tumor is consistently located within the

Spinal meningioma, T13, in a dog. Note widening of the contrast column on the right ("golf-tee sign") indicating a mass within the subarachnoid space (myelogram). Courtesy of Dr. William Thomas.

dura mater between T10 and L2, causing progressive paraparesis. Diagnosis of spinal neoplasia is based on radiography, myelography, CT or MRI, and surgical biopsy. Surgical excision is possible in some cases, but in general, prognosis is poor.

In **cats**, lymphoma is the most common neoplasia to affect the spinal cord. Adult cats of any age can be affected. There is an acute or slowly progressive onset of signs referable to a focal, often painful, lesion of the spinal cord. Approximately 85% of affected cats have positive test results for feline leukemia virus (*see* p 790), and many have leukemic bone marrow. Myelography, CT, or MRI shows extradural compression. Treatment consists of combination

chemotherapy, such as prednisone, vincristine, and cyclophosphamide. Remission is possible in many cases, but long-term prognosis is poor.

In **cattle**, lymphosarcoma may develop in the epidural space at any level, causing spinal cord compression. Often, there is an acute onset of paraparesis or recumbency. Usually, there is other evidence of bovine leukosis (*see* p 743). Definitive diagnosis is based on histopathologic examination.

Neoplasia is a rare cause of spinal cord disease in horses, pigs, sheep, and goats.

NUTRITIONAL DISORDERS

Copper Deficiency: Deficiency of copper causes CNS disease in sheep, goats, and pigs. **Swayback** is the congenital form in lambs and is characterized by degeneration and necrosis of the cerebrum. The acquired form, **enzootic ataxia**, affects lambs, kids, and pigs. Affected animals appear normal at birth but develop progressive paraparesis with hyporeflexia and muscle atrophy within the first few months of life. Other signs include diarrhea and unthriftiness and, in lambs, abnormal fleece. Histologically, there is chromatolysis and loss of neurons and degeneration of axons, primarily in the spinal cord and caudal aspect of the brain stem. Animals may improve with copper supplementation, but permanent neurologic deficits are likely in severely affected animals.

Hypervitaminosis A: Cats fed excess vitamin A, usually from diets consisting largely of liver, develop extensive exostoses, most prominent in the cervical and thoracic spine. Clinical signs include neck pain and rigidity and forelimb lameness. Vertebral lesions are evident on radiographs. Reduction of dietary vitamin A prevents further exostosis but does not significantly reduce the lesions already present.

Thiamine Deficiency: Thiamine deficiency is most common in cats but has also been reported in dogs. Causes include inadequately formulated commercial diets, vegetarian diets, food preserved with sulfur dioxide (which destroys thiamine), and raw fish diets (which contain thiaminase). Affected cats typically exhibit brain dysfunction characterized by vestibular signs, head tremor, ataxia, depression, severe ventroflexion of the head, seizures, and death. Clinical signs in dogs include anorexia, depression, paraparesis, seizures, coma, and death. Pathologic findings are

polioencephalomalacia, most prominent in the midbrain. Diagnosis is based on clinical signs, dietary history, and response to thiamine administration (thiamine hydrochloride, 10–20 mg/day, IM, in cats; 25–50 mg/day, IM, in dogs).

TRAUMA

Acute spinal cord injuries are commonly associated with spinal fracture or luxation. Common causes in dogs and cats are automobile accidents, bite wounds, and gunshot wounds. Falls are common causes in horses. Cattle are susceptible to injuries from breeding. Pathologic fractures are common in cattle, sheep, and pigs with malnutrition or vertebral osteomyelitis. Damage to the spinal cord is caused not only by the primary mechanical injury but also as a result of secondary pathologic changes, including edema, hemorrhage, demyelination, and necrosis. These secondary changes are due to biochemical factors, including the release of free radicals, leukotrienes, and prostaglandins that cause further injury to nervous tissue and compromise blood flow to the spinal cord.

Signs of spinal trauma are typically acute and may progress in instances of unstable fractures or luxations. Severe thoracolumbar spinal cord injury may cause paraplegia with increased extensor tone in the thoracic limbs (**Schiff-Sherrington phenomenon**). Radiographs usually demonstrate vertebral fractures and luxations. However, in dogs with trauma, radiographs, compared with CT, reveal only ~75% of spinal fractures, so advanced imaging is indicated in animals with suspected spinal trauma and normal radiographs. Treatment with methylprednisolone may be helpful for animals with severe neurologic deficits if instituted within the first few hours of injury. One protocol is 30 mg/kg, IV, followed 2 hr later by 15 mg/kg, IV, followed 6 hr later by 15 mg/kg, IV, every 6 hr for a total of 24 hr of treatment. Dexamethasone is less effective and is associated with an increased risk of GI ulceration and pancreatitis. NSAIDs have minimal benefit in acute spinal cord injury and increase the risk of complications, especially if used in conjunction with corticosteroids. DMSO (0.5–1 g/kg/day of a 10%–20% solution, given slowly IV for 3 days) is recommended in horses with acute spinal cord injury. Animals with mild neurologic deficits often recover with 4–6 wk of cage or stall rest and analgesics. Surgical reduction and stabilization is indicated for unstable vertebral injuries causing severe neurologic

dysfunction. The prognosis is guarded for recumbent horses and cattle. In animals that have lost deep pain perception caudal to the lesion, the prognosis for return of neurologic function is poor.

TOXIC DISORDERS

Arsenic Poisoning: Poisoning can be seen in swine due to an overdose of organoarsenicals, which are often used as feed additives to promote growth and to control swine dysentery. With 3-nitro-4-hydroxyphenylarsonic acid ("3-nitro") poisoning, there is degeneration of the spinal cord, optic nerve, and peripheral nerves. Clinical signs consist of tremors and paraparesis. Mildly affected animals can recover after withdrawal of the offending feed. (See *also* ARSENIC POISONING, p 3071.)

Delayed Organophosphate Intoxication: Intoxication can be seen after oral or topical administration of organophosphate-containing insecticides or anthelmintics, including haloxon. In addition to the acute signs, delayed paralysis can develop 1–4 wk after exposure. Suffolk sheep have an inherited predisposition to this neurotoxicity, because they have low levels of plasma arylesterase activity. Affected animals have progressive, symmetric paraparesis and occasionally become tetraplegic. Diagnosis is based on clinical signs and history of exposure. On histopathologic examination, there is Wallerian degeneration, most prominent in the spinal cord and brain stem. The prognosis for severely affected animals is poor. (See *also* ORGANOPHOSPHATES (TOXICITY), p 3064.)

Sorghum Poisoning: *Sorghum* spp, such as Sorghum, Sudan, and Johnson grass, can cause degeneration of the spinal cord in horses and occasionally in cattle and sheep. The pathogenesis may be related to the high content of hydrocyanide in these grasses. There is ataxia and weakness of the pelvic limbs and incontinence. Urine retention often leads to cystitis and hematuria. Diagnosis is based on clinical features and a history of exposure. Signs may improve with removal of the offending feed, although persistent deficits are possible. (See *also* SORGHUM POISONING, p 3155.)

Tetanus: Tetanus (see p 611) is caused by toxins produced by the vegetative form of *Clostridium tetani*. Susceptibility varies markedly among species; dogs and cats are fairly resistant compared with horses. Clinical signs usually develop within

Fibrocartilagenous embolism in a dog, MRI. Note T2 hyperintensity (bright) within the spinal cord dorsal to the L3-4 disc space. Courtesy of Dr. William Thomas.

5–10 days of infection. These include localized or generalized muscle stiffness and extensor rigidity, dysphagia, protrusion of the third eyelid, and contracted masticatory (lockjaw) and facial (risus sardonicus) muscles. In severe cases, the animal may be recumbent with opisthotonos and reflex muscle spasms. Diagnosis is based on characteristic clinical features. Treatment consists of wound care, antibiotics to kill any remaining organisms, and tetanus antitoxin. In mild cases, prognosis is good with early treatment. In severe cases, death may occur due to respiratory paralysis.

VASCULAR DISEASES

Fibrocartilagenous Embolism: Infarction of the spinal cord can be caused by occlusion of spinal cord arteries or veins (or both) with fragments of fibrocartilage, believed to arise from the intervertebral

discs. It is seen primarily in adult dogs, especially large and giant breeds. Miniature Schnauzers and Shetland Sheepdogs also may be predisposed. It is rare in cats, horses, and pigs. Affected dogs have an abrupt onset of gait dysfunction, often occurring during activities such as running or jumping. Deficits are referable to a focal, often asymmetric, lesion in the spinal cord and rarely progress past 12 hr. Spinal pain is typically absent.

Diagnosis is based on clinical findings and MRI, which shows focal T2 hyperintensity within the spinal cord with no compressive lesion. In the acute stage, the CSF may have a mild increase in neutrophils and protein concentration. Mildly affected dogs often improve substantially within 1–2 wk. Prognosis is poor if deep pain perception is absent or if there is no improvement within several weeks.

Postanesthetic Hemorrhagic Myelopathy in Horses: Postanesthetic hemorrhagic myelopathy is a rare complication seen in horses positioned in dorsal recumbency under general anesthesia. The cause may be related to impaired venous drainage of the spinal cord due to compression of the caudal vena cava or azygous vein because of the weight of abdominal viscera. There is paraplegia immediately after recovery from anesthesia. Pathologic findings consist of hemorrhagic necrosis of the thoracolumbar spinal cord segments. The prognosis is poor. Positioning the horse slightly tilted off the perpendicular and maintaining adequate blood pressure may help prevent this complication.

DYSAUTONOMIA

FELINE DYSAUTONOMIA

Feline dysautonomia is characterized by widespread dysfunction of the autonomic nervous system. All breeds and age groups are susceptible, although the disease appears to be more common in younger cats. Feline dysautonomia was first reported in 1982 and initially became widespread in the UK (under the name Key-Gaskell syndrome). The incidence has declined considerably, but a few cases were recorded in Europe in the 1990s; sporadic

cases have been seen in Dubai, New Zealand, and Venezuela; and a few cases have been reported in the USA, in eastern Kansas and western Missouri. The etiology is unknown. Dysautonomias in horses, dogs, rabbits, and hares share striking similarities to the condition in cats.

Clinical Findings: Affected cats initially are anorectic and often have upper respiratory signs or transient diarrhea. The onset of more definite signs varies from peracute to chronic. Failure of the

autonomic system of the GI and urinary tracts can cause esophageal distention and/or dysfunction, gastric and bowel distention and hypomotility, and urinary bladder distention. Other common signs include dilated, nonresponsive pupils, ptosis, and third eyelid protrusion; a dry rhinarium; and reduced lacrimal secretion. In addition, dry oral mucous membranes, prolapse of the nictitating membrane, bradycardia, and urinary or fecal incontinence may be seen. These signs reflect both sympathetic and parasympathetic dysfunction, and there is a wide range in the severity of presenting signs. A dilated anus is sometimes noted, but the underlying somatic lesion is undetermined. Clinical pathology findings are nonspecific.

Lesions: Necropsy may show megaeosophagus, diphtheritic mucous membranes, an atonic bladder, and retention of fecal material. During the first few weeks after onset, chromatolysis and neuronal degeneration of pre- and postganglionic sympathetic and parasympathetic neurons is typical. A very specific distribution of chromatolytic autonomic and somatic lower motor neurons is found in the brain stem and spinal cord. The central lesions are identical to those found in the equivalent disease in horses, dogs, rabbits, and hares. Chronic cases can be difficult to confirm because surviving neurons appear normal, and diagnosis depends on an assessment of their numbers relative to surrounding stromal cells.

Diagnosis: Definitive diagnosis depends on histopathologic examination of autonomic ganglia. Clinical confirmation may be aided by contrast radiography (including fluoroscopy) of the esophagus and by reduced lacrimal secretion (<5 mm/min when measured by the Schirmer tear test). Pilocarpine (0.1%) applied to the cornea causes profound miosis within 10–15 min due to denervation hypersensitivity but has no effect on a healthy cat. Dilute (0.5%) phenylephrine reverses the ptosis and protruding third eyelid. Although feline leukemia virus (FeLV, see p 790) infection can cause both anisocoria and urinary incontinence, cats with dysautonomia usually show other clinical signs and are FeLV-negative.

Treatment and Prognosis: The main aim of therapy is first to rehydrate the cat and then to maintain adequate fluid balance. Total parenteral nutrition is useful initially but later can be replaced by gastrostomy or

nasogastric tube feeding when regurgitation resolves. Maintaining an upright posture after oral intake is important, because the main complication of this condition is inhalation pneumonia. Thrice daily evacuation of the bladder, provision of warmth, use of artificial tears and steam inhalation, and assistance with grooming are all important nursing considerations. Liquid paraffin PO is helpful for constipation but increases the risk of aspiration. Other parasympathomimetics, such as bethanechol (1–2.5 mg, PO, bid-tid), may be of use; however, their effect is crude, and overdose requires treatment with atropine. Metoclopramide (0.1 mg/kg, IV, or 0.3 mg/kg, SC, tid) may improve gastric emptying.

A small proportion of cats have recovered, and others are able to cope with residual autonomic deficits. Such improvements often require up to 1 yr. In general, the prognosis is poor for severely affected cats.

CANINE DYSAUTONOMIA

Canine dysautonomia is a degenerative polyneuropathy characterized by neuronal degeneration within the autonomic, somatic, central, peripheral, and/or enteric nervous system causing multisystemic effects similar, if not identical, to the dysautonomia in horses, cats, rabbits, and hares. Canine dysautonomia was first described in England in 1983, and there have been no new cases reported in the past decade. Although individual cases have been reported in Scotland, Norway, Belgium, Germany, and Greece, canine dysautonomia is less commonly reported in Europe than in the USA, with higher numbers primarily in the Midwest. In the USA, risk factors were reported to include a rural habitat and spending $>50\%$ of the time free outdoors.

Clinical Findings: The most consistent history and physical examination findings are acute-onset vomiting, diarrhea, mild obtundation, inappetence, reduced or absent anal tone, absence of pupillary light responses and lacrimal secretion, mydriasis, and protrusion of the nictitating membrane. Secondary effects of autonomic dysfunction, such as aspiration pneumonia and lethargy, may develop. Weight loss is often dramatic.

Laboratory findings are nonspecific. Pharmacologic testing of the pupils is probably the best single test for confirming the diagnosis. Dilute pilocarpine (0.05% ophthalmic solution) results in rapid

pupillary constriction in dogs with dysautonomia because of supersensitivity of the denervated muscle to cholinergic drugs. The prognosis is grave.

LEPORINE DYSAUTONOMIA

Leporine dysautonomia occurs in rabbits and wild hares, and fatal cases have been reported in the UK. Gross lesions are similar to those of equine dysautonomia, including gastric distention, colonic impaction, and weight loss. Histopathologic changes in the central and peripheral nervous systems are almost identical to those found in horses, cats, and dogs.

EQUINE DYSAUTONOMIA

(Grass sickness)

A fatal dysautonomia of unknown etiology, equine grass sickness causes marked reduction of GI motility due to widespread degeneration within the autonomic nervous system. It is seen throughout northern Europe, and a few cases have been diagnosed in the USA in the same geographic area (Midwest) that has a high prevalence of canine dysautonomia.

Grass sickness is seen at any age after weaning and at any time of year, but incidence is highest in spring and in horses 2–7 yr old. Although associated with recently acquired horses kept solely at grass, the condition has very rarely been seen in housed stock. All equidae appear susceptible. Acute, subacute, and chronic forms are recognized, categorized by whether death occurs within 24 hr, 7 days, and 1 wk, respectively. However, chronic cases can survive for weeks or months, and a few cases have recovered. The exact etiology is unknown, but the causal agent is thought to be associated with grazing. A *Clostridium botulinum* toxin may be involved.

Clinical Findings: Horses are afebrile and show tachycardia, ileus, and colic. Patchy sweating and fine muscular fasciculations are often seen over the shoulders and flanks, and penile prolapse may develop. Horses adopt a “tucked up” stance, similar to that seen in equine motor neuron disease (see p 1248). In contrast to feline dysautonomia, pupillary light reflexes and tear production are normal. Ptosis, with “droopy” eyelashes, tends to be prominent because of smooth muscle paresis. Rhinitis sicca (dry nose) commonly develops in chronic cases and is

considered to indicate a poor prognosis. Affected horses often have dysphagia and esophageal dysfunction, which cause drooling, difficulty passing a stomach tube, nasal reflux of gastric contents, and pooling of barium contrast in the thoracic esophagus. On rectal palpation, the mucosa is dry and tacky, and feces are scant and hard. Distended loops of small intestine and an impacted large colon are seen in the more acute cases. Secondary ileal dilation/impaction and displacement of the large colon can be confusing features. Cachexia can be profound in chronic cases.

Lesions: In acute cases, the stomach and small intestine are markedly distended with fluid (which can result in gastric rupture), and the large intestine is impacted. In chronic cases, the GI tract is usually empty. All forms may show linear ulceration of the esophagus and hard, tarry fecal balls. Neuronal degeneration of pre- and post-ganglionic sympathetic and parasympathetic neurons is characteristic. A specific distribution of chromatolytic autonomic and somatic lower motor neurons is found in the brain stem and spinal cord.

Diagnosis: No reliable in vivo diagnostic test is available, but dysphagia, tachycardia despite few signs of pain, decreased GI tract motility, a tucked-up stance (chronic cases), and ptosis are useful features. Administration of dilute (0.5%) phenylephrine to one eye should, within 20 min, result in marked decrease in ptosis (most easily seen as a decrease in the angle of the eyelashes to the head when viewed from the front). Biopsies of ileal and rectal tissue (1-cm long, formalin-fixed biopsies preferred) can confirm the diagnosis when examined by a pathologist experienced with grass sickness lesions. Postmortem confirmation of diagnosis depends on histopathologic examination of autonomic ganglia. The cranial cervical ganglia are the most accessible ganglia on postmortem examination and can be found in a fold of mucosal tissue in the caudal wall of the medial compartment of the guttural pouch.

Treatment: A proportion of mildly affected (chronic) cases can survive with dedicated nursing care; a wide variety of feeds should be offered to encourage feed intake. Acute and subacute cases have not survived and should be euthanized on humane grounds. Stabling at-risk stock for part of the day has been recommended.

FACIAL PARALYSIS

Asymmetry of facial expression is common with unilateral lesions of the facial nucleus or nerve in most species. Bilateral facial paralysis may be more difficult to recognize, but affected animals drool and have a dull facial expression. Complete facial paralysis is an inability to move the eyelids, ears, lips, or nostrils. Facial paresis is reduced movement of the muscles of facial expression and indicates milder nucleus or nerve involvement. The nucleus of the facial nerve is located in the rostral medulla oblongata of the brain stem. The facial nerve, cranial nerve VII, exits the brain stem near the vestibulocochlear nerve, passes through the petrous temporal bone, and then exits the skull through the stylomastoid foramen and splits into auricular, palpebral, and buccal branches.

Clinical Findings and Lesions: Clinical signs of facial paralysis vary with the location, severity, and chronicity of the lesion. If a unilateral lesion is located in the facial nucleus or proximal portion of the facial nerve, paresis or paralysis of the eyelids, ears, lips, and nostrils on that side are seen. A lesion of the auriculopalpebral branch of the facial nerve, near the zygomatic arch, results in paresis or paralysis of the eyelids and ear only. A lesion of the palpebral branch of the facial nerve, crossing the zygomatic arch, results in paresis or paralysis of the eyelids only. A lesion of the buccal branch of the facial nerve, as it courses along the surface of the masseter muscles, results in paresis or paralysis of the lips and nostrils only.

In small animals with facial paralysis, the palpebral fissure may be slightly larger on the affected side; in horses and food animals, the palpebral fissure is slightly smaller because of a loss of tone in the frontalis muscles above the eyelid. When the medial or lateral canthus of the eyelids or cornea are touched, the eyelids do not close, but the eyeball will retract into the orbit (if the trigeminal and abducent nerves are functioning properly). The third eyelid will passively elevate as the globe retracts. If both eyes are tested simultaneously, movement on each side can be compared. When the animal is unable to blink the eye, corneal irritation may result in excessive tear production. In acute denervation, the ear carriage is often lower on the side of the lesion in all species, but in chronic denervation with muscle fibrosis and

contracture, the ear carriage may be higher. The fibrosis of the auricular muscles can be palpated, and the ear becomes adhered in the abnormal position. In acute lesions, the lips on the paralyzed side may hang loosely, exposing mucosa. When the animal eats or drinks, food and fluids may fall from the lips. The animal may drool excessively, and food may collect between the lips and teeth. In chronic lesions, fibrosis of the lip muscles can be palpated, and the lip on the affected side is higher than on the normal side. In acute, unilateral lesions, the nose deviates away from the side of the lesion, owing to a loss in muscle tone on the affected side. In horses, the affected nostril is unable to dilate on inspiration. In chronic lesions, muscle fibrosis and contracture cause the nose to deviate toward the lesion, and the muscles feel firm and inflexible. Because the facial nerve provides sensory innervation to the distal tongue, a bitter substance such as atropine will not be recognized when placed on the distal tongue.

Often, the parasympathetic portion of the facial nerve is also affected, and tear and saliva production on the side of the lesion is reduced or absent. Reduced or absent tear production, with eyelid paresis or paralysis, can result in corneal exposure with resultant ulceration. In cases of facial nerve paralysis, a Schirmer tear test can be used to determine whether administration of artificial tears is needed. Reduced saliva production can result in dry mucous membranes, and food may collect in the buccal folds. Dryness on the side of the lesion can be detected by simultaneously palpating the mucous membranes on both sides and comparing the degree of moisture.

Other concomitant neurologic deficits can further localize the facial nerve lesion. If the animal has ataxia, hemiparesis, quadriparesis, or conscious proprioceptive deficits associated with facial nerve paralysis, a brain-stem lesion is probable. If the animal has facial paralysis with a head tilt, nystagmus, or other evidence of vestibular deficits, but no hemiparesis, quadriparesis, or conscious proprioceptive deficits, then a lesion of the facial nerve exists as it exits the brain stem or passes through the petrous temporal bone. If a small animal has facial paralysis with ptosis, miosis, and enophthalmos (Horner syndrome), a lesion of the middle ear is likely.

Diagnosis and Treatment: Trauma is a common cause of facial paralysis in all species. In horses, halter injuries and prolonged lateral recumbency may injure the buccal branches of the facial nerve on the side of the jaw and cause unilateral or bilateral paresis or paralysis of the lips and nostrils. Cattle that struggle in stanchions may injure the palpebral branch of the facial nerve as it crosses the zygomatic arch, causing unilateral or bilateral paresis or paralysis of the eyelid(s). Small animals may incur peripheral facial nerve injuries from rough handling, automobile accidents, or surgery such as bulla osteotomy and total ear ablation. Electromyography, including electrical stimulation of the facial nerve, can be used to determine the location and severity of the injury; however, changes will not be evident until 5–7 days after injury.

Therapy for injury may include massage and heat of denervated muscles for 15 min, 2–3 times/day, to maintain their integrity while awaiting any nerve regeneration. Laser therapy, also known as cold laser, low level light therapy, or photobiomodulation, can help nerve regeneration. The facial nerve can regenerate ~1–4 nm/day, so serial neurologic examinations can also help determine the prognosis. If there has been no improvement after 6 mo, the chance of recovery is poor. Horses with collapsing nostrils may require corrective surgery. Species that need the lips for drinking and prehending food must be given deep water containers and wet bulky mashes.

Otitis media is another common cause of facial paralysis in all species, especially in dogs with chronic dermatitis. Otitis externa and a ruptured or diseased tympanic membrane are often seen on otoscopic examination under general anesthesia. Despite an intact tympanum, 16% of animals with acute otitis externa may have otitis media, and as many as 89% of animals with chronic otitis externa may have otitis media (See also OTITIS EXTERNA, p 527, and OTITIS MEDIA AND INTERNA, p 531). Skull radiographs, CT, and MRI may be necessary to confirm otitis media. The prognosis can be good if the diagnosis is made early and the animal is treated for 4–6 wk with

the appropriate antibiotic, determined by culture and sensitivity on a sample obtained via myringotomy. Corticosteroids should be avoided because they may encourage osteomyelitis. The facial nerve paralysis can be permanent, and longterm administration of artificial tears may be necessary.

Guttural pouch infections (see p 1463) can produce facial paralysis in horses. Lesions of the facial nerve nucleus can result in facial nerve paralysis in equine protozoal myeloencephalitis (EPM, see p 1309). CSF analysis and titers for EPM are essential for diagnosis and institution of appropriate therapy.

Idiopathic facial nerve paralysis is common in dogs and is diagnosed by excluding other diseases. Otitis media must be excluded with examination and radiographs. Because hypothyroidism (see p 553) can cause facial nerve paralysis, levels of thyroxine (T_4) and thyroid-stimulating hormone should be determined in all dogs with facial paralysis. Thyroid replacement therapy may not always resolve facial paralysis in hypothyroid dogs. If there is no infection, thyroid function is normal, and there has been no known trauma, the diagnosis of idiopathic facial paralysis is made. There is no therapy. Artificial tear administration may be necessary. Facial paralysis can be unilateral or bilateral and can resolve spontaneously or be permanent. It can occur on one side, resolve, and then occur on the other side at a later time. Permanent paralysis may be disfiguring but does not affect the quality of life in dogs.

Primary neoplasia of the facial nerve is rare, but dogs and cats can develop a neoplastic process that affects middle ear structures, including the facial nerve. Squamous cell carcinoma and polyps of the middle ear are most common in cats. Otoscopy of the external ear canal under anesthesia with biopsy and histologic examination of abnormal tissue can assist with the diagnosis. CT and MRI of the osseous bulla are necessary to determine the extent of the lesion before surgery. Early radical excision of the tumor and radiation, if indicated, may afford a good longterm prognosis depending on tumor type.

LIMB PARALYSIS

Paralysis of one limb is referred to as monoplegia and is most often associated with diseases of the peripheral spinal nerves. Paralysis of the thoracic limb is usually

associated with a lesion of the C6 to T2 nerve roots, the brachial plexus, or musculocutaneous, radial, median, or ulnar nerves. Paralysis of the pelvic limb is usually

associated with a lesion of the L4 to S2 nerve roots, the lumbosacral plexus, or femoral, sciatic, peroneal (fibular), or tibial nerves.

Clinical Findings and Lesions: Evaluation of the posture and gait, spinal reflexes, superficial and deep nociception, and muscle mass of the affected limb can localize the lesion to the nerve roots or plexus or to a specific nerve branch. Determining the exact location of the lesion is important for an accurate prognosis because the closer a nerve injury is to the muscle to be reinnervated, the better the prognosis for recovery. In general, nerve root or plexus lesions have a poorer prognosis than do peripheral nerve lesions.

Muscle atrophy from denervation develops within a few days and is faster to develop and more severe than disuse atrophy. With disease of the suprascapular nerve, the supraspinatus and infraspinatus muscles are atrophied; generally, little gait deficit is noted in small animals. However, in horses, the shoulder drops ventrally and rotates laterally, and the hoof may scuff or drag the ground slightly. If the musculocutaneous nerve is affected, the animal is unable to flex the elbow, and the biceps muscle is atrophied. With radial nerve disease, the elbow is dropped, the digits are knuckled onto their dorsal surface, and the limb is unable to bear weight. The thoracic limb flexor reflex (withdrawal reflex) is depressed or absent with lesions of the radial nerve (sensory portion), axillary nerve (shoulder flexion), musculocutaneous nerve (elbow flexion), or median and ulnar (carpal and digit flexion) nerves. The triceps and extensor carpi muscles may also atrophy in radial nerve disease. Superficial and deep digital flexor muscles atrophy with lesions of the median and ulnar nerves. There is little gait abnormality with ulnar nerve injury.

Superficial sensation is tested by observing a behavioral response (such as looking, wincing, crying, or biting) when the skin is pinched with hemostatic forceps or pricked with a needle. Regions of skin sensation associated with specific nerves are less distinct in equine and food animal species than in small animals. A loss of sensation on the rostral skin surface of the thoracic limb from the elbows to the paws indicates radial nerve disease. The skin of the caudal aspect of the limb, from the elbow to the pads, is desensitized in median and ulnar nerve disease, and the skin of the lateral aspect of the antebrachium and paw is desensitized with damage to the ulnar nerve.

Deep pain is tested by applying hemostatic forceps to the bones of the digits or hoof testers to the hoof and observing a behavioral response. The presence of deep pain from the fifth digit in small animals indicates integrity of the ulnar nerve. The presence of deep pain from the other digits of the thoracic limb indicates integrity of the radial and median nerves.

The eye on the side of the thoracic limb paralysis will show Horner syndrome (ptosis, miosis, and enophthalmos) when the lesion involves the T1 to T2 nerve roots as they exit the spinal cord. Horner syndrome is manifest in horses by ocular changes and ipsilateral sweating of the face and neck and in cattle by ocular changes and a unilateral loss of moisture on the muzzle.

Inability to extend the stifle to support weight in the pelvic limb is seen with L4 to L5 nerve root or femoral nerve disease; the patellar reflex is reduced or absent, the quadriceps muscle is atrophied, and sensation of the skin is reduced or absent on the medial surface of the limb. Inability to actively flex the stifle, hock, and digits or to extend the hock and digits is seen with lesions of the sciatic nerve, L6 to S2 nerve roots. The animal will support some weight if the femoral nerve is spared but will stand knuckled on the dorsum of the paw or hoof with the hock excessively flexed. If only the peroneal branch of the sciatic nerve is affected, the hock will be overextended and the digits knuckled. If only the tibial branch of the sciatic nerve is affected, the hock will be overflexed and the digits overextended. The prognosis for tibial or peroneal nerve lesions may be better than that for sciatic lesions, so differentiation is important.

The pelvic limb flexor reflex is diminished or absent with sciatic nerve lesions. The gastrocnemius reflex is diminished or absent with lesions of the sciatic or tibial nerve. The cranial tibial muscle reflex is diminished or absent with lesions of the sciatic or peroneal nerve. The distribution of denervation muscle atrophy can indicate whether the sciatic or only one of its branches is involved. Atrophy of gluteal, semimembranosus, semitendinosus, and all muscles below the stifle indicates a lesion of the L6 to S2 nerve roots as they exit the spinal cord. If the gluteal muscles are normal but the others are atrophied, then a lesion of the sciatic nerve is located at the sciatic notch or the proximal two-thirds of the femur. Atrophy of the cranial tibial or gastrocnemius muscles alone indicates a lesion of the peroneal or tibial nerve, respectively. If superficial sensation is

reduced or absent on the cranial and caudal aspects of the limb and in the perineal region on the same side, then a lesion of the L6 to S2 nerve roots is likely. With peroneal nerve lesions, superficial sensation on the cranial surface of the hock and tibia and on the dorsal aspect of the foot is reduced or absent. With tibial nerve lesions, superficial sensation of the caudal surface of the hock and tibia and plantar surface of the paw is reduced or absent. Sciatic nerve lesions cause a loss of superficial sensation in the cranial, caudal, dorsal, and plantar regions. A loss of deep pain may be associated with sciatic nerve lesions. Preservation of sensation on the medial aspect of the pelvic limb is attributable to preservation of the saphenous nerve.

Electromyography can be used 7–10 days after a nerve insult to detect denervation in muscles and to outline the distribution of the nerve lesion. Denervation of limb and paravertebral muscles indicates nerve root lesions. Denervation of a specific muscle group indicates a lesion in its respective nerve. Electrical stimulation of the nerve can be used to determine nerve integrity. If some nerve integrity is present, the prognosis is better if motor nerve conduction velocity is normal than if it is slowed.

Diagnosis and Treatment: Trauma is the most common cause of acute monoplegia. Traumatic loss of nerve function may be due to neurapraxia, axonotmesis, axonostenosis, or neurotmesis. **Neurapraxia** is a temporary nerve conduction dysfunction that can last several weeks, but recovery is complete. **Axonotmesis** is rupture of some axons within the nerve but with an intact nerve sheath. Most closed nerve injuries from stretch or compression are a combination of neurapraxia and axonotmesis. Ruptured axons regenerate 1–4 mm/day, but functional recovery depends on the integrity and diameter of the nerve sheath and on the distance between injury and reinnervation sites. Nerves injured >180 mm from their respective muscles may be unable to make anatomic contact. If anatomic contact is made, the nerve sheath contracture, which develops over time, may not leave enough room to develop sufficient myelin to conduct an effective electrical impulse. **Axonostenosis**, or narrowed nerve sheaths with reduced nerve function, may be a sequela of nerve injuries. **Neurotmesis** is total nerve rupture, and surgical reattachment is required for regeneration. If no nerve function is found on the initial neurologic examination, neurapraxia, axonotmesis, and neurotmesis can be difficult to differentiate.

Electrical stimulation of a nerve with neurapraxia is usually normal, and the prognosis is good, regardless of the findings of the initial neurologic examination. If the affected nerve does not respond to electrical stimulation distal to the site of the lesion ≥ 3 days after injury, the prognosis for recovery is guarded. Serial neurologic examinations throughout a 6-mo period are necessary if electromyographic evaluation is not performed.

Injury to the **brachial plexus** or the C6 to T2 nerve roots is common in most species due to direct shoulder trauma or abnormal shoulder abduction (eg, in small animals hit by automobiles). Horses and cattle cast on hard surfaces for foot or other surgeries may develop a brachial plexus injury. If Horner syndrome is present on the same side as a thoracic limb that has lost sensation and is areflexic and paralyzed, a brachial plexus avulsion is likely, and the prognosis for recovery grave. With brachial plexus avulsion, the nerve roots are torn from the spinal cord and cannot be repaired. If there is also no response to radial nerve stimulation, recovery is hopeless. If the limb drags on the ground, it can be held up with a neck sling or amputated in small animals to avoid laceration of the dorsal surface of the paw. Three-legged dogs and cats generally have a good quality of life. If no Horner syndrome is present with thoracic limb paralysis, the prognosis for recovery may be better.

Lumbosacral plexus injuries are less common than brachial plexus injuries but can be associated with automobile accidents or extreme limb abduction. Fractures of long bones can injure peripheral nerves locally. Surgical intervention for pelvic and hip disease and injection injuries are common causes of sciatic nerve injuries. Sustained pressure on the lateral aspect of the stifle can cause peroneal nerve injury. Heat application, massage, and stretching of tendons should be performed for 15 min 2–3 times/day to keep muscles, tendons, and joints healthy while the nerve is regenerating. A light bandage may prevent damage to the foot from dragging, but reduction of circulation should be avoided. No specific therapy is currently available to assist nerve regeneration, but recent studies with laser therapy, also known as cold laser, low level light therapy, or photobiomodulation, has shown some promise in assisting nerve regrowth. In traumatic injuries with accompanying swelling, small animals may be given NSAIDs or a short course of anti-inflammatory oral prednisone at 0.5 mg/kg/day for 5–7 days. This will help reduce edema, which can compromise

circulation to the nerve. NSAIDs and corticosteroids should not be used concurrently. NSAIDs can be given to horses to reduce edema. If voluntary movement, nociception, and spinal reflexes improve within 1–2 mo, the prognosis is good. Limb mutilation can be transient in recovering nerve injuries and may be prevented by temporary use of an elizabethan collar. If nerve injury is suspected to be permanent and the animal is mutilating the limb, amputation is recommended in small animals. Enough time should be allowed to pass for possible regeneration of the nerve, typically 3–6 mo, before amputation.

Neoplasia of nerve roots and peripheral nerves can cause a chronic, progressive, often painful paresis of a thoracic or pelvic limb. (See also NEOPLASIA OF THE PERIPHERAL NERVES AND NEUROMUSCULAR JUNCTION, p 1242, and NEOPLASIA OF THE NERVOUS SYSTEM, p 1267.) Nerve sheath tumors are common in dogs. Lymphosarcoma of the brachial or lumbosacral

plexus is seen in dogs, cattle, and cats. If the nerve roots within the spinal canal are affected, an extramedullary mass may be visualized with a myelogram, CT, or MRI in dogs and cats. Surgical exploration and removal or biopsy are essential to determine diagnosis or prognosis. The long-term prognosis for nerve sheath tumors is poor, even after attempted surgical removal and limb amputation. Nerve sheath tumors often affect multiple nerve roots, and the tumor is difficult to completely remove. If appropriate chemotherapy is instituted for lymphosarcoma, the length and quality of life may be improved. Chemotherapy is not very helpful to treat nerve sheath tumors, but radiation therapy may have some benefit.

Horses with equine protozoal myeloencephalitis (EPM, see p 1309) may develop monoparesis and focal muscle atrophy. CSF analysis and CSF and serum EPM titers should be evaluated so appropriate therapy can be administered.

MENINGITIS, ENCEPHALITIS, AND ENCEPHALOMYELITIS

Inflammation of the meninges (meningitis) and inflammation of the brain (encephalitis) are seen in animals and often manifest concurrently (meningoencephalitis). Many of the inflammatory diseases of the CNS of animals are diffuse, involving both the brain and spinal cord (encephalomyelitis and meningoencephalomyelitis). Because many inflammatory processes are disseminated throughout the CNS at the time of clinical observation, differentiation between meningeal-only inflammation vs extension of disease into the neuropil is often difficult to make antemortem. Thus, from a clinical standpoint, any one of these conditions may be the case in an animal with an inflammatory condition of the CNS.

In animals with meningoencephalitis or meningoencephalomyelitis, the clinical signs of meningitis often precede those of encephalitis and may remain the predominant feature of the illness. This is especially apparent in meningitis involving neonates. Causes of meningitis, encephalitis, and meningoencephalitis include bacteria, viruses, fungi, protozoa, rickettsia, parasite migrations, chemical agents, and idiopathic or immune-mediated diseases. In ruminants, generally bacterial infections are more common than

other causes of meningitis or encephalitis. In species other than ruminants, especially adult animals, viruses, protozoa, rickettsia, and fungi are as or more frequent causes of meningitis or encephalitis than are bacteria. The appearance of many etiologic agents such as arboviruses, certain rickettsia, and bacteria are seasonal. Age is an important consideration for bacterial meningitis associated with neonatal sepsis. Even within species (eg, production animals), there can be a difference in risk factors. For instance, sporadic bovine encephalomyelitis (see p 1308), caused by *Chlamydia pecorum*, and thromboembolic meningoencephalitis (see p 754), caused by *Histophilus somni*, usually occur in feeder beef cattle (6 mo to 2 yr old) and not replacement dairy calves unless managed on feedlots. Vaccine history is also an essential factor in consideration of differential diagnoses in animals with clinical signs of inflammation of the CNS, especially those caused by viruses.

Etiology and Pathogenesis: The incidence of meningitis, encephalitis, and encephalomyelitis is fairly low compared with that of infections of other organs. However, with the recent global expansion

of the flaviviruses and tickborne *Anaplasma phagocytophilum* and other vectorborne diseases, the incidence and risk of infectious brain and spinal cord infections of animals has likely increased.

Bacterial Infections: When bacterial infections occur, they are more likely to be sporadic than epidemic. The risk of hematogenously disseminated CNS infections is likely to be low in adult animals because of the blood-brain barrier. Many infections of the nervous system are the result of some injury to its protective barriers. In all species, direct extension of bacterial or mycotic infections into the CNS can develop from sinusitis, otitis media or interna, vertebral osteomyelitis, or discospondylitis. In calves with *Mycoplasma bovis* otitis, meningitis can occur. Infections can also be secondary to migrating grass awns or other foreign bodies, deep bite wounds, or traumatic injuries adjacent to the head or spine; this is common in hunting dogs. Iatrogenic infections are possible from diagnostic and surgical procedures.

Brain abscesses also can arise from direct infections or by septic embolism of cerebral vessels. Pituitary abscesses in ruminants are thought to originate from bacterial invasion of the rete mirabile (intracranial carotid mirabile) surrounding the pituitary gland. In chronic brain abscesses, an adjacent or occasionally diffuse fibrinous leptomeningitis may develop. *Streptococcus equi equi* is one of the most common causes of brain abscessation in horses, and *Rhodococcus equi* abscesses have been described in foals, both of which are secondary to primary infection of lymph or other tissues.

Spontaneous bacterial meningitis or meningoencephalitis develops in dogs rarely, occurs more commonly in food animals, and is most common in septic neonatal animals. Various aerobic bacteria (*Pasteurella multocida*, *Staphylococcus* spp, *Escherichia coli*, *Streptococcus* spp, *Actinomyces* spp, and *Nocardia* spp) and anaerobic bacteria (*Bacteroides* spp, *Peptostreptococcus anaerobius*, *Fusobacterium* spp, *Eubacterium* spp, and *Propionibacterium* spp) have been isolated from animal infections. Bacterial endocarditis with associated septicemia is important in the etiopathogenesis of CNS infection in adult dogs. In Lyme endemic areas, neurologic infection in dogs with *Borrelia burgdorferi* has been implicated. Other non-neonatal hematogenously derived infections are well-recognized disease entities, such as thromboembolic meningoencephalitis of cattle (*Histophilus somni*, see p 754), Glässer's

disease of pigs (*Haemophilus parasuis*, see p 720), and *Haemophilus agni* septicemia in feeder lambs.

Streptococcus suis causes suppurative meningitis of pigs in addition to other syndromes such as pleuritis, epicarditis, and arthritis. (See also STREPTOCOCCAL INFECTIONS IN PIGS, p 731.) Several species of *Mycoplasma* cause nonseptic encephalitis in their natural hosts such as goats (*M. mycoides*), poultry (*M. gallisepticum*), cats (*M. felis*), dogs (*M. edwardii*), and rodents (*M. pulmonis*). Outbreaks of *C. pecorum* occur in yearling cattle and cause spontaneous encephalomyelitis with polyserositis and peritonitis. Bacterial meningoencephalitis often affects neonatal animals as a sequela of gram-negative septicemia. Members of the Enterobacteriaceae (*E. coli*, *Salmonella* spp, and *Klebsiella pneumoniae*) are the most commonly isolated pathogens, as well as streptococci (commonly *Enterococcus* spp). *Actinobacillus equuli* infection is an important cause of meningoencephalitis in foals. Failure of passive transfer of immunoglobulins is the single most important factor predisposing neonates to omphalophlebitis or enteritis, with subsequent hematogenous spread of the infection to the CNS. *Elizabethkingia* (formerly *Chryseobacterium*) *meningosepticum* is a bacterium that can cause meningitis in newborn and immunocompromised people and animals.

Listeriosis (see p 2839), which is caused by *Listeria monocytogenes* and is a common infection in cattle, sheep, and goats and less common in horses, is an example of a multifocal brain stem meningoencephalitis that ascends to the CNS via transaxonal migration in cranial nerves. *Mannheimia haemolytica* and *Pasteurella multocida*, although usually resulting in fibrinous pneumonia and hemorrhagic septicemia in ruminants, occasionally produce a localized fibrinopurulent leptomeningitis. Meningoencephalitis due to *M. haemolytica* has also been reported in horses, donkeys, and mules. *Actinomyces*, *Klebsiella*, and *Streptococcus* spp are sporadic causes of meningitis in adult horses.

Viral Infections: Viruses commonly cause nonsuppurative meningitis, encephalitis, and encephalomyelitis. Several viruses are specifically neurotropic or exhibit predilection for the CNS, causing a fulminate or fatal encephalitis, the most notorious being rabies virus infection (see p 1302). Although rabies viruses primarily spread to the CNS transaxonally, several other common DNA (adenoviruses, herpesviruses, parvoviruses) and RNA

(bunyavirus, lentiviruses, morbilliviruses, alphaviruses, flaviviruses) viruses are likely spread via the bloodstream but exhibit high neuropathogenesis once within the CNS. Both hematogenous and transaxonal routes of spread are thought to occur in flavivirus infections. Recently, minute viruses (Parvoviridae) have been implicated in dogs and nonhuman primates, respectively. Reoviruses cause encephalitis in mice and nonhuman primates. Colorado tick virus, a Coltivirus, has been implicated in infections in domestic species. Most animals have viral species-specific infections that exhibit predilection for the CNS. Rarely, a postvaccination encephalomyelitis in dogs is associated with immunizations against canine distemper virus, rabies virus, and canine coronavirus-parvovirus vaccines. Herpesviruses cause encephalomyelitis syndromes in each of their respective hosts.

Infections Caused by Parasites: Many parasitic agents can cause meningoencephalitis in both large and small animals. Neuropathogenic protozoa include *Toxoplasma gondii*, *Neospora caninum*, and *Encephalitozoon cuniculi* in dogs and cats. *E. cuniculi* can cause encephalomyelitis in rabbits. *Sarcocystis neurona* and *N. hughesii* are important causes in horses, with *Trypanosoma* spp important in equids outside of the USA. A wide variety of protozoa can infect and cause severe CNS disease in adult cattle, including *Babesia bovis*, *Theileria parva* (theileriosis), and *Trypanosoma* spp, whereas *N. caninum* and *T. gondii* can cause congenital encephalitis in calves. Free-living amoebae, *Naegleria fowleri*, *Acanthamoeba* spp, and *Balamuthia mandrillaris* are associated with amoebic meningoencephalitis in dogs.

Aseptic suppurative or eosinophilic meningoencephalitis associated with aberrant migration of parasites throughout the CNS can develop in a number of animal hosts. In dogs and cats, CNS infections have been reported with *Dirofilaria immitis*, *Toxocara canis*, *Ancylostoma caninum*, *Cuterebra* spp larva, and *Taenia* spp. A wide variety of nematodes have been reported to cause severe meningoencephalitis in horses, including *Setaria* spp, *Habronema* spp, *Strongylus* spp, *Halicephalobus gingivalis*, and *Angiostrongylus cantonensis* (the rat lungworm). In cattle, migrating *Setaria* and *Hypoderma* larva are commonly implicated. Recently, *A. cantonensis* has been identified as a cause of eosinophilic meningoencephalitis in nonhuman primates. *Parelaphostrongylus tenuis* is especially important in goats and llamas.

Fungal Infections: Pathogenic fungi, including *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Histoplasma capsulatum*, can cause meningoencephalitis. Opportunistic invasion with *Cryptococcus neoformans* and *Aspergillus* spp has also been described in several mammalian species. Rarely, other fungi, such as *Candida* spp, *Cladosporium trichoides*, *Paecilomyces variotii*, *Geotrichum candidum*, and dematiaceous fungi (*Bipolaris* sp and *Alternaria* spp) cause meningoencephalitis. Unicellular plants, *Prototheca wickerhamii* and *P. zopfii*, can also produce an eosinophilic meningoencephalomyelitis in dogs, cattle, and horses.

Idiopathic/Immune Mediated: Several idiopathic meningoencephalitis are recognized in dogs. Granulomatous meningoencephalomyelitis (see p 1252) is a relatively common CNS disease of dogs that most often affects young to middle-aged, small-breed females. A pyogranulomatous meningoencephalomyelitis has been seen in mature Pointer dogs. This acute, rapidly progressive disorder is characterized by extensive mononuclear cells and neutrophils infiltrating the leptomeninges and parenchyma, especially in the cervical spinal cord and brain stem. A necrotizing meningoencephalitis of unknown etiology has been reported in young, adult Pug dogs, as well as in Yorkshire Terriers and Maltese dogs. A steroid-responsive suppurative meningitis affecting mainly young (<2 yr), large-breed dogs and a severe necrotizing vasculitis and meningitis syndrome has been documented in Beagles, Bernese Mountain Dogs, and German Shorthaired Pointers, and both have been identified as possible immunologic disorders with a hereditary predisposition. (See also CONGENITAL AND INHERITED ANOMALIES OF THE NERVOUS SYSTEM, p 1222.) An eosinophilic meningoencephalitis that has been described in adult dogs (Golden Retrievers, Rottweilers, and South African Boerboels) and cats is also believed to have an immunologic basis.

Clinical Findings: In the early stages of inflammatory diseases of the CNS, nonlocalizing clinical signs are frequent. In dogs, for example, meningitis can easily be mistaken for intervertebral disc extrusion, polyarthritis, pleuritis, pancreatitis, or pyelonephritis. In horses, initial clinical signs can appear as lameness, myositis, vertebral instability, or even colic. In foals, extreme hyperexcitability and irritability can be an early indication of sepsis in the

CNS. Cattle can demonstrate anorexia, depression, and bizarre behavior.

The usual signs of meningitis are fever, hyperesthesia, neck rigidity, and painful paraspinal muscle spasms. Dogs and occasionally horses display this syndrome acutely and sometimes chronically without clinical signs of brain or spinal cord involvement. However, in diffuse meningoencephalitis due to any agent, depression, blindness, progressive paresis, cerebellar or vestibular ataxia, opisthotonos, cranial nerve deficits, seizures, dementia, agitation, and depressed consciousness (including coma) can develop, depending on the rapidity of onset, pathology, and location of the lesions. Visual deficits, neck pain, seizures, behavioral disturbances, ataxia, weakness, cranial nerve deficits, and depression may be seen in either focal or disseminated CNS disease.

In neonatal infections, omphalophlebitis, polyarthritis, and ophthalmitis with hypopyon can accompany the CNS inflammation. Because of its unusual pathogenesis, listeriosis often causes asymmetric vestibular dysfunction, with head tilt and circling, in addition to other cranial nerve deficits such as facial and pharyngeal paralysis. In histophilosis of cattle, the nervous signs tend to be peracute, with sudden collapse and profound depression of consciousness (stupor or coma); fever and limb stiffness may be the only signs detectable in the prodromal stages. In sporadic bovine encephalomyelitis, calves demonstrate incoordination that can progress to recumbency and opisthotonos.

Lesions: Gross lesions are extremely variable depending on cause and location and whether the disease is diffuse or multifocal. Pathologic changes characteristic of meningitis include diffuse infiltration of leukocytes into the leptomeninges. This can be mild if flaviviral, or florid if granulomatous (thickened) or alphaviral (hemorrhagic). Frequently, the entire subarachnoid space of the brain and spinal cord is inflamed. Vasculitis of meningeal vessels and CNS arterioles may also be apparent. In meningoencephalitis, the inflammation extends into the CNS parenchyma, resulting in leukocyte infiltration with large areas of perivascular cuffing. Necrosis and malacia of the CNS may be seen, with infiltrations of macrophages, neutrophils, and plasma cells. Grossly, this is seen as local areas of discoloration. Listeriosis uniquely causes microabscesses deep within the CNS parenchyma, which consist of accumulations of neutrophils and microglial cell reaction with central liquefactive necrosis.

Diagnosis: Often, there are no related changes in a CBC or serum biochemical profile to indicate CNS infection. The analysis of CSF is the most reliable and accurate means to identify an encephalitis, meningitis, or meningoencephalitis. CSF should be collected whenever history, species, or breed predisposition suggests meningitis or encephalitis, or whenever clinical signs indicate a disseminated or multifocal CNS disorder. Without CSF analysis, an animal exhibiting back or neck pain with an increase in rectal temperature may be misdiagnosed.

Adult large animals and dogs with bacterial meningitis and encephalitis or with steroid-responsive suppurative meningitis typically have a marked neutrophilic pleocytosis in the CSF, with cell counts in the hundreds to thousands. The protein content of the CSF is usually also significantly increased (>100 mg/dL), with an increase in the globulin component of CSF.

Rickettsial infections most often cause a mild to moderate mononuclear pleocytosis, although Rocky Mountain spotted fever can cause neutrophilic inflammation secondary to vasculitis.

In foals with meningitis, the CSF has an increased protein content, and even slight increases in WBCs in the CSF are significant (>10 WBC/ μ L). Any neutrophils observed on cytology in CSF from a foal warrant treatment with antimicrobials that can obtain high therapeutic levels in the CNS.

Viral infections and listeriosis typically produce a mild to moderate mononuclear pleocytosis in CSF, with an associated increase in protein levels. However, the CSF is normal in rabies virus infections. Herpesvirus infections cause markedly increased proteins and xanthochromia (yellow to reddish discoloration) without dramatic increase in cell count. Feline infectious peritonitis (FIP) in cats and Eastern equine encephalitis in horses are exceptions and can cause markedly high neutrophil counts. In FIP, a markedly high protein concentration (>200 mg/dL) can also be seen.

Parasitic and fungal meningoencephalitis cause eosinophilic or occasionally a highly degenerate neutrophilic pleocytosis. Granulomatous inflammations usually induce moderate to high cell numbers and increased protein in the CSF. The cell population is predominantly mononuclear or a mixed population of neutrophils and mononuclear cells. Distinguishing a granulomatous infection due to a fungal or protozoal organism from granulomatous meningoencephalitis is often difficult. The necrotizing encephalitis typically cause a

mild increase in CSF mononuclear cells and protein concentration.

Occasionally, bacteria are seen on cytologic examination of the CSF and identified with Gram stain. Successful culture of bacteria from CSF is more likely in large animals than in dogs. In some cases, serial blood cultures are more successful, especially in foals. Fungi and occasionally protozoa have been identified in CSF, but serology is usually necessary to confirm mycotic and protozoal infections *in vivo*. Many of these diseases are fatal, and final identification is made at postmortem with *in situ* identification of the organism.

For premortem etiologic identification, agent-specific testing is recommended; however, most agents, once in the CNS, are not detectable by direct testing through culture or nucleic acid–based testing of body fluids. Serologic testing is available for most viral encephalitides and, in particular, for arboviruses the most reliable test examines IgM in a single sample. Paired serum is required for IgG-based tests, especially those confounded by vaccination. Although CSF analysis is rewarding in terms of clinical pathology, detection of a pathogen within the CSF can also be unreliable depending on the location and pathogen load within the CNS. Culture of the CSF will often yield growth of the organism in bacterial meningitis; however, the detection rate is often <40% for many viruses. Detection of antibody within the CNS can be nonspecific if there is leakage through the blood-brain barrier. IgM detection is likely a more reliable indication of intrathecal antibody production. Most confirmatory testing is performed postmortem if the animal dies.

Treatment: Other than for animals with the probable immune-mediated, steroid-responsive inflammatory CNS diseases and for animals with meningoencephalitis caused by rickettsia and certain bacteria, the prognosis is guarded. The case fatality rate in calves with bacterial meningitis has been reported to be 100%; however, the case fatality rate in foals is much lower.

Appropriate use of antibiotics, according to culture or serology results, is basic to successful therapy. Relapses are common, and prolonged therapy is often necessary. Correction of failure of passive transfer is critical in neonatal large animals. Broad-spectrum antibacterials that can penetrate the blood-brain barrier should be selected, and bactericidal drugs are preferred over bacteriostatic agents. Recommended drugs include ampicillin, metronidazole,

tetracyclines, potentiated sulfonamides, fluoroquinolones, and third-generation cephalosporins; higher than normal dosages may be necessary to achieve and maintain adequate concentrations in the CNS. In farm animals, selection of drugs must be based not only on drug efficacy but also on whether the available drug is appropriate for use in a food animal.

For viral infections, the case-fatality rate varies. The most lethal viral infections are rabies (100%) in all mammals, Eastern equine encephalomyelitis in horses (85%–100%), and distemper virus in dogs (50%). Availability of antivirals is limited, and cost can be prohibitive. The most commonly treated viral infection of the CNS is likely that of the neurotropic form of equine herpesvirus 1; however, the prognosis is guarded in recumbent horses.

Mycotic infections of the CNS have been treated successfully in people, but results in veterinary medicine are less rewarding. Treatment with itraconazole or fluconazole may be of benefit, but longterm therapy is required and relapses are frequent. Protozoal infections (eg, toxoplasmosis, neosporosis, sarcocystosis) may respond to a potentiated sulfonamide (trimethoprim, pyrimethamine and sulfonamides). These are commonly used in combination with clindamycin in small animals. However, relapse may occur because of the inability to clear encysted organisms from the CNS. Antiprotozoal medications have been approved for use in horses, such as the triazine analogues, including diclazuril and ponazuril. In balantidiasis, a disease in working donkeys, secnidazole has been shown to decrease fecal cyst counts, which should theoretically decrease the risk of development of CNS disease.

Glucocorticoids are usually contraindicated in animals with meningitis or meningoencephalitis with an infectious etiology; however, a high-dose, short-term course of dexamethasone or methylprednisolone may control life-threatening complications such as acute cerebral edema and impending brain herniation. Immunosuppressive doses of corticosteroids are required for successful therapy of the idiopathic CNS inflammations seen in dogs.

Radiation therapy and immunomodulatory drugs have been used to treat granulomatous meningoencephalitis.

Supportive care should be specific for the needs of the individual animal and may include analgesics, anticonvulsants, fluids, nutritional supplementation, and physical therapy.

MOTION SICKNESS

Motion sickness is characterized by signs referable to stimulation of the autonomic nervous system, including excessive salivation and vomiting. Affected animals may also yawn, whine, or show signs of uneasiness and apprehension; severely affected animals may also develop diarrhea. Motion sickness is seen during travel by land, sea, or air, and signs usually disappear when vehicular motion ceases. The principal causative mechanism involves stimulation of the vestibular apparatus in the inner ear, which has connections to the emetic center in the brain stem. The chemoreceptor trigger zone (CRTZ) and H_1 -histaminergic receptors are involved in this pathway in dogs but apparently are less important in cats. Recent evidence has revealed that the neurokinin 1 substance P receptors (NK1) in the emetic center play a major role in motion sickness in both dogs and cats and are more important than the receptors in the CRTZ. Fear of the vehicle may also become a contributory factor in dogs and cats that develop a conditioned response to the event; signs may be seen even in a stationary vehicle. In this situation, behavioral modification may be needed to eliminate this fear, or the use of drugs that provide a sedative effect may be needed.

In some cases, motion sickness can be overcome by conditioning the animal to travel. In others, ataractic and antinausea drugs can be used with good results. Antihistamines (such as diphenhydramine hydrochloride, dimenhydrinate, meclizine,

and promethazine hydrochloride) prevent motion sickness, provide sedation, and inhibit drooling. The centrally acting phenothiazine derivatives (such as chlorpromazine, prochlorperazine, and acepromazine maleate) have antiemetic as well as sedative effects. Cats have no histamine receptors in the CRTZ; therefore, antihistamines are ineffective in treating motion sickness in this species. Motion sickness in cats probably is best treated with an α -adrenergic antagonist (eg, chlorpromazine) instead of a pure H_1 -histaminergic antagonist.

Maropitant, an NK1 receptor antagonist, is effective in treating motion sickness in dogs. NK1 receptors are located in the emetic center of the brain stem, which is the source most responsible for the vomiting and nausea of motion sickness. Blocking these receptors is more effective than inhibiting the CRTZ. Therefore, maropitant is probably the drug of choice to treat motion sickness in dogs. Another benefit is that treatment is given once daily. The drug is approved and available in tablet and injectable forms for use in dogs, while only the injectable form is approved for use in cats. Cats should be 16 wk old and dogs 8 wk old before using maropitant.

Phenobarbital and diazepam can be used to produce a general sedative effect if anxiety is a problem. Oral administration of one of these drugs several hours before departure should reduce or eliminate the signs of motion sickness. (See also DRUGS TO CONTROL OR STIMULATE VOMITING (MOTION SICKNESS), p 2547.)

NEOPLASIA OF THE NERVOUS SYSTEM

Neoplasia of the nervous system has been reported in all domestic animal species. Nervous system tumors have been detected in 1%-3% of necropsies in dogs. In cats, nervous system tumors are less common and are mainly meningiomas and lymphomas. Primary nervous system tumors originate from neuroectodermal, ectodermal, and/or mesodermal cells normally present in (or associated with) the brain, spinal cord, or peripheral nerves. Secondary tumors affecting the nervous system may originate from surrounding structures such as bone

and muscle or from hematogenous metastasis of a primary tumor in another organ. Tumor emboli can lodge and grow anywhere in the brain, meninges, choroid plexus, or spinal cord. Dissemination or metastasis of CNS tumors is rare but may occur via the CSF pathways, especially if the tumors are located close to the subarachnoid space or ventricular cavities (eg, choroid plexus papilloma, ependymoma, medulloblastoma, neuroblastoma, pinealoblastoma), or via a hematogenous route such as the dural sinus, with later development of

remote metastasis, most often in the lung. Tumors may also spread by direct extension to surrounding tissues, especially bone. The osseous tentorium may be used as a reference point to localize different areas of the brain within the cranial vault. Thus, tumors in the cerebral hemispheres are often referred to as supratentorial or anterior fossa tumors, while those in the brain stem or cerebellum are called infratentorial or posterior fossa tumors.

Classification: Classification of nervous system tumors in animals follows the criteria used for tumors in people and is based primarily on the characteristics of the constituent cell type, its pathologic behavior, topographic pattern, and secondary changes seen within and around the tumor (see TABLE 2).

Immunocytochemical studies and imaging techniques may aid classification. Primary tumors typically grow slowly,

TABLE 2 TUMORS OF THE NERVOUS SYSTEM IN DOGS AND CATS

Tumor Origin	Predilection Sites	Species	Incidence
PRIMARY TUMORS			
Nerve cells			
Ganglioneuroma (gangliocytoma)	Variable, eg, cerebellum, cranial nerve roots, eye, cervical ganglion	Dogs	Rare
Ganglioneuroblastoma			
Neuroblastoma			
Primitive neuroectodermal tumors			
Neuroepithelium			
Ependymoma	Third and lateral ventricles	Dogs, cats	Uncommon
Nephroblastoma	Meninges, thoracolumbar spinal cord	Dogs (German Shepherd)	Uncommon
Choroid plexus papilloma	Fourth ventricle	Dogs	Common
Neuroglia			
Astrocytoma (fibrillary, protoplasmic, gemistocytic, anaplastic)	Piriform area, convexity of cerebral hemispheres, thalamus, hypothalamus	Dogs (brachycephalic), cats	Common
Oligodendroglioma	Cerebral hemispheres	Dogs (brachycephalic)	Common
Glioblastoma	As for astrocytoma	Dogs (brachycephalic)	Uncommon
Spongioblastoma	Variable, eg, ependymal surfaces, cerebellum, optic nerve and tracts	Dogs (brachycephalic)	Rare
Medulloblastoma	Cerebellum	Dogs, cats	Uncommon
Gliomas (unclassified)	Periventricular areas, especially in cerebral hemispheres	Dogs	Common
Peripheral nerves and nerve sheaths			
Nerve sheath tumors (schwannoma, neurofibrosarcoma, neurofibroma, neurinoma)	Peripheral nerves	Dogs, cats	Common

(continued)

TABLE 2 TUMORS OF THE NERVOUS SYSTEM IN DOGS AND CATS (*continued*)

Tumor Origin	Predilection Sites	Species	Incidence
Meninges, vessels, and other mesenchymal structures			
Meningiomas (fibrous, transitional, psammomatous, angiomatous, papillary, granular cell, myxoid, anaplastic)	Convexities of cerebral hemispheres and floor of the vault	Dogs (dolicocephalic), cats	Common
Angioblastoma	Variable	Dogs, cats	Rare
Sarcoma	Variable	Dogs, cats	Common
Histiocytic sarcoma (focal granulomatous meningoencephalomyelitis reticulosis)	Cerebral hemispheres and brain stem	Dogs, cats	Rare (in dogs)
Pineal gland, pituitary gland, and craniopharyngeal duct			
Pinealoma	Pineal body	Dogs	Rare
Pituitary adenoma	Pituitary gland	Dogs (brachycephalic), cats	Common
Craniopharyngioma	Hypophyseal-infundibular areas	Dogs	Rare
Heterotopic tissues (malformation tumors)			
Epidermoid, dermoid, teratoma, teratoid, intra-arachnoid cyst	Variable (fourth ventricle and cerebellopontine angle for epidermoid, quadrigeminal cistern for intra-arachnoid cyst)	Dogs	Rare
Germ cell tumors	Base of brain above sella turcica	Dogs	Rare
Hamartoma	Variable (eg, hypothalamus)	Dogs	Rare
SECONDARY TUMORS			
Metastatic tumors			
Manummary gland adenocarcinoma, pulmonary carcinoma, prostatic carcinoma, chemodectoma, malignant melanoma, lymphosarcoma, salivary gland adenocarcinoma, hemangiosarcoma, etc	Variable	Dogs, cats	Relatively common
Primary tumors from surrounding tissues			
Osteosarcoma, lipoma, osteochondroma, chondrosarcoma, fibrosarcoma, nasal adenocarcinoma, hemangiosarcoma, multiple myeloma, calcifying aponeurotic fibromatosis, epidermoid cyst, etc	Variable	Dogs, cats	Relatively common

whereas secondary, highly malignant, metastatic tumors and bone tumors generally progress more rapidly. Many animal tumors have characteristics analogous to corresponding human neoplasms; however, 15%–20% of neuroectodermal tumors (especially gliomas) remain unclassified. Many of these are related topographically to the ventricular system and/or subependymal cell nests. As many as 26% of neuroectodermal brain tumors are undifferentiated, as shown by immunocytochemical staining. Although brain tumors are occasionally reported in animals <1 yr old, most are found in mature and aged animals. No sex predilection for nervous system tumors has been identified.

Incidence: The reported incidence of nervous system neoplasia in animals varies. However, such tumors are reported more often in dogs than in other domestic animals. In one survey, 2.83% of 6,175 dogs examined at necropsy had intracranial neoplasia. In another report, incidence of intracranial neoplasia was 14.5/100,000 dogs at risk and 3.5/100,000 cats at risk. A retrospective study of young dogs (<6 mo old) indicated that the three most common sites for neoplasia (in decreasing order) were the hematopoietic system, brain, and skin. Brachycephalic breeds are at increased risk of some neuroectodermal tumors.

Brain Tumors: In dogs and cats, the brain is a more common site of primary tumors of the nervous system than the spinal cord or peripheral nerves. Meningiomas, gliomas (eg, astrocytomas, oligodendrogliomas), undifferentiated sarcomas, pituitary tumors, and ventricular tumors (eg, choroid plexus papillomas, ependymomas) are commonly reported primary brain tumors in dogs. Previously reported cases of neoplastic reticulosis, gliomatosis, microgliomatosis, malignant histiocytosis, or the malignant form of granulomatous meningoencephalomyelitis are now classified as histiocytic sarcomas or lymphomas. Other primary brain tumors (eg, malformation tumors), tumors of nerve cells (eg, neuroblastoma, ganglioneuroblastoma, and ganglioneuroma), pinealomas, craniopharyngiomas (a suprasellar ectodermal tumor that may destroy the pituitary gland), spongioblastomas (embryonal glioma), and medulloblastomas are rare. Adult dogs of several brachycephalic breeds—Boxers, English Bulldogs, and Boston Terriers—are often cited as having the highest incidence of brain

tumors among domestic animals; glial tumors, including unclassified gliomas, are the most numerous tumors in these breeds. One study of 97 dogs indicated that Golden Retrievers also have a high incidence of brain tumors (especially meningiomas).

Secondary tumors extending into the cranial vault from the nasal sinuses are relatively common in dogs. In some cases, usually those involving caudal nasal tumors, the only clinical signs are neurologic abnormalities such as behavioral changes, circling, paresis, seizures, or visual deficits. Respiratory signs such as epistaxis, nasal discharge, sneezing, dyspnea, stertor, or mouth breathing may develop after neurologic signs or may be absent. Nasal tumor types include adenocarcinoma, anaplastic chondrosarcoma, epidermoid carcinoma, esthesioneuroblastoma, neurofibrosarcoma, neuroendocrine carcinoma, and squamous cell carcinoma. Unlike nasal cavity tumors, tumors that originate in middle or inner ear structures rarely extend into the brain (see TABLE 2). Metastatic brain tumors are also commonly recognized in dogs, with hemangiosarcoma being the most common metastatic tumor type. In cats, metastases most frequently originate from mammary carcinomas and lymphosarcomas.

Astrocytomas are probably the most common neuroectodermal brain tumor in dogs. They are usually found in adult dogs, but they have been reported in dogs <6 mo old. They are common in brachycephalic breeds but can be seen in any breed. Astrocytomas consist of relatively large, protoplasmic-rich cells or smaller cells with many processes. The cells tend to be arranged around blood vessels. There are several variants (eg, anaplastic, fibrillary, gemistocytic, protoplasmic, and pilocytic), most of which stain positively for glial fibrillary acidic protein (GFAP), the chemical subunit of the intracytoplasmic intermediate filaments of astrocytes. Regressive changes found histologically include necrosis, mucinoid degeneration, cyst formation, vascular proliferation (often in the form of glomeruloid nests), and multinucleated giant cells. Hemorrhage is rare. Malignant astrocytomas display nuclear polymorphism, mitotic figures, and small cells with dense, hyperchromatic nuclei. In one study using CT, astrocytomas and oligodendrogliomas appeared similar to one another, because both tumors had ring-like, irregular enhancement and poorly defined margins. Differentiating oligodendrogliomas from malignant astrocytomas with MRI has been difficult. In some

instances, however, MRI is considered superior to CT in defining diffuse leptomeningeal and low-grade cerebral astrocytomas. Astrocytomas are uncommon in cats; in one report of four cats, the tumors invaded the third and lateral ventricles.

Choroid plexus papillomas are common tumors in dogs, with reported frequency similar to that of glioblastomas (~12% of neuroglial tumors). Developmentally, the choroid plexus epithelium differentiates from the primitive medullary epithelium and is related to the ependymal cells. These tumors are reddish, papillary growths that may bleed. Histologically, they are well defined, grow by expansion, and have a granular papillary appearance. Tumor papillae consist of vascular stroma lined by one layer of cuboidal or cylindrical epithelium. Immunocytochemical studies reveal that these tumors express epithelial but not glial differentiation, based on absence of staining with GFAP. Keratin may be expressed from some of these tumors. In both benign and malignant variants of choroid plexus papillomas, dissemination to other areas of the brain or spinal cord via the CSF pathways may occur after exfoliation. Obstructive hydrocephalus may occur. Meningeal carcinomatosis may follow spread of the tumor in the subarachnoid space. Choroid plexus tumors are seen as well-defined, hyperdense masses with marked, uniform contrast enhancement on CT scans. Marked enhancement, potentially including hemorrhage and mineralization, is also seen with MRI. Choroid plexus papillomas have no apparent predilection for brachycephalic breeds and are rare in cats.

Ependymomas originate from the epithelium lining the ventricles and central canal of the spinal cord. They are rare but have been reported most frequently in brachycephalic breeds. The gray to reddish, soft, lobular masses tend to invade the ventricular system and meninges, which may result in obstructive hydrocephalus. Metastases within the CSF system may be seen. Ependymomas of the fourth ventricle may encircle the brain stem. Both epithelial and fibrillary varieties have been described. Histologically, cells are isomorphic, with pale or transparent cytoplasm and round, chromatin-rich nuclei. Nucleus-free zones around blood vessels are characteristic. Some ependymomas appear hemorrhagic, with mucinoid degenerative changes and cyst formation. Malignant or anaplastic ependymomas have moderate degrees of pleomorphism and necrosis and may merge into glioblastoma multiforme. In one study,

only one of nine ependymomas was positive for GFAP. In a CT study of brain tumors, ependymomas had no definitive distinguishing features.

Gangliocytomas are rare intracranial tumors reported in adult dogs of several breeds. Histologic findings include mature, neuronal-like cells with multiple processes, a central nucleus, and a nucleolus. Neuroblast-like immature cells may also be seen, and occasionally, newly formed myelin sheaths. They seem to be seen most often in the cerebellum. Pure gangliocytomas have no glial elements and do not express GFAP. Mineralization and extensive necrosis accompanied by edema and capillary proliferation may also develop.

Suprasellar germ cell tumors are located dorsal to the sella turcica at the base of the brain. They are often intimately associated with the pituitary gland, which may be trapped within or replaced by the germ cell tumor. They are thought to result from extensive migration of germ cells during embryogenesis. Neurologic signs may be acute in onset and may include lethargy; depression; bradycardia; dilated, nonresponsive pupils; ptosis; visual deficits; and blindness. Germ cell tumors may be large—extending from the olfactory peduncles to the pons and pyriform lobes—and may envelop other cranial nerves (eg, nerves III–VII). Histologically, the tumors usually contain a mixture of primitive germ cells, cords resembling hepatocytes, and acini and tubules of tall columnar epithelial cells. They may stain positively for fetoprotein. Affected animals are usually 3–5 yr old; Doberman Pinschers may be at higher risk than other breeds. Some germ cell tumors have been misdiagnosed as pituitary tumors or craniopharyngiomas.

Glioblastoma multiforme, considered to be equated with the more malignant forms of astrocytomas, has been reported with varying frequency in dogs. In one study, the incidence was 12% of 215 neuroglial tumors. Most are large and found in the cerebrum. The tumor cells consist of medium-sized, round or fusiform cells with isomorphic nuclei. Some glioblastomas display considerable pleomorphism, with small and large mononucleated and multinucleated cells. They are locally invasive and destructive, well vascularized, and often contain necrotic zones. Glioblastomas sometimes express GFAP and are most common in brachycephalic breeds.

Hamartomas are formed by disorderly overgrowth of tissues normally present at a site. They are focal malformations

resembling neoplasms and have been reported only rarely in dogs, usually as a subclinical finding.

Hematogenous metastatic brain tumors commonly originate from extracranial sites. In dogs, they often develop from carcinomas of the mammary glands, thyroid, bronchopulmonary epithelium, kidneys, chemoreceptor cells, nasal mucosa, squamous epithelium of the skin, prostate, pancreas, adrenal cortex, and salivary glands. Brain metastasis from a transmissible venereal tumor has been reported in a 5-yr-old male mixed breed dog. Common sarcoma metastases in dogs include fibrosarcomas, hemangiosarcomas, lymphosarcomas, and melanoblastomas. Brain metastases may accompany intramedullary spinal cord metastasis in dogs with lymphosarcomas or hemangiosarcomas. In cats, metastases stem most often from mammary carcinomas or lymphosarcomas. Most CNS lymphomas, especially in dogs, are one part of a multicentric disease, with extensive infiltration of the choroid plexus and leptomeninges a common finding. Neoplastic angioendotheliomatosis in dogs is thought to be an angiotropic lymphoma, possibly of the B-cell line. Extraneural tumor cells sometimes localize in the meninges (e.g., meningeal carcinomatosis), often in association with intestinal carcinoma or mammary adenocarcinoma.

Histiocytic sarcomas (previously named malignant histiocytosis or primary/neoplastic reticulosis) are rarely reported in dogs. Proliferation and/or infiltration of neoplastic histiocytes in the basilarachnoidal and ventricular areas (bilateral) is a characteristic feature. These cells may also infiltrate the spinal dura mater, arachnoidal space, leptomeninges, and spinal nerve roots. Histologically, the cells may have characteristic histiocytic morphology but exhibit moderate pleomorphism and numerous mitotic figures.

Intracranial intra-arachnoid cysts have been reported in dogs. These rare malformation tumors seem to develop most often in the quadrigeminal cistern. Of the six dogs in one report, three were <1 yr old, four were males, and five of the six weighed <11 kg. One dog had additional developmental anomalies (abnormal corpus callosum and block vertebrae). On CT scans and MRI, the cysts were extra-axial, had sharply defined margins, contained fluid isodense to CSF, and did not show contrast enhancement.

Malformation tumors, including epidermoid and dermoid cysts and teratomas, originate from heterotopic tissue

and are rare tumors in dogs. They typically lie close to embryonal lines of closure. Epidermoid and dermoid cysts result from inclusion of epithelial components of embryonal tissue at the time of closure of the neural tube. They reportedly have a predilection for young dogs (eg, 3–24 mo old), although cysts have been found in older dogs. They usually involve the cerebellopontine angle, fourth ventricle, or both. Cysts within the fourth ventricle may secondarily compress the medulla oblongata and cerebellum. Some epidermoid cysts are incidental findings at necropsy.

Histologically, epidermoid cysts may have a multilocular structure; most are lined by stratified squamous epithelium and contain keratinaceous debris, desquamated epithelial cells, and occasional inflammatory cells. In contrast, dermoid cysts contain adnexal structures such as hair follicles, sebaceous glands, and sweat glands. Cysts may measure as much as 2.5 cm in diameter. Because of the tumor's location, dogs may show signs of a pontomedullary syndrome (eg, trigeminal, facial, cerebellar, and/or vestibular dysfunction). Teratomas are well-differentiated germ cell tumors (*see above*) arising from several embryonic germ cell layers.

Medulloblastomas are highly malignant, uncommon neuroectodermal canine tumors that almost always develop in the cerebellum. The tumors tend to bulge into the fourth ventricle, often replacing part of the cerebellar vermis and compressing the midbrain rostrally and the brain stem ventrally. They may infiltrate the meninges, metastasize within the CSF pathways, and cause obstructive hydrocephalus. Histologically, these tumors include sheets of densely packed cells with pale cytoplasm and oval or carrot-shaped nuclei with coarse, granular chromatin. Mitotic figures are common. Regressive changes include pyknosis and karyorrhexis. Although most cases are seen in young dogs, a cerebellar medulloblastoma with multiple differentiation has been described in a 4-yr-old Border Collie.

Meningioangiomas is a rare, benign malformation of CNS blood vessels, characterized by proliferation of the vessels and spindle-shaped, perivascular meningeothelial cells in the cerebral cortex and brain stem of juvenile and adult dogs. The meningeothelial cells stain positively for vimentin, which, along with the presence of mucopolysaccharides and collagen among proliferating cells, suggests a mesenchymal and fibroblastic origin.

Meningiomas are extra-axial tumors.

They arise from elements of the dura within the cranial and spinal spaces and are the most commonly reported brain tumors in cats. They are also one of the most common intracranial tumors in dogs, with a reported incidence of 30%–39%. In most studies, meningiomas are seen in dogs >7 yr old and in cats >9 yr old, although they have been seen in young cats (<3 yr old) with mucopolysaccharidosis type I and in dogs <6 mo old. They are often found in dolichocephalic breeds, especially Golden Retrievers. Canine and feline meningiomas have estrogen, progesterone, and androgen receptors. These usually benign tumors tend to grow slowly under the dura mater, although direct brain invasion has been reported.

Pathologic findings include globular, irregular, lobulated, nodular, ovoid, or plaque-like masses ranging in diameter from a few millimeters to several centimeters. Meningiomas are typically discrete and often are firm, rubbery, and encapsulated. They may contain granular calcifications known as psammoma bodies. In addition, there may be focal or massive calcification of the tumor. A substantial proportion of basal and plaque-like meningiomas involve the floor of the cranial cavity, especially when located near the optic chiasm or suprasellar area. They also commonly are found over the convexities of the cerebral hemispheres, less often in the cerebellopontomedullary region, and infrequently in the retrobulbar space (arising from the optic nerve sheath). In cats, common locations include the tela choroidea of the third ventricle and the supratentorial meninges. Cats also have a higher incidence (17%) of multiple meningiomas. Hyperostosis, a thickening of bone adjacent to the meningioma, may develop, especially in cats.

Meningiomas rarely metastasize outside the brain, but may extend into paranasal regions and lungs or be seen as primary extracranial masses as a result of embryonic displacement of arachnoid cells or meningocytes. Those in extracranial locations differ from intracranial meningiomas primarily in their more aggressive behavior and anaplastic/malignant nature. Meningiomas may be distinguishable from tumors within the brain parenchyma on contrast CT scans by their appearance as broad-based, peripherally located masses. Cystic and edematous meningiomas have been detected using CT scans and MRI. When a dural tail (a linear enhancement of thickened dura mater adjacent to an extra-axial mass) is detected by MRI, a meningioma is the most likely cause.

The histologic classification of canine meningiomas includes angioblastic, fibroblastic, meningothelial or syncytial, psammomatous, and transitional. Papillary and microcystic forms may also be seen. The tumors usually consist of large meningothelial cells or fusiform cells arranged in whorls, nests, islands, or stream-like patterns. Cell boundaries are typically ill defined, and the nuclei contain little chromatin. Canine meningiomas commonly have vimentin intermediate filaments. Regressive changes may include cavernous vascular formations, hemorrhage, hyalinization of connective tissue, and deposits of fat, lipopigments, or cholesterol. Many have evidence of focal necrosis with suppuration. This is the likely cause of the reported predominance of polymorphonuclear cells in CSF in many dogs with meningioma.

A grading system in human patients has recently been adapted for dogs and may predict tumor behavior. Grade I tumors are considered benign, grade II tumors are considered atypical, and grade III tumors are considered malignant.

Most feline epitheliomas are meningotheliomatous or psammomatous, often with cholesterol deposits.

In **meningeal sarcomatosis**, sarcomas cause diffuse thickening of the meninges; extensive hemorrhages are common. These rare tumors tend to infiltrate nervous tissue and run along blood vessels. Cell types include lymphoid, plasmacytoid, mature plasma cells, immunoblastic cells, and multinucleate giant cells.

Oligodendrogliomas are common tumors in dogs, particularly in brachycephalic breeds. In one report, they comprised 28% of neuroectodermal tumors. These tumors consist of chromatin-rich, densely packed, round cells with perinuclear halos. Most grow by infiltration and destroy invaded tissue. Capillaries tend to proliferate within these tumors, producing glomerulus-like structures. Regressive changes are similar to those seen in astrocytomas (*see* p 1270). Necrosis and extensive calcification are uncommon. These tumors do not stain with GFAP; in one study, 3 of 11 oligodendrogliomas reacted with myelin-associated glycoprotein, while none reacted with myelin basic protein. Many canine oligodendrogliomas are mixed tumors with areas of astrocytic and, in some cases, ependymal differentiation. The MRI features are similar to those seen with high-grade (malignant) astrocytomas. Oligodendrogliomas are rare in cats.

Pituitary tumors are common in dogs, with an apparent predilection for brachycephalic breeds. They are infrequent in cats. Tumors may be functional or nonfunctional. Either type may cause hypopituitarism by mechanical or functional impairment of remaining pituitary tissue, although this effect is uncommon. Nonfunctional canine pituitary tumors are common and are usually chromophobe adenomas, although adenocarcinomas have also been reported. Functional pituitary tumors associated with the adenohypophysis are typically characterized by pituitary-dependent hyperadrenocorticism (PDH). (See also HYPERADRENOCORTICISM, p 543.) ● Of the cases of pituitary Cushing disease, ≥80% are reportedly associated with a pituitary tumor.

In dogs, these tumors may stem from the pars distalis (80%) or the pars intermedia (20%), because both regions contain cells that can produce adrenocorticotrophic hormone. The tumors are generally chromophobic microadenomas (<1 cm in diameter) that do not produce neurologic signs. MRI studies suggest that as many as 60% of dogs with PDH and no neurologic signs have pituitary tumors 4–12 mm in diameter. As many as 50% of dogs with PDH and large chromophobic macroadenomas (>1 cm in diameter on MRI) may not show clinical signs related to an intracranial mass. In one study, seven of eight dogs with pituitary neoplasia that had been treated for PDH for varying periods of time (between 1 and 2 yr) developed neurologic signs, including abnormal behavior (eg, head pressing, lethargy, hiding, wandering, pacing, tight circling, and trembling), seizures, and positional nystagmus. Most pituitary tumors, especially those derived from the pars distalis, tend to grow dorsocaudally because the diaphragma sellae is incomplete. Chromophobic canine tumors from the pars intermedia are smaller and less destructive. Dorsal extension of pituitary tumors may lead to compression and obliteration of the infundibulum, ventral portion of the third ventricle, hypothalamus, and thalamus and may eventually impinge on the internal capsule and optic tract. Hypothalamic or median eminence involvement may cause central diabetes insipidus (especially in middle-aged and older dogs with neurologic signs), manifesting as polyuria, polydipsia, and isosthenuria or hyposthenuria. Alteration in water balance results from interference with the synthesis of antidiuretic hormone (ADH) in the supraoptic nucleus or release of ADH into capillaries of the pars nervosa. Although pituitary tumors generally do not

lead to visual impairment, acute blindness and dilated, nonresponsive pupils have been noted in seven dogs and one cat with pituitary masses that compressed the optic chiasm.

Approximately 80% of cats diagnosed with Cushing disease have PDH; tumor types include pituitary microadenomas, macroadenomas, and adenocarcinomas. Pituitary acidophil adenomas, especially the large variety, have been associated with acromegaly and nervous system signs (eg, circling, seizures) in cats, accompanied by insulin-resistant diabetes mellitus and high serum growth hormone concentrations.

Histologically, pituitary tumors include polygonal, round, and cylindrical cells arranged in close contact with blood vessels or formed into islands of cells divided by connective tissue. The cell pattern may be uniform, resembling normal pituitary tissue. Many pituitary tumors contain both chromophobic and chromophilic cells. Regressive changes include cyst formation, necrosis, and hemorrhage. MRI with contrast enhancement is extremely helpful to visualize microtumors (3–10 mm in diameter) and macrotumors (≥24 mm) in dogs with PDH, regardless of neurologic signs. MRI and CT scans of pituitary tumors reveal minimal peritumoral edema, uniform contrast enhancement, and well-defined margins; however, tumors <3 mm in diameter may not be visible. Adrenal and pituitary tumors may coexist in dogs with hyperadrenocorticism, complicating test results and making diagnosis and treatment more difficult.

Primary skeletal tumors do not typically cause neurologic signs. Multilobular osteochondroma originates in the flat bones of the skull, usually in older, medium- or large-breed dogs and appears as a firm, fixed mass. It may erode the cranium and compress, rather than infiltrate, underlying brain tissues. Radiographically, the tumor contains nodular or stippled areas of mineralization, resulting in a characteristic “popcorn ball” appearance. Microscopically, the tumor contains multiple lobules of osseous and chondroid tissue. Local recurrence is common in high-grade tumors (78%) and occurs in 30% and 47% of low- and intermediate-grade tumors, respectively. Metastasis frequently occurs (as many as 58%) but usually late in the disease course (>1 yr) and also depends on grade, with rates of 75% in high-grade tumors and 60% in intermediate-grade tumors, as opposed to 30% in low-grade tumors. Vertebral osteochondroma is the spinal cord counterpart.

Vascular malformations are considered developmental lesions rather than true neoplasms and are uncommon in both dogs and cats. They may be located in the cingulate gyrus, pyriform-hippocampal area of the temporal lobe, basal ganglia, cerebellum, occipital lobe, or septum pellucidum and fornix and comprise variable combinations of arteries, veins, and capillaries. The vessels tend to be dilated, sinusoidal in shape, and accompanied by hemorrhages.

Spinal Cord Tumors: Spinal cord tumors are relatively common in cats and dogs. They are generally classified according to their relationship with the spinal cord and meninges as extradural, intradural-extramedullary, or intramedullary. Depending on tumor location, any of the four spinal cord syndromes may be anticipated (eg, cervical, cervicothoracic, thoracolumbar, or lumbosacral syndromes). Regardless of type, the mean age of most dogs with spinal tumors is ~6 yr, and tumors appear to be more common in medium and large breeds. Cats with lymphosarcoma tend to be younger (mean age of ~3.5 yr), possibly because of the infectious etiology (ie, feline leukemia virus) of most cases. However, age alone does not preclude a diagnosis of spinal tumor. The clinical course for the various tumor types and locations is not clearly defined. In one study, the rate of progression was fastest with intramedullary tumors (1.7 wk), followed by extradural tumors (3.4 wk) and intradural-extramedullary tumors (5.7 wk).

Extradural tumors are found outside the dura mater and cause spinal cord compression. They are the most common spinal tumors in both cats and dogs. The most frequent types of canine spinal cord tumors are primary, malignant bone tumors (chondrosarcoma, fibrosarcoma, hemangiosarcoma, hemangioendothelioma, multiple myeloma, osteochondromas or multiple cartilaginous exostoses, and osteosarcoma) and tumors metastatic to bone and soft tissue. Reports of secondary vertebral tumors in dogs include anaplastic tumors, aortic body tumors, bronchogenic carcinoma, chemodectoma, fibrosarcoma, ganglioglioma, hemangiosarcoma, lymphosarcoma, malignant melanoma, mammary carcinoma, osteosarcoma, pancreatic adenocarcinoma, perianal gland carcinoma, prostatic carcinoma, rhabdomyosarcoma, Sertoli cell carcinoma, squamous cell carcinoma, transitional cell carcinoma, thyroid carcinoma, and tonsillar carcinoma. An extradural ganglioglioma

and its undifferentiated counterpart, ganglioneuroblastoma, have also been reported in dogs.

Primary vertebral tumors are rare in cats, with osteosarcoma being the most frequently reported. Metastatic, extradural spinal cord tumors are unusual in dogs, but extradural lymphosarcoma is the most common spinal tumor in cats. In most cases, these tumors are secondary to lymphosarcoma elsewhere in the body, although primary spinal cord lymphosarcomas have been reported sporadically in dogs. In one study in cats, extraneural involvement was not found in ~50% of the cases, and the tumors were solitary in 22 of 23 cats. A predilection for the thoracic and lumbar vertebral canal was seen, but the tumors may develop in any spinal region. Three of the tumors affected the brachial plexus cervical roots (see p 1276). Spinal lymphomas in cats may extend over multiple vertebral bodies and involve more than one level of the spinal cord. Leptomeningeal spinal cord involvement is not common in cats. A tumor termed myxoma-myxosarcoma has been described in four dogs. These malignant tumors resembled soft-tissue myxomas, with polygonally shaped cells with gray, vacuolated cytoplasm that stained positive for S-100 protein antibody. The masses were extradural in three cases and intradural-extramedullary in the other.

Intradural-extramedullary tumors are found in the subarachnoid space and are estimated to account for ~35% of all spinal cord tumors. They are most commonly meningiomas or nerve sheath tumors (eg, neurofibromas, neurilemmomas, and schwannomas) that grow into the vertebral canal and compress the spinal cord. Approximately 14% of CNS meningiomas in dogs (but only 4% in cats) reportedly involve the spinal cord. Tumors may be seen in the cervical, lumbar, or thoracic cord regions. In a report of spinal cord tumors in 29 dogs, nerve sheath tumors were the second most common type after vertebral tumors. In another review of canine spinal tumors, 39 of 60 nerve sheath tumors involved the spinal cord. Nerve sheath tumors often affect the brachial plexus (see below).

A primary intradural-extramedullary tumor with a predilection for T10–L2 spinal cord segments in young dogs, particularly retrievers and German Shepherds, has been variously diagnosed as ependymoma, medulloepithelioma, nephroblastoma, or neuroepithelioma. The origin of this tumor is uncertain, and immunocytochemical studies have not supported a neuroectodermal

origin. Monoclonal antibody studies suggest it may be a neuroblastoma. Most cases are seen in dogs 5–36 mo old, with males and females affected equally. Clinical signs include a thoracolumbar syndrome. CSF is usually normal, although the protein level was increased in one dog. The extramedullary masses are a tan to grayish white color and 1–3 cm long. They are generally found dorsal and lateral to the spinal cord, may entrap the spinal roots, and may be accompanied by areas of hemorrhage and severe spinal cord compression. Histologic findings include solid sheets of ovoid to fusiform cells interspersed with areas of acinar and tubular differentiation, rudimentary glomeruli, and focal squamous metaplasia.

Intramedullary tumors are the least common of the three categories of spinal cord tumors, with a reported frequency of 15%–24%. Primary glial tumors (eg, astrocytoma, choroid plexus papilloma, ependymoma, oligodendroglioma, and undifferentiated sarcoma) are the most commonly diagnosed. Intramedullary spinal cord metastasis is an uncommon complication of systemic malignancy in dogs, and neurologic signs may be the first indication of systemic malignancy. The mean age of affected dogs is ~6 yr, any part of the spinal cord may be involved, and there may be accompanying brain metastasis.

Malformation tumors rarely affect the spinal cord. In one report, a 2-yr-old, female Rottweiler presenting with a thoracolumbar syndrome had an intramedullary epidermoid cyst. The gray to off-white cyst was ~2 cm long, 1 cm in diameter, and extended from T13 to L2 spinal cord segments. The empty lumen was lined by simple stratified squamous epithelium or, in a few regions, by desquamating keratinized epithelium containing keratohyaline granules. The spinal cord was severely compressed. These cysts may arise from growth of primordial epithelial cells entrapped during closure of the neural tube.

Peripheral Nerve Tumors: Tumors of cranial and spinal nerves and nerve roots are common in dogs, cattle, and horses but are rarely seen in cats. In one report, peripheral nerve tumors accounted for ~27% of canine nervous system tumors. Differing opinions on the cell of origin have led to confusion over the terminology used to describe these tumors. While schwannoma, neurilemmoma, and neurofibroma are common, interchangeable designations, the term malignant peripheral nerve sheath tumors (MPNST) is recommended because many of these tumors are malignant (based

on cytologic criteria), and determining the cell of origin is usually impossible. Mid to caudal cervical and/or rostral thoracic nerve roots, especially ventral roots, are the most common sites for MPNST. These tumors frequently involve nerves of the brachial plexus, often appearing as bulbous or fusiform thickenings of one or more nerves. They can spread to other nerves once they advance to the common brachial plexus bundle. The tumors typically result in slow, progressive, unilateral thoracic limb lameness and muscle atrophy, often involving the infraspinatus and supraspinatus muscles. Affected animals may display a unilateral Horner syndrome, pain on leg movement, axillary pain on palpation (an axillary mass may be palpable), and may lick or chew at the foot or carpus of the affected limb. Intradural-extramedullary spinal cord compression is most common with tumors located at the spinal nerve roots, although more peripherally located tumors occasionally may invade the vertebral canal. The trigeminal is the cranial nerve most often affected by MPNST, producing signs of unilateral trigeminal nerve dysfunction (eg, unilateral atrophy of the masseter and temporalis muscles). Brain-stem compression and local vertebral erosion have been reported.

Peripheral nerves may also be affected by other tumor types (eg, giant cell sarcoma with cervical involvement, a malignant tumor of the apocrine sweat glands, and sarcoma extending into the brachial plexus have been described in dogs). Peripheral tumors of neuronal origin, such as gangliogliomas and their more undifferentiated counterpart, ganglioneuromas, are extremely rare but have caused extradural spinal cord compression in dogs. Sympathetic ganglia are thought to be the source of gangliogliomas. Lymphosarcomas may involve cranial and spinal nerves and nerve roots in cats and dogs and may extend intracranially. Myelomonocytic neoplasia of the trigeminal nerve and ganglia, leading to a dropped mandible and symmetric atrophy of masticatory muscles, has been reported in dogs. Tumors of the ear canal (eg, ceruminous adenocarcinoma, fibrosarcoma, and squamous cell carcinoma), as well as osteosarcoma of the skull, may affect the facial nerve or one of its branches. Neurofibromas rarely involve the vestibulocochlear nerve. Cranial nerves may be compressed by meningiomas located on the floor of the cranial vault. The vagosympathetic trunk may be compressed by aortic body tumors.

See also DISEASES OF THE PERIPHERAL NERVES AND NEUROMUSCULAR JUNCTION, p 1238.

Clinical Findings: Some of the clinical signs and syndromes associated with various CNS tumors have already been mentioned. Cerebral, hypothalamic/diencephalic, midbrain, cerebellar, pontomedullary, and vestibular syndromes associated with focal discrete intracranial masses might be expected, depending on tumor location. Accurate anatomic localization is possible in many cases, especially in the early stages of tumor growth. However, correlation of clinicopathologic signs with tumor location may be impossible because tumor location may be masked by secondary changes (eg, brain herniation, cerebral edema, hemorrhage, obstructive hydrocephalus, tissue necrosis, and tumor spread within the brain) that independently cause clinical signs. Partial brain herniation may result from increased intracranial pressure and/or shifts in the brain caused by the tumor. Care must be taken to maintain optimal oxygenation and avoid intracranial hypertension during diagnostic tests that involve anesthesia and CSF sampling because of the increased risk of herniation.

Several types of herniation have been described. **Cingulate gyrus herniation** under the falx cerebri toward the unaffected hemisphere leads to compression of the opposite cingulate gyrus. **Occipital or temporal lobe herniation** (primarily the parahippocampal gyrus) under the tentorium cerebelli (caudal transtentorial herniation) often causes dorsoventral and lateral compression of the midbrain at the rostral colliculi and partial occlusion of the mesencephalic aqueduct. Caudal displacement of the diencephalon and midbrain may also occur. Clinical signs include initial pupillary constriction, often followed by mydriasis, tetraplegia, and coma. **Rostral cerebellar vermis herniation** under the tentorium cerebelli (rostral transtentorial herniation) may lead to flattening of the rostral cerebellum, marked compression and rostral displacement of the brain stem, and compression of the temporal cortex. Despite the gross pathology, clinical deficits may be absent. **Cerebellar herniation** (especially the caudal lobe of the cerebellar vermis) through the foramen magnum compresses the underlying medulla oblongata and may cause malacia and hemorrhage. Apnea, hypoxia-induced coma, and tetraplegia may be seen. Concurrent foramen magnum and caudal transtentorial herniation may cause dysfunction in both the midbrain and medulla oblongata. Herniation combined with attenuation of the ventricular system, especially at the

level of the mesencephalic aqueduct, can create obstructive hydrocephalus. The increased intracranial pressure may lead to ischemic necrosis of the herniated tissue.

Initially, seizures and behavioral changes may be the only abnormalities associated with tumors involving the rostral cerebrum (eg, olfactory and frontal lobes). Lesions of the frontal and prefrontal lobes may result in no clinical signs. Acute blindness may be the initial clinical sign in animals with tumors in the region of the optic chiasm (eg, pituitary tumors, paranasal sinus carcinoma, polycentric lymphosarcoma, and suprasellar germ cell tumors). Papilledema (often bilateral) is thought to result from a generalized increase in intracranial pressure. A variety of causes (eg, multiple, small metastatic masses from extracranial tumors, especially with malignant melanoma and hemangiosarcoma) may lead to multifocal clinical signs associated with CNS tumors. Other tumors, such as carcinomas (pulmonary or mammary), tend to produce fewer, larger metastases. The cerebrum, hippocampus, and cerebellar cortex are common sites for hematogenous metastases. Extraneural tumor cells sometimes localize in the meninges (eg, meningeal carcinomatosis associated with mammary adenocarcinoma or intestinal carcinoma). Multifocal syndromes may also result from primary CNS tumors in multiple sites, extension of an original tumor to another site, or metastasis via the CSF.

Choroid plexus papillomas and ependymomas tend to obstruct cerebrospinal pathways because of their ventricular orientation, especially when they arise in the fourth ventricle. Neurologic signs associated with ventricular tumors result from the tumor location and the degree of ventricular dilation caused by obstructive hydrocephalus. Clinical signs often are insidious with either of these tumors; the clinical course generally is protracted, ranging from months to years. Extraneural immunoproliferative diseases in dogs and cats (eg, multiple myeloma and macroglobulinemia-associated lymphocytic leukemia) may also result in a range of intermittent cranial neurologic signs, including disorientation, ataxia, intention tremor of the head, visual impairment, circling, and staggering or falling. Intravascular erythrocyte aggregation impairs blood flow in the affected areas and probably leads to the transient signs.

Pituitary tumors are associated with various endocrine signs, including acromegaly, abnormal hair coat, gonadal atrophy, polydipsia, polyuria, and obesity. (See also

THE PITUITARY GLAND, p 542). Behavioral changes, circling, paresis, seizures, or visual deficits may result from extension of primary nasal cavity tumors into the cranial vault. Respiratory signs, such as dyspnea, epistaxis, nasal discharge, sneezing, stertor, or mouth breathing, may follow neurologic signs or may not occur at all.

Diagnosis: A variety of diagnostic imaging aids, including plain-film radiography, contrast radiography (eg, myelography), and specialized radiographic techniques such as radionuclide imaging (scintigraphy), CT scans, and MRI are used to diagnose nervous system tumors. These techniques provide information (eg, axial origin, location, shape, pattern of growth, and edema) that can be important when determining prognosis, therapy, and outcome. Bone neoplasia may be observed with plain-film radiography. Intracranial tumors are better evaluated with MRI. Some indices of malignancy (eg, edema, extension of growth across the midline, poor margin definition, and tissue invasion) have been defined using MRI, and many tumor types can be presumptively diagnosed based on location, appearance, and contrast-enhancement patterns. Caution must be exercised, however, because presumptive diagnoses made after imaging are found to be incorrect in ~30% of patients after a histopathologic diagnosis is obtained.

Signs of extradural, intradural-extramedullary, and intramedullary tumors vary on myelography. Extradural lesions are located outside the dura mater, resulting in attenuation of the dural tube and spinal cord. Deflection of the contrast column away from the vertebral canal, resulting in a widened epidural space, confirms an extradural lesion. Intramedullary-extramedullary lesions develop in the subarachnoid space, where they act as wedges, displacing the dura mater toward the bony vertebral canal and the spinal cord toward the contralateral vertebral canal. Contrast material abuts the cranial and caudal margins of the tumor, resulting in a characteristic cup or golf tee appearance. In contrast, intramedullary tumors displace the spinal cord material from within, enlarging the circumference of the spinal cord and attenuating the contrast material in the subarachnoid space surrounding the tumor.

Results from one study suggest that CT is better than survey radiographs to visualize bony changes associated with extradural lesions but that myelography is better than CT to classify spinal cord lesions. In another canine study, MRI was used to determine

tumor location in all dogs and bone infiltration in all but one. Localization of tumors in the intradural-extramedullary space was not always possible, however. Myelographic interpretation of intramedullary spinal cord metastasis may be difficult; intramedullary tumors must be differentiated from hemorrhage and spinal cord edema. Classically, myelograms of intramedullary masses reveal widening of the spinal cord shadow and tapering and attenuation of contrast in both lateral and ventrodorsal views.

Electrodiagnostic techniques (eg, electromyography, nerve conduction velocity determination), in conjunction with myelography and imaging techniques, can facilitate diagnosis of peripheral nerve tumors. Myelograms reportedly often are negative in animals with cervical MPNST.

Analysis of CSF may reveal moderate increases in total protein content, total white cell count, and CSF pressure. There is a low frequency of tumor cells in CSF from animals with brain or spinal cord neoplasia, but malignant cells have been reported in dogs and cats with intracranial and spinal cord (extradural and intramedullary) lymphosarcomas.

Prognosis and Treatment: The prognosis for animals with nervous system tumors is generally guarded to poor but depends on the extent of tissue damage, tumor location, surgical accessibility, and rate of tumor growth. Recent improvements in treatment have centered mainly on surgical resection, radiation therapy, and chemotherapy, based on more accurate tumor localization and identification using imaging techniques, such as CT scans and MRI. Better identification and characterization of tumors from tissue biopsies obtained via stereotactically guided biopsy devices may lead to additional improvement. Although success rates for different tumor types and locations are not currently known, cerebral tumors (including meningiomas and ependymomas) without brain-stem signs appear to have the best prognosis, especially in cats. Radiation therapy may be the most successful treatment for a range of intracranial tumors and, if surgery is performed, postoperative radiation therapy may prolong survival times. Radiation therapy is beneficial for treatment of inoperable tumors and may be better than surgery for dogs with infiltrative masses. A retrospective study of 86 dogs with brain tumors showed that dogs treated with ^{60}Co radiation, with or without other combinations of therapy, lived significantly

longer than dogs that underwent surgery (some with ^{125}I implants) or dogs that received symptomatic treatment. Dogs with a solitary site of involvement had a better prognosis. Longterm control of primary brain tumors using cytotoxic chemotherapy alone is poor; symptomatic treatment (eg, use of anticonvulsants and/or anti-inflammatory doses of corticosteroids) is palliative at best, with survival time generally measured in weeks. Corticosteroids may relieve signs by reducing edema near the tumor and by causing temporary regression of lymphoid and reticulohistiocytic tumors.

The treatment of choice for meningioma in cats is surgery, because these tumors are usually removable in toto, with postoperative survival times reaching a median of ~2 yr. Recurrence is possible, with reports of up to 20% and with a median disease-free interval of 9 mo; however, second surgical resections are also feasible. In dogs, the ability to completely resect meningiomas is more limited, because tissue invasion is more frequent. The use of surgical aspirator devices and intraoperative ultrasound or endoscopic imaging may improve the surgeon's ability to perform complete removal. Recent reports of dogs with tumors removed by a surgical aspirator and/or endoscopic-assisted removal yielded median survival times of >3–5 yr. In earlier reports, surgical resection alone resulted in median survival times of ~200 days. Postoperative radiation therapy appears beneficial in some studies, with median survival times increasing by ~1 yr over surgery alone. Radiation therapy as a sole treatment, either in standard fractionated courses (usually throughout 3–4 wk) or in stereotactic radiosurgery (SRS) approaches (usually one to four treatments), has also been attempted. Success rates are difficult to determine, because confirmation of tumor type is rarely performed, and only preliminary reports for SRS have been published. Addition of cytotoxic drugs (most commonly hydroxyurea or CCNU) postoperatively or at recurrence may lengthen survival time.

Astrocytic tumors/gliomas are usually not treated surgically because of location but may be treated with radiation therapy, with reported survival times of 6–11 mo. Additionally, newer drugs, such as temozolamide, which has shown some promise in people, may have some use in the treatment of these tumors in dogs.

Metastatic brain lesions are usually treated palliatively, with a combination of medical therapy, radiation, and/or chemo-

therapy. More invasive treatments, such as surgery, should be reserved for animals in which the primary tumor is well controlled and no other systemic metastases can be documented.

Most extradural spinal tumors are primary bone tumors, and removal often causes decreased spinal stability, pathologic fractures, or spinal subluxation. In a study of canine malignant extradural tumors, postsurgical survival times were short. A report of 20 vertebral tumors (primary or metastatic fibrosarcomas or osteosarcomas) in dogs treated with combinations of surgery, radiation, and chemotherapy supports a guarded prognosis for dogs with vertebral neoplasia. Median survival time was 135 days, with a range of 15–600 days. Survival time after surgical resection of spinal lymphoma and myxosarcoma in dogs was 560–1,080 days in another report, although some dogs received postsurgical radiotherapy and chemotherapy. Methods recommended to treat spinal lymphosarcoma in cats include focal radiotherapy, surgical cytorreduction, and systemic chemotherapy, including L-asparaginase, cyclophosphamide, vincristine, and prednisone. Longterm results are poor, partly associated with a positive feline leukemia virus status in these patients.

Animals with MPNST have a generally poor prognosis, because only a small percentage of these tumors can be completely resected, and their recurrence rate is high. Metastasis, often to the lungs, is another complication. Early diagnosis of MPNST may lead to better results. Mean survival of 180 days after surgical resection was reported in one study. Many intradural-extradural tumors (eg, lipomas and meningiomas) can be successfully removed, with long postsurgical survival. However, intradural-extradural tumors that 1) involve spinal cord segments of an intumescence, 2) are ventrally located, or 3) invade adjacent neural parenchyma have a poor prognosis.

Surgical resection is rarely possible for intramedullary masses. However, there are successful reports of removal of a thoracolumbar intramedullary ependymoma and a tumor resembling a nephroblastoma (by exploratory laminectomy, followed by durotomy and myelotomy). Prognosis for dogs with intramedullary spinal cord metastasis is poor because of the frequent presence of disseminated disease, although corticosteroid therapy may lead to temporary improvement.

Peripheral nerve and nerve root tumors can be successfully resected but may

necessitate removal of the affected nerve and nerve root. If atrophy of all muscle groups is extreme—as may develop with tumors involving multiple nerves of the brachial plexus—or if more than one root is involved, complete amputation of the limb may be required. Recurrence is common after resection of peripheral tumors, with

average time to recurrence of 5 mo in one report. Long-term survival times (18–42 mo) have been reported. Even untreated, dogs with trigeminal nerve tumors can have prolonged survival times (as much as 21 mo in seven dogs). In 45 cats, median survival time was 21.5 mo, with a 20% local recurrence rate.

PARANEOPLASTIC DISORDERS OF THE NERVOUS SYSTEM

Paraneoplastic syndromes are nonmetastatic complications of cancer with effects distant from the primary tumor. They are unrelated to neurologic complications secondary to metabolic or nutritional disorders, infection, cerebrovascular incidents, or adverse effects of treatments. They can affect all parts of the nervous system, including the brain, cranial nerves, spinal cord, dorsal root ganglia, peripheral nerves, and the neuromuscular junction. Some are thought to be immunologically mediated through cross-reactivity by immune cells against antigens expressed by tumors and neural tissues (molecular mimicry), whereas others are related to the production of circulating hormones, peptides, or other substances that exert systemic effects.

Paraneoplastic syndromes affecting the CNS are rarely recognized in animals, but lack of awareness may lead to a low detection rate. Sporadic case reports suggest that brain and spinal cord effects can result from various tumor types. An 8-yr-old, male German Shepherd with a history of acute pelvic limb paralysis, progressive loss of motor function, conscious proprioceptive deficits, loss of superficial and deep pain sensation over the trunk and pelvic limbs, and Schiff-Sherington-like hyperextension in the thoracic limbs was diagnosed with hepatocellular carcinoma with metastasis to the lungs, liver, spleen, and lymph nodes at necropsy. Severe necrotizing myelopathy was present throughout the gray and white matter of the thoracic spinal cord, including spongy degeneration, gliosis, demyelination, axonal swelling and degeneration, and neuronal necrosis. In a second case, a range of neurologic deficits in a 17-mo-old, male Poodle was attributed to hyperviscosity syndrome secondary to macroglobulinemia-

associated lymphocytic leukemia. A 3-yr-old Doberman Pinscher developed diencephalic syndrome, associated with a diencephalic tumor (an astrocytoma) that produced growth hormone, resulting in extreme emaciation despite adequate or increased nutritional intake.

Paraneoplastic myasthenia gravis (MG) has been strongly associated with the presence of thymic disease. MG can manifest as systemic weakness, or more focally, especially as megaesophagus. In one review of canine thymoma, 47% of the dogs had MG, 33% had concurrent nonthymic cancer (including pheochromocytoma, mammary adenocarcinoma, or pulmonary adenocarcinoma), and 20% had concurrent signs of polymyositis. Dogs with thymoma-associated MG often have antibodies to nicotinic acetylcholine receptors, which can be used to diagnose and/or monitor treatment response. These dogs may produce autoantibodies to several other neuromuscular antigens, including ryanodine (a skeletal muscle calcium-release channel receptor) and the muscle protein titin. Other tumors that have rarely been reported to cause MG include osteosarcoma, lymphoma, and bile duct carcinoma. MG can improve with immunosuppression or treatment of the underlying tumor but may also be persistent or occur after removal of a thymoma.

An association between myositis (eg, dermatomyositis and polymyositis) and malignant neoplasia in people has been well established. Dogs with malignant tumors such as bronchogenic carcinoma, myeloid leukemia, or tonsillar carcinoma may also have muscular necrosis and low-grade myositis, but the frequency of this potentially paraneoplastic association is unknown. Two dogs with multicentric

lymphoma were found to have polymyositis, but the presence of lymphocyte infiltration within the muscle makes differentiating between primary and paraneoplastic disease difficult.

Peripheral neuropathy is commonly associated with neoplasia in people, and is likely so in animals, as well, although less recognized clinically. A large survey on dogs with various malignancies revealed multiple histopathologic changes in the nerve fibers, including paranodal-segmental demyelination, remyelination, axonal degeneration, and myelin globules. Associated tumor types included insulinoma, multiple myeloma, lymphoma, bronchogenic carcinoma, mammary adenocarcinoma, malignant melanoma, thyroid adenocarcinoma, leiomyosarcoma,

hemangiosarcomas, undifferentiated sarcomas, and mast cell tumor.

Clinical signs may include reduced or absent spinal or cranial reflexes, flaccid weakness, reduced muscle tone, paralysis of limb or head muscles, and, after 1–2 wk, neurogenic muscle atrophy. Dysphonia may also be present.

Dogs and cats with clinical signs of nervous system disease (or with myositis or necrotizing myopathy confirmed by histopathology) that do not respond to therapy or that relapse should be carefully screened for malignancy, because paraneoplastic syndromes may be the first clinical sign related to tumor presence. Blood tests or imaging may be indicated. Such vigilance may detect tumors at a more treatable stage.

POLIOENCEPHALOMALACIA

(Cerebrocortical necrosis)

Polioencephalomalacia (PEM) is an important neurologic disease of ruminants that is seen worldwide. Cattle, sheep, goats, deer, and camelids are affected. PEM is a pathologic diagnosis and a common end point of several conditions. Historically, PEM has been associated with altered thiamine status, but more recently an association with high sulfur intake has been seen. Other toxic or metabolic diseases (eg, acute lead poisoning, sodium toxicosis/ water deprivation) can result in PEM as well.

Etiology, Pathogenesis, and Epidemiology:

Polioencephalomalacia is seen sporadically in individual animals or as a herd outbreak. Younger animals are more frequently affected than adults. Pastured animals can develop PEM, but animals on high-concentrate diets are at higher risk, as are cattle exposed to high levels of sulfur, whether in water, feed (rations with byproducts of corn or beets processing), or a combination. The patterns of PEM occurrence depend on the etiologic factors involved.

PEM has been associated with two types of dietary risks: altered thiamine status and high sulfur intake. Thiamine inadequacy in animals with PEM has been suggested by several types of observations, including decreased concentrations of thiamine in

tissues or blood and deficiency-induced alterations of thiamine-dependent biochemical processes (decreased blood transketolase activity, increased thiamine pyrophosphate effect on transketolase, and increased serum lactate). Unfortunately, many of these biochemical features of altered thiamine status are inconsistently observed in cases of PEM, and decreased thiamine status has been observed in diseases other than PEM.

Preruminant animals depend on dietary thiamine. In adult ruminants, thiamine is produced by rumen microbes. Thiamine inadequacy can be caused by decreased production by rumen microbes or factors that interfere with the action of thiamine, eg, plant thiaminases or thiamine analogues. Thiaminases can be produced by gut bacteria or ingested as preformed plant products. They can either destroy thiamine or form antimetabolites that interfere with thiamine function. Thiaminase I, produced by *Bacillus thiaminolyticus* and *Clostridium sporogenes*, and thiaminase II, produced by *B. aneurinolyticus*, catalyze the cleavage of thiamine. The latter microorganism proliferates under conditions of high grain intake.

A neurologic disorder in Australia has been associated with the Nardoo fern (*Marsilea drummondii*), which may

contain high levels of a thiaminase I enzyme. Other ferns, such as bracken (*Pteridium aquilinum*) and rock fern (*Cheilanthes sieberi*), contain a similar thiaminase I. Although PEM has been produced experimentally by feeding high doses of extracts of such plants, field cases are uncommon, because these plants are unpalatable (see p 3089).

Overall, there is not a linear relation among the presence of ruminal and fecal thiaminase, decreased concentrations of tissue and blood thiamine, and development of disease.

A beneficial response to thiamine therapy by PEM-affected animals is sometimes considered evidence of thiamine inadequacy. This thiamine-responsiveness is often seen if treatment is initiated early in the course of the disease. However, the assumption that this response indicates that deficiency of thiamine is the true etiology should be viewed with caution. Large doses of thiamine, beyond maintenance needs, may have nonspecific, beneficial effects in the energy-impaired brain.

PEM associated with high sulfur intake is recognized with increasing frequency. The basis of sulfur-related PEM appears to be the production of excessive ruminal sulfide due to the ruminal microbial reduction of ingested sulfur. Hydrogen sulfide (H_2S) gas, which has the odor of rotten eggs, accumulates in the rumen gas cap. Concentrations can be demonstrated with commercially available H_2S detection tubes via percutaneous gas sampling. Although nonreduced forms of sulfur, such as sulfate and elemental sulfur, are relatively nontoxic, H_2S and its various ionic forms are highly toxic substances that interfere with cellular energy metabolism. The CNS, by virtue of its dependence on a high and uninterrupted level of energy production, is likely to be significantly affected by energy deprivation. When cattle undergo a transition to high sulfur intake, ruminal sulfide concentrations peak 1–4 wk after the change. This pattern is probably due to alterations in ruminal microflora. The occurrence of PEM peaks during the time period when ruminal sulfide concentrations are the highest. Animals with sulfur-associated PEM do not have altered thiamine status.

A variety of sulfur sources can result in excessive sulfur intake, including water, feed ingredients, and forage. Many geographic areas have surface and deep waters high in sulfate. When evaporation occurs, water sulfate concentrations increase. Water consumption by cattle is temperature dependent and increases

greatly at high temperatures, leading to increased sulfur intake due to concurrent increases in water consumption and sulfate concentrations in water. Alfalfa, by virtue of its high protein and sulfur-containing amino acid content, can serve as a significant source of sulfur. Although grasses tend to be low in sulfur, some circumstances can result in high sulfate concentrations. Certain weeds, including Canada thistle (*Cirsium arvense*), kochia (*Kochia scoparia*), and lambsquarter (*Chenopodium* spp), can accumulate sulfate in high concentration. Cruciferous plants normally synthesize sulfur-rich products and serve as important sources of excess sulfur. These include turnips, rape, mustard, and oil seed meals. Byproducts of corn, sugar cane, and sugar beet processing commonly have a high sulfur content, apparently due to the addition of sulfur-containing acidifying agents. PEM has been associated with the use of these types of byproducts as feed ingredients. Corn-based ethanol production has resulted in increased availability of corn byproducts that may vary widely in sulfur content. Wet distillers grains plus solubles have been shown to have sulfur content ranging from 0.44%–1.74% sulfur as dry matter. A high molasses-urea diet has been associated with a form of PEM that lacks altered thiamine status.

Clinical Findings: PEM may be acute or subacute. Animals with the acute form often manifest blindness followed by recumbency, tonic-clonic seizures, and coma. Those with a longer duration of acute signs have poorer responses to therapy and higher mortality. Animals with the subacute form initially separate from the group, stop eating, and display twitches of the ears and face. The head is held in an elevated position. There is cortical blindness with absent menace response but normal bilateral pupillary light reflex. Dorsomedial strabismus may develop. Animals may show ataxia and sometimes a hypermetric gait. As the disease progresses, there is cortical blindness with a diminished menace response and unaltered palpebral and pupillary responses. Dorsomedial strabismus may develop. Head pressing, opisthotonos, and grinding of the teeth may also be seen.

The subacute form of PEM is frequently followed by recovery with only minor neurologic impairment. However, in a few cases, the subacute form may progress to a more severe form with recumbency and seizures. Animals that survive the acute

form or advanced subacute form often manifest significant neurologic impairment that necessitates culling.

Lesions: Gross lesions are inconsistent and frequently subtle, especially early in the disease. Acutely affected animals may have brain swelling with gyral flattening and coning of the cerebellum due to herniation into the foramen magnum. Slight yellowish discoloration of the affected cortical tissue may be present. The brains of acutely affected animals may also have autofluorescent bands of necrotic cerebral cortex evident on meningeal and cut surfaces of the brain when viewed with ultraviolet illumination. As the pathologic process progresses, the affected cerebrocortical tissue has macroscopically evident cavitation, sometimes sufficient to result in apposition of the pia meninges to the white matter.

The initial histologic lesions are necrosis of cerebrocortical neurons. The neurons are shrunken and have homogeneous, eosinophilic cytoplasm. Nuclei are pyknotic, faded, or absent. Cortical spongiosis is sometimes present in the early phases of the acute form. Vessel cells undergo hypertrophy and hyperplasia. At later stages, the affected cortical tissue undergoes cavitation as macrophages infiltrate and necrotic tissue is removed. A pattern seen in brains of cattle with early, severe, acute sulfur-related PEM features multifocal vascular necrosis, hemorrhage, and parenchymal necrosis in deep gray matter, including the striatum, thalamus, and midbrain.

Diagnosis: The pattern of clinical signs should arouse suspicion of PEM. At necropsy, macroscopically evident cerebrocortical autofluorescent areas under ultraviolet illumination provide a presumptive diagnosis of PEM. Characteristic histologic lesions are confirmatory.

Differential diagnoses for cattle include acute lead poisoning, water deprivation/sodium toxicosis, *Histophilus* meningoencephalitis, rabies, coccidiosis with nervous involvement, and vitamin A deficiency. Differential diagnoses for sheep include pregnancy toxemia, type D clostridial enterotoxemia (focal symmetric encephalomalacia), and listeriosis.

Confirmation of etiology or pathogenesis requires laboratory testing of samples from affected animals or their environment. Assessment of thiamine status is difficult, and results should be interpreted with caution. Few laboratories are capable of routinely measuring thiamine content of

blood and tissues, transketolase activity, or the thiamine pyrophosphate effect on transketolase. Demonstration of clinical improvement after thiamine therapy is not adequate evidence for a specific diagnosis.

The possibility of sulfur-associated PEM can be assessed by measuring the sulfur content of the water and dietary ingredients and then estimating the total sulfur intake on a dry-matter basis. The maximal tolerated concentration of sulfur for cattle and sheep depends on the type of diet. For diets >85% concentrate, the maximal tolerable level of total sulfur is 0.3% dry matter. For diets ≥45% forage, the maximal tolerable level of total sulfur is 0.5% dry matter. Because multiple factors are involved in determining the actual risk of developing PEM, these should not be considered as absolute maximal concentrations. Many cattle adapt adequately to sulfur intake levels greater than the maximal tolerable level, although negative effects on performance may occur.

Treatment and Prevention: The treatment of choice for PEM regardless of cause is thiamine administration at a dosage of 10 mg/kg, tid-qid, for cattle or small ruminants. The first dose is administered slowly IV; otherwise, the animal may collapse. Subsequent doses are administered IM for 3–5 days. Therapy must be started early in the disease course for benefits to be achieved. If brain lesions are particularly severe or treatment is delayed, full clinical recovery may not be possible. Beneficial effects are usually seen within 24 hr and sometimes sooner; however, if there is no initial improvement, treatment should be continued for ≥3 days. Reduction of cerebral edema can be attempted with administration of dexamethasone at a dosage of 1–2 mg/kg, IM or SC. Symptomatic therapy for convulsions may be necessary.

Dietary supplementation of thiamine at 3–10 mg/kg feed has been recommended for prevention, but the efficacy of this approach has not been carefully evaluated. During a PEM outbreak, sufficient roughage should be provided. When the problem could be associated with high sulfur intake, all possible sources of sulfur, including water, should be analyzed and the total sulfur concentration of the consumed dry matter estimated. Dietary ingredients or water with high sulfur concentration should be avoided; if this is not possible, then more gradual introduction to the new conditions can improve the chances of successful adaptation.

BOVINE SPONGIFORM ENCEPHALOPATHY

Bovine spongiform encephalopathy (BSE) is a progressive, fatal, infectious, neurologic disease of cattle that resembles scrapie of sheep and goats (*see* p 1288). It was first diagnosed in the UK in 1986. Approximately 200,000 cases of BSE have been diagnosed in cattle, with 97% reported from the UK. In 1992, at the peak of the UK outbreak, 37,280 cases were reported in a single year. Lower incidences were found in cattle native to most European countries and to Israel, Japan, USA, Canada, and Brazil. The economic consequences of the BSE epidemic are important. Countries with BSE cases experienced a dramatic drop of consumer confidence in beef products and trade restrictions of cattle commodities. Since effective control measures have been implemented, BSE incidence has decreased to single cases in 2013.

Etiology: In the 1990s, there was intensive debate on the nature of the BSE pathogen. To date, the most widely accepted hypothesis is that a proteinaceous infectious particle (prion) causes the disease. Prions are misfolded conformational isoforms of host-encoded proteins that induce protein misfolding, protein aggregation, and disease upon transmission to other organisms. This hypothesis is supported by the agent's apparent resistance to heat, freezing, ultraviolet light, and chemical disinfectant procedures effective against bacteria and viruses. Prions are also responsible for scrapie of sheep and goats (*see* p 1288); chronic wasting disease of cervidae (*see* p 1286); transmissible mink encephalopathy (*see* p 1874); and kuru, Creutzfeldt-Jakob disease, fatal familial insomnia, and similar disorders of people. All these conditions are also termed prion diseases, and the related protein is the prion protein (PrP^d, in which d stands for "disease associated"). Based on the anticipated mechanisms that trigger initial PrP^d misfolding, prion diseases are classified as infectious, sporadic, or genetic. The classic type of BSE is caused by infectious prions; however, in the past decade, rare, so-called atypical BSE cases have been described. There is epidemiologic and experimental evidence that classic and atypical BSE differ in their etiology.

Transmission, Epidemiology, and Pathogenesis:

Classic BSE develops as a result of foodborne exposure to prions via contaminated animal-source proteins (meat and bone meal [MBM]) in cattle rations. Horizontal transmission is not a significant source of new BSE infections. Calves born to infected cows are at greater risk of acquiring BSE than calves born to noninfected cows; however, this mode of transmission is of minor importance relative to infections acquired through contaminated feed sources. BSE is not transmitted horizontally by contact or aerosols. There is no sex or breed predisposition. In the UK, clinical disease was more common in dairy cows, probably because they were more likely to be fed animal-source protein supplements. Most cases are diagnosed in cattle 3–6 yr old. The incubation period after exposure is ~2–8 yr, and animals as young as 22 mo have been diagnosed with BSE. The details of pathogenesis are unknown, but studies indicate that after oral exposure the agent replicates in the Peyer's patches of the ileum followed by migration, via peripheral nerves, to the CNS. Atypical BSE cases have been described from countries with no apparent classic BSE epidemic. Moreover, animals affected with atypical BSE are relatively old, and the incidence rates do not follow the trends observed for classic BSE. Together, these findings led to the hypothesis that atypical BSE results from spontaneous prion protein misfolding and is not related to ingestion of prion-contaminated feed. However, the mechanisms that induce the spontaneous prion formation remain obscure. It has been postulated that atypical BSE was at the origin of the BSE epidemic in the UK.

BSE has been transmitted experimentally to many animal species by intracerebral inoculation. During the epidemic of BSE in the UK and continental Europe, a few cases were seen in several species of captive-bred wild ungulates and in domestic companion cats as well as in big cats in zoologic gardens. BSE has also been confirmed in two goats, one from France and another from Scotland, but there is no evidence that BSE infected the small ruminant population on a broader scale.

Clinical Findings: Initial clinical signs are subtle and behavioral in nature. The spectrum increases and progresses over weeks to months, with most animals reaching a terminal state by 3 mo after clinical onset. Commonly observed clinical signs include hyperesthesia, nervousness, difficulty negotiating obstacles, reluctance to be milked, aggression toward either farm personnel or other animals, low head carriage, hypermetria, ataxia, and tremors. Weight loss and decreased milk production are common. Yet, in a large portion of affected animals, clinical signs may be nonspecific, and involvement of the nervous system is not obvious in every case.

Diagnosis: Clinical examinations do not provide a definitive diagnosis. In case of a clinical suspicion of BSE, the animal should be euthanized and the brain subjected to neuropathologic examination. In most countries, BSE is a notifiable disease, and a suspect case must be reported to the veterinary authorities. The OIE has nominated OIE Reference Laboratories to assist national authorities of OIE member states in the diagnosis of BSE. Confirmatory diagnostic methods include PrP^d immunohistochemistry and Western immunoblot in brain tissue. The identification of characteristic vacuolar changes by histopathology in specific target structures of the CNS alone is no longer the method of choice for BSE confirmation. In most countries with a BSE case history, active surveillance programs have been established. Approximately a dozen commercial BSE screening tests are available for active disease surveillance: ELISA, Western immunoblot, and immunochromatographic test formats. All these tests are based on the immunologic detection of PrP^d in medulla oblongata samples.

Differential diagnoses include nervous ketosis, hypomagnesemia, polioencephalomalacia, lead poisoning, ingestion of plant or fungal tremoragens, rabies, listeriosis, and other viral and bacterial neuroinfectious diseases. In contrast to these differential diagnoses, BSE typically has a slow onset of clinical signs, with an extended and progressive clinical course. Veterinarians considering BSE as a likely differential diagnosis should contact national veterinary authorities and ensure that definitive postmortem diagnostic tests are performed.

Treatment and Control: There is no effective treatment or vaccine for BSE. Euthanasia is advisable as soon as there is some certainty of the clinical diagnosis, because animals become unmanageable, and their welfare is at risk.

The most effective control measure is prohibition of the feeding of MBM to cattle. MBM supplements for cattle have been banned in many countries as a consequence of the BSE epidemic. Because of the risk of cross-contamination in feed mills, control has been effected in the UK and other European countries by similar statutory prohibitions of the use of MBM in all farm animal diets.

With the drastic decline of classic BSE cases over the past years, there is an ongoing discussion on possible alleviations of the complete MBM ban from feed of animals other than cattle, ie, of pigs and poultry. In this regard, it is important to remember that any reemergence of BSE will remain unrecognized for years because of the extraordinarily long incubation period of the disease. Moreover, with atypical BSE persisting in the cattle population, there is a constant risk of reintroduction of BSE in the population. This highlights the need to maintain a high level of disease awareness as well as effective surveillance and control measures.

Zoonotic Risk: A novel variant of Creutzfeldt-Jakob disease (vCJD) in the human population in Great Britain, initially seen in 1996, has been associated with the emergence of the BSE agent. Cases of vCJD have also been seen outside the UK. A proportion of the affected individuals had been living in the UK, but cases have been seen in Italy and France among people who had not visited the UK. The single person diagnosed with vCJD in the USA was a recent immigrant from the UK, and it is presumed that this person was exposed and infected while residing in the UK. Infection of people is thought to result from eating infected bovine tissues. As a result, many countries have introduced the statutory removal of high-risk bovine tissues from the human food chain and/or banned human consumption of cattle >24 mo old. No cases of vCJD have been seen in laboratory workers, but appropriate safety precautions for handling the BSE agent and conducting necropsies of cattle suspected of being infected are recommended. Safety precautions should primarily be aimed at avoiding accidental exposures.

CHRONIC WASTING DISEASE

Chronic wasting disease (CWD) is a contagious disease of captive and free-ranging deer, elk, and moose that causes progressive, fatal neurodegenerative disease in adult animals. It is a member of the transmissible spongiform encephalopathy (TSE) family of diseases, or prion diseases, that includes bovine spongiform encephalopathy; scrapie of sheep and goats; transmissible mink encephalopathy; and kuru, Creutzfeldt-Jakob disease (CJD), and variant CJD of people. CWD was first identified as a clinical syndrome in the late 1960s among captive mule deer in Colorado; a decade later, it was recognized to be a spongiform encephalopathy with characteristics similar to those of scrapie (*see* p 1288). It is found in free-ranging populations of mule deer, white-tailed deer, and elk (wapiti) in 18 states (USA) and 2 Canadian provinces. Recently, the first cases of CWD in free-ranging moose were diagnosed in Colorado and in Alberta, Canada. CWD has also been found in farmed elk and white-tailed deer in a number of western states and Canadian provinces and a few midwestern states. CWD has been identified outside of North America only once; a few elk imported into Korea from Canada had CWD. Many states and provinces have developed regulations for control and management of CWD in farmed populations, and federal regulations are in place in Canada and the USA. It is a reportable disease in most jurisdictions.

Etiology: CWD is caused by prions. These unconventional pathogens consist solely of protein, namely the misfolded isoform PrP^{Sc} of the normal host-encoded cellular prion protein (PrP^C), which is a cell surface glycoprotein with highest expression levels in the CNS. On direct binding of PrP^C to PrP^{Sc}, PrP^C adopts the disease-associated conformation. In contrast to PrP^C, PrP^{Sc} is partially resistant to protease digestion and accumulates within neurons, which eventually leads to neuronal death.

CWD is known to naturally affect mule deer, white-tailed deer, elk, and moose. Transmission after oral inoculation of other cervid species, eg, reindeer, has been reported. Experimentally, CWD can be transmitted by intracerebral inoculation to cattle, sheep, goats, domestic ferrets, mink, mice, hamsters, and squirrel monkeys.

Transmission efficiency to cattle varies depending on the cervid species from which the CWD-infected brain homogenate used for infection is derived. A large study to investigate susceptibility of cattle by the more natural route of oral or contact exposure began in 1997, and there has been evidence of CWD in the experimentally exposed cattle. Differences in species susceptibility to CWD probably relate to sequence differences among normal host PrP proteins.

Transmission, Epidemiology, and Pathogenesis: CWD is transmitted horizontally. Because prions are highly resistant to environmental and chemical inactivation, they may accumulate in the environment and thus be available to infect susceptible cervids. Consequently, close confinement of farm-raised cervids will likely potentiate the spread of CWD. Likewise, winter feeding of deer and elk will concentrate cervid populations and likely potentiate horizontal transmission. Foraging on feeding grounds contaminated by urine or feces of infected animals or contact with either infected animals or decomposing carcasses of animals with CWD results in transmission of disease to other susceptible cervids. Vertical transmission has also been reported. The agent probably enters a susceptible host via ingestion and is taken up by lymphoid tissues associated with the GI tract. The agent can be detected in lymphoid, nervous tissues, muscle tissue, antler velvet, blood, saliva, urine, and feces. Prions can be detected in the blood and saliva of infected animals as soon as 3 mo after infection. In urine and feces, detection of prions is also possible already at a preclinical stage of the disease. The agent most likely arrives in the brain by retrograde movement up the vagus nerve to the dorsal motor nucleus of the vagus at the obex region of the medulla oblongata. Spongiform lesions in the brain develop first in the vagal nucleus at about the time of onset of clinical disease. This occurs naturally with an incubation period of ~1.5–3 yr; however, incubation periods in all species known to be affected by CWD are influenced by certain PrP polymorphisms. Prevalence in captive herds of deer and elk may reach nearly 100% in heavily contaminated facilities; prevalence in

free-ranging cervids is extremely variable, from <1% to 40%, in some hunting areas in Wyoming.

The movement of CWD in populations of free-ranging deer and elk follows natural migration routes, often along waterways and natural corridors. In the past, movement of CWD in farmed deer and elk in commerce was through human-facilitated transportation of animals incubating CWD. Now that programs and regulations are in place in most jurisdictions, movement of CWD in live animals should be curtailed. Surveillance, however, should continue, and submission of samples from hunter-harvested animals may be mandatory in areas with a high prevalence of CWD.

Clinical Findings: Animals with clinical CWD are >16 mo old and show a spectrum of signs. The earliest and most difficult to appreciate are subtle changes in behavior and weight loss. These changes are often detectable only by animal caretakers familiar with the individual animal. As the disease progresses, behavioral changes may include alterations in how the animal interacts with herdmates and caretakers, loss of wariness, somnolence, persistent walking, polydipsia and polyuria, and hyperexcitability when handled. Affected animals may show variable locomotor signs, including ataxia (especially posterior ataxia) and head tremors. Late in the disease, animals may have a low head carriage, drooped ears, and fixed staring gaze; they may hypersalivate and grind their teeth. Death after routine chemical immobilization has been noted. Aspiration pneumonia may be the only presenting clinical sign and is often the cause of death. CWD should be suspected in any adult cervid with aspiration pneumonia. Weight loss is progressive throughout the course of disease, even when adequate feed is present, but it is important to recognize that CWD may be present in cervids that are not emaciated. Death of CWD-affected animals may be precipitated by cold weather or other acute stressors. Affected cervids are more susceptible to hunting, predation, vehicle collisions, and other forms of death by misadventure. Carcasses and offal should be disposed of in a manner that limits the exposure of farm-raised and free-ranging cervids to any potentially infectious material.

Lesions: Lesions are seen in the gray matter of the CNS. Lesions are bilaterally symmetrical and anatomically constant among animals. Spongiform appearance is

obvious; vacuolization occurs in neuronal perikarya and neuronal processes. Along with neuronal degeneration, astrocytic hyperplasia and hypertrophy may appear. H&E staining of brains of affected animals reveals amyloid plaques that appear as pale, fibrillar, eosinophilic areas of neuropil and are sometimes surrounded by vacuoles (florid plaques). Detection of PrP^{Sc} in brain sections by immunohistochemistry (IHC) provides a very good way to visualize CWD pathology while maintaining the structural context. A drawback of IHC is that it is not useful in diagnosis of subclinical CWD because spongiform encephalopathy develops about the same time clinical features do. PrP^{Sc} is detected by IHC or immunoblot in a variety of tissues in cervids showing clinical symptoms. Although PrP^{Sc} can be found in regions of the brain not exhibiting spongiform change, typically there is correlation between PrP^{Sc} deposition and spongiform appearance.

Diagnosis: Diagnosis based on clinical signs is not reliable, because they are unspecific and mild at the beginning of disease. Therefore, it depends on detecting disease-associated PrP^{Sc} in CNS or lymphoid tissues. In mule deer and white-tailed deer, the CWD PrP accumulates in the retropharyngeal lymph node before arriving in the brain; thus, it is considered to be the most important tissue to collect for testing. Both brain and lymph node samples should be collected from elk. The correct portion of the brain (ie, the obex, at the caudal end of the fourth ventricle below the cerebellum) must be collected for a meaningful test. The laboratory should be consulted to determine whether the samples must be fixed in 10% buffered formalin, chilled or frozen, or if portions of the samples should be sent both fixed and frozen. Samples should be, and in many jurisdictions are required to be, submitted to certified laboratories to be tested for evidence of CWD. It is good practice either to send the carcass to the diagnostic laboratory or to collect a wide variety of samples, so that if diseases other than CWD are present they will be identified. At a minimum, samples for CWD testing should include brain and retropharyngeal lymph nodes. Many laboratories accept whole heads from cervids for testing. Surveillance programs for free-ranging cervids vary depending on the jurisdiction and are usually conducted by the local wildlife management agency, which should be consulted if CWD is suspected in a free-ranging deer or elk. Surveillance depends mainly on submission of heads

from hunter-harvested animals. In some areas, active surveillance is done by taking biopsies from tonsils, retropharyngeal lymph nodes, and recto-anal mucosa-associated lymphoid tissue (RAMALT). Diagnostic tests include detection of PrP^{Sc} by IHC, ELISA, or Western blot in brain and/or lymphoid tissues. In the USA, these tests are run only at USDA-certified laboratories. ELISA is used as a screening test, and IHC, which is considered the preferred test, is used to confirm positive ELISA.

Nevertheless, more sensitive *in vivo* diagnostic tests are desirable. Using *in vitro* conversion such as protein misfolding cyclic amplification (PMCA) or real-time quaking-induced conversion assay (RT-QuIC), CWD prions are detectable already at a preclinical stage in specimen that can be obtained antemortem by noninvasive methods, such as blood, urine, feces, or saliva. However, these newly developed assays are not yet certified.

Differential diagnoses for animals suspected of CWD include brain abscesses, traumatic injuries, meningitis, encephalitis, peritonitis, pneumonia, arthritis, starvation and nutritional deficiencies, dental attrition, and anesthetic deaths.

Treatment and Control: There are no treatments available for any TSE. Control in farmed cervids is by depopulation with indemnity and development of a National CWD Herd Certification Program in the USA. This is designed to be a voluntary federal-state-industry cooperative program administered by the USDA Animal and Plant Health Inspection Service. This plan typically requires 5 yr of monitoring to achieve the highest status. The bases for CWD control programs in the farmed cervid industry are individual animal identification, CWD testing in all animals in the herd that die over a certain age, and limiting new herd additions to animals from herds of comparable or higher CWD status.

Control of CWD in free-ranging populations is extremely difficult and varies depending on the location. All jurisdictions have banned movement of live cervids from endemic areas for translocations, and many have regulations on movement of parts of hunted deer and elk. In areas where CWD occurs, attempts at control have included population reduction, test and removal, and intensified surveillance.

Only a few disinfectants and methods of disposal inactivate prions. Fresh household bleach at 50% concentration for 30–60 min or sodium hydroxide (1 M) for 60 min will inactivate the agent and is inexpensive and readily available but may be corrosive to some surfaces and instruments. Additional disinfectants are being considered for general use but are not yet approved. Incineration in a medical incinerator, alkaline digestion in specially designed equipment, and disposal in certified municipal landfills are used for disposal of tissues and carcasses of animals with CWD.

Zoonotic Risk: Although CWD has been present in hunted populations of deer and elk for >30 yr, no case of human CWD has been identified. The risk to people appears to be minimal. The CWD agent has been detected in the muscle tissue of infected cervids. Public health authorities and wildlife management agencies suggest the following precautions for hunters and people handling cervids in areas where CWD is found to further reduce risk of human exposure: do not harvest deer or elk that appear to be sick or abnormal; wear rubber, plastic, or latex gloves when dressing the carcass; avoid contact with brain, spinal cord, and lymphoid tissues; debone the meat when processing; disinfect knives, saws, and tables with 50% bleach; and have the animal tested for CWD. All public health authorities recommend that animals positive for any TSE not be consumed by people or other animals.

SCRAPIE

Classic scrapie, a natural disease of sheep and goats, is seen worldwide except in Australia and New Zealand. It is one of the transmissible spongiform encephalopathies (TSE), related to bovine spongiform encephalopathy and chronic wasting

disease of deer and elk, all of which are thought to result from the accumulation of an abnormal form of a cellular protein in the brain. Natural transmission of scrapie to other species has not been shown. In the USA, scrapie primarily affects black-faced

sheep breeds (eg, Suffolk, Hampshire, and their crosses), accounting for ~96% of cases. In other countries, the disease is commonly seen in other breeds, including those with white faces.

Etiology, Transmission, and Pathogenesis:

An abnormal protein designated as PrP^{Sc}, found in all TSE, appears to convert a normal cellular protein called prion protein (PrP^C) to its abnormal form (PrP^{Sc}) in susceptible animals. In sheep, the susceptibility is controlled genetically; however, genetic susceptibility has not been established in goats. As it accumulates within a cell, PrP^{Sc} is deposited as an amyloid plaque in lymphoreticular and nervous tissue, where its accumulation is hypothesized to cause the nervous signs associated with the disease. Although some researchers still do not believe that PrP^{Sc} itself is the disease agent, its presence is a reliable diagnostic test for prion disease.

When PrP^C is induced to change to PrP^{Sc}, the conformation of the protein's structure is reconfigured. Although the chemical composition of the molecule is the same, its chemical properties change. The normal protein is soluble in denaturing detergents and is digested by cellular proteases such as proteinase K. However, PrP^{Sc} (as well as the infectivity) is not destroyed by detergents and is resistant to breakdown by rendering processes presently used, heat sterilization temperatures, ultraviolet light, ionizing radiation, and most disinfecting agents. It is only partially inactivated by protease K.

The genetics of scrapie in sheep is located on chromosome 13, and three codons (136, 154, and 171) seem to control most of the susceptibility to scrapie. Codon 136 codes for either valine (V), alanine (A), or threonine (T); 154 codes for arginine (R) or histidine (H); and codon 171 codes for glutamine (Q), lysine (K), H, or R. Resistance to scrapie is correlated with 136A, 154H, and 171R. These small changes in the amino acid components of PrP^C apparently enable it to resist reconfiguration. Scrapie is usually related to polymorphisms at codon 171. Among sheep in the USA, 91% of brain samples testing positive for scrapie originated from sheep with the 136/154/171 AARRQQ genotype. However, sheep with codon 136V are at the highest risk of developing scrapie, even when they also carry one R at codon 171. Recently, it was shown that these cases are actually affected by another strain of the agent that at one time was referred to as the V-dependent strain. It was first described in Cheviots by Irish researchers and has been reported in

Europe and the USA. The 171RR genotype is considered to be resistant to classic scrapie. Scrapie is also rare in sheep with the 136/171 AAQR genotype. However, at least 83 atypical cases of scrapie from more than 110,000 tested samples have been recorded by The Veterinary Laboratories Agency of Great Britain. These discordant cases, most classified as Nor 98 (first found in Norway in 1998) usually involve only a single sheep in a flock with no obvious contacts between affected flocks. Nor 98 has been seen in sheep with genotypes considered to be resistant, and many of them have one or two of the amino acid leucine (L) at codon 131. This has led to the belief that such cases represent a spontaneous prion disease, analogous to sporadic Creutzfeldt-Jakob disease in people, and that the prion is not transmitted by direct contact. It has been reported in almost every European country, the Falklands, Canada, and New Zealand, even though classic scrapie has not been reported from New Zealand. Eight such cases have been reported in the USA since 2003; the World Health Organization has classified this as a separate disease and declared that it should not affect trade.

The classic disease is naturally transmitted during lambing from infected dams via ingestion of infected placenta or allantoic fluids by flock mates and newborn lambs. Infected males are not believed to transmit the disease, although there is one report of PrP^{Sc} detected in semen of several 131/171 VVQQ and AVQQ V-dependent scrapie affected-rams. This occurred after apparent transmission of scrapie to some of their offspring from 131/171 VVQQ scrapie eyelid and rectal mucosa-negative ewes. However, because of the rarity of 136/171 VVQQ genotype in the USA at this time, it is unlikely that this should be of concern.

The embryo or fetus is not exposed to scrapie while in utero in a scrapie-infected dam, because there is physical separation from PrP^{Sc}-containing allantoic fluid and chorioallantois by the amnion, which remains free of PrP^{Sc} even when the other placental tissues are infected. Lambs delivered via cesarean section from infected dams, kept separate from the allantoic fluid, and isolated from infected sheep remain disease free. Despite the wide distribution of normal prion protein in reproductive, placental, and fetal fluids, PrP^{Sc} has been detected only in the caruncular portion of the endometrium and cotyledonary chorioallantois (the fetal-maternal interface) of pregnant scrapie-infected ewes—but only if both the dam and fetus are of a susceptible genotype. Although

tissues of the maternal side of the placenta carry a susceptible prion protein, it requires susceptible prion-containing cells from the fetal side of the placenta for conversion to PrP^{Sc}. However, there can be partial or incomplete anastomosis between fetal blood supply to the cotyledons among fetuses of different genotypes on the same side of the uterine horn, which in rare cases can result in PrP^{Sc} accumulation in cotyledons with resistant genotypes.

Previous contamination of premises is believed to be another source of scrapie infection. Anecdotal accounts abound of flock depopulation and premises decontamination that are followed by recurrence of disease in repopulated infection-free but susceptible sheep.

Clinical Findings: Classic scrapie, which results from ingestion of PrP^{Sc} by a genotypically susceptible sheep, is a longterm, progressive, and debilitating neurologic illness believed to always be fatal. Clinical signs may be noticed 18 mo to 5 yr after exposure and include progressive weight loss with no concurrent loss in appetite, progressive ataxia, fine head tremors (most apparent in the ears), and cutaneous hypersensitivity. Pruritus develops in ~70% of cases. Sheep may assume a vacant, fixed stare or, less often, become suddenly aggressive. Signs of hypersensitivity are often elicited by rubbing or scratching the sheep's back, which induces the sheep to throw its head back, make chewing motions and lick at the air, or compulsively nibble at the limbs below the carpus.

Ataxia is first detected when sheep are running. The hindlimbs appear to be uncoordinated with the forelimbs, and affected animals adopt a bunny-hopping gait. Sheep often have a high-stepping gait in the forelimbs, resembling a prancing horse. As signs worsen, the hindquarters sway while standing.

Clinical signs last from 1 to >3 mo; sheep generally become recumbent because of weakness and incoordination. If helped up, an affected sheep may be able to remain standing for hours but cannot rise unassisted if it falls or lies down. Death follows 1–2 wk after a sheep can no longer right itself. Blindness, resembling that seen with polioencephalomalacia, occasionally develops. The clinical signs of scrapie can vary, depending on the sheep's genotype and the strain of scrapie. The V-dependent strain has a substantially more rapid clinical course of 3–30 days and death in 2–3 days after recumbency. In these cases, weight

loss and signs of pruritus are often not seen. This strain, found in the University of Idaho research flock, made up of local flocks found to have scrapie, mainly infects 131/171 VVQQ and 131/171 AVQR sheep. It is probably present whenever scrapie and the 136AV and VV genetics are found together. Most veterinarians or producers would not recognize sheep with the V-dependent gene as having scrapie.

Diagnosis: A complete necropsy should be performed on any sheep dying mysteriously, including submission of the brain for immunohistochemical (IHC) testing for scrapie. Differential diagnoses include caseous lymphadenitis, abomasal emptying disease, Johne disease, ovine progressive pneumonia (visna), dentition problems, and meningitis.

Currently, all diagnostic tests for TSE require infected tissue and the use of antibody reactions. Because animals generally do not produce antibodies against self, antibodies are mostly monoclonal in origin or are made in rodents bred to have no prion protein. IHC and ELISA are used for routine testing. In the EU, ELISA tests are used for slaughter surveillance, but they are not licensed for scrapie testing in the USA. However, several test kits are used for diagnosis of chronic wasting in wild elk and deer. The IHC test is used as a confirmatory test and is considered to be the gold standard worldwide.

Detection of PrP^{Sc} in reticuloendothelial organs (spleen, lymph nodes) before appearance of clinical signs or PrP^{Sc} in the brain is possible. Detection of PrP^{Sc} has been reported in 76% of tonsils examined and 57% of lymphoid tissue specimens collected from the third eyelid of infected sheep. A small percentage of sheep in which the brain contains PrP^{Sc} do not have detectable PrP^{Sc} in the lymph nodes, which may be influenced by genotype or scrapie strain. The atypical strains are not often found in lymphoid tissues.

The palatine tonsil has been used for biopsy and diagnosis; biopsy of the lymph follicles of the third eyelid is simpler and is validated in the USA as a diagnostic test. It yields a high percentage of unreadable samples due to lack of follicles in the sample in as many as 40%–60% of adult sheep. Biopsy of the lymphoid ring in the rectal mucosa has also been validated and yields positive diagnoses in ~55%–65% of positive sheep. Use of the mandibular lymph nodes has not been validated; however, biopsy of that site may be useful diagnostically, because examination of

several tissues improves the chances of a positive diagnosis. It has not been established in the course of the disease when the agent will consistently appear in these tissues, but it may be as early as 14 mo after exposure. The interval likely depends on the age of the sheep at exposure and genotype or strain of scrapie.

The pathologic changes associated with scrapie are confined to the CNS and include vacuolation, neuronal loss, astroglyosis, and accumulation of amyloid plaques. However, because histologic changes are often lacking, diagnosis is made on the basis of IHC staining of the obex, other parts of the brain, and/or lymphoid tissue for PrP^{Sc}.

Control: For disinfection, instruments should be soaked in 2.5N NaOH or a disinfectant shown to be effective against abnormal prions. Incineration or digestion by sodium hydroxide are considered appropriate to adequately inactivate infected carcasses.

Individual and premises identification are required for all breeding sheep leaving their original premises as part of the USA mandatory Scrapie Eradication Program. A scrapie slaughter surveillance program initiated by the USDA/APHIS has been underway since 2003 in which brains and

lymphoid tissue of aged black-face and black-face crosses and sheep sold for slaughter with signs of scrapie (ataxia, poor body condition scores, alopecia from rubbing) are tested for scrapie by IHC. Sheep found to be positive are traced back to the herd of origin, which is quarantined, and all animals are tested. All positive sheep and those with the 171QQ genotype are euthanized. Animals sold from the flock are also traced and tested. Since the program was initiated, the prevalence of scrapie has decreased 90%, from ~0.5% to ~0.015% as of the end of 2013. The goal is to have the USA declared free of scrapie by 2017.

Voluntary efforts to control and eliminate the disease have been undertaken by producers in the USA by selecting sheep with at least one 171R codon and culling sheep with susceptible genotypes; the expectation is that the remaining sheep will be resistant to scrapie infection. However, some concern has been expressed that reliance on genetics for elimination of the disease may inadvertently select for the atypical strain of scrapie that infects the 171RR genotype. So far there are no data to support that concern.

Rules prohibiting ruminant-to-ruminant protein feeding have been in place in many countries for >10 yr.

EQUINE ARBOVIRAL ENCEPHALOMYELITIS

(Equine viral encephalitis)

Equine encephalitides can be clinically similar, usually cause diffuse encephalomyelitis (see p 1262) and meningoencephalomyelitis, and are characterized by signs of CNS dysfunction and moderate to high mortality. Arboviruses are the most common cause of equine encephalitis, but rabies virus, *Sarcocystis neurona* (see p 1309), *Neospora hughesii* (see p 663), equine herpesviruses, and several bacteria and nematodes may also cause encephalitis. Arboviruses are transmitted by mosquitoes or other hematophagous insects, infect a variety of vertebrate hosts (including people), and may cause serious disease. Most pathogenic arboviruses use a mosquito to bird or rodent cycle. Tickborne encephalitides are also a differential cause in the eastern hemisphere. Arboviral diseases are ever emerging, and there are

arboviruses pathogenic to horses on virtually every continent.

Etiology and Epidemiology of Arboviral Encephalitides:

Alphaviruses: North America is home to some of the most pathogenic encephalitic viruses because of the enduring endemic status of alphaviruses of the family *Togaviridae*. Endemic species in North, Central, or South America include Eastern equine encephalitis virus (EEEV), Western equine encephalitis virus (WEEV), Highlands J virus, Venezuelan equine encephalitis virus (VEEV), Everglades virus, and Una virus (see TABLE 3). Other alphaviruses associated with equine encephalitis are Semliki Forest virus in Africa and Ross River virus in Australia and the South

TABLE 3

ARBOVIRUSES THAT CAN CAUSE OR ARE LINKED TO EQUINE ENCEPHALOMYELITIS

Virus Species or Variant	Geographic Location	Most Important Reservoir
ALPHAVIRUSES		
North American Eastern equine encephalitis virus	Eastern North America, primarily east of Mississippi river	Birds
Madariaga virus	South America, Caribbean	Rodents
Western equine encephalitis virus	Western South America	Birds, rabbits, and snakes
Highlands J virus		Birds
Venezuelan equine encephalitis virus	Central and South America, Caribbean	Cotton rat and other rodents
Everglades virus	South Florida (USA)	Rodents
Ross River virus	Australia, Papua New Guinea	Marsupial and placental mammals
Semliki Forest virus	East and West Africa	Unknown
Una virus	South America	Birds
FLAVIVIRUSES		
Japanese encephalitis	Asia, India, Russia, Western Pacific	Birds, swine
Murray Valley	Australia, Papua New Guinea	Birds, marsupials, and foxes
Kunjin virus	Australia	Birds (herons and ibis)
St. Louis encephalitis	North, Central, and South America	Birds
Usutu	Europe, Africa	Birds
West Nile	Africa, Middle East, Europe, North, Central, and South America, Australia	Passerine birds
Louping ill	Iberian Peninsula, UK	Sheep, grouse
Powassan	North America, Russia	Lagomorphs, rodents, mice, skunks
Tickborne encephalitis	Asia, Europe, Finland, Russia	Small rodents

Pacific. EEEV has two distinct antigenic variants that are separated longitudinally. The North American variant is the most pathogenic and is found in eastern Canada; all states within the USA east of the Mississippi River and in Arkansas, Minnesota, South Dakota, and Texas; and in the Caribbean Islands. The South American variant is less pathogenic and confined to central and South America and is now called Madariaga virus (MADV).

EEE and WEE viruses are separated in North America primarily latitudinally; however, WEEV is relatively heterogeneous, with several subtypes consisting of WEE, Highlands J virus, Sindbis, Aura, Ft. Morgan, and Y 62-33. Several variants have been found in horses (see TABLE 3). WEE is found in western Canada, states in the USA west of the Mississippi, and in Mexico and South America. WEE previously isolated in the south and eastern USA has been shown to

belong to the Highlands J virus serogroup. VEE has six antigenically related subtypes: subtype I, Everglades, Mucambo, Pixuna, Cabassou, and AG80-663. Subtype I serovars AB and C primarily cause epizootics; subtype I and serovar IE caused a large outbreak in Mexico in 1993. Epizootic strains are not generally found in the USA, although there was an epizootic of VEE in 1971. Sylvatic subtype II (Everglades) has been isolated from people and mosquitoes in Florida; subtype III has been isolated in the Rocky Mountains and northern plains states.

The general life cycle of alphaviruses involves transmission between birds and/or rodents and mosquitoes. In North America, theoretically, EEEV is perpetuated in a sylvatic cycle between avian hosts (passerine birds) and mosquitoes, with primary transmission in this cycle via *Culiseta melanura*. Birds do not develop disease but develop sufficient viremia for transmission to mosquitoes unless the bird belongs to an introduced species that in North America includes European starlings, house sparrows, pheasants, and enus. Field work in Alabama indicates that the northern cardinal is the primary target for *C. melanura* feeding; however, other mosquitoes (*C. erraticus*) are capable of feeding on a wider variety of birds, including robins, chickadees, owls, and mockingbirds. Mammalian reservoirs may also be important during years of high EEEV transmission. Experimental infection of cotton rats, a marshland rat found throughout the Americas, resulted in viremia just being capable of transmitting EEEV, with juvenile rats developing higher titers and 100% mortality to infection.

Horses and people are clinically affected but do not develop viremia sufficiently high enough to transmit virus to mosquitoes and so are considered "dead-end" hosts. However, young animals are more susceptible to EEEV, and it is not known how important non-neural tissues are for harboring high viral infection. Presumed extraneural sites of infection include cardiac tissue and bone marrow. During epizootics, alpacas, llamas, cattle, swine, cats, and dogs can develop disease. Snakes have been identified as a possible reservoir.

Freshwater hardwood swamps are the most associated enzootic niche for EEEV. In the southern USA, which has the highest number of reported annual cases, reemergence within mammalian hosts is associated with "tree farms" that often function as inland freshwater swamps. Nonetheless, EEEV disease occurs frequently in naive

horses in southeastern habitats not associated with sylvatic field ecology, so a full understanding of the epizootic cycle still remains to be elucidated. Intense focal activity has been reported in Michigan, Wisconsin, Ohio, Massachusetts, and New Hampshire. In 2005, Massachusetts experienced a human case affected rate more than five times that of the preceding 10 yr; affected people resided within 1/2 mile of a cranberry bog or swamp associated with forest habitat.

In Central and South America, the principal vectors of MADV belong to *Culex (Melanoconion)* spp. These vectors feed on birds, rodents, marsupials, and reptiles, with rodent reservoirs possibly featuring more importantly in this life cycle. Before the year 2000, comparatively few epizootics of disease caused by MADV in horses were recorded in South America, with minimal disease reported in people. Furthermore, there are notable differences in virulence between EEEV strains in South America vs in North America. In 2008 and 2009, larger outbreaks occurred in Central and South America. In northeastern Brazil, 229 horses were affected, with a case fatality rate of 73% and disease severity similar to that of EEEV in North America.

WEE is transmitted primarily by *C. tarsalis*, which is found just west of the Mississippi river and throughout the West. This mosquito breeds in sunlit marshes and in pools of irrigation water in pastures. WEE can also be transmitted by the tick *Dermacentor andersoni*. Epizootics of WEE are associated with increased rainfall in early spring followed by warmer than normal temperatures.

Sylvatic VEE viruses are found throughout North, Central, and South America in jungle or swampy areas. Two cycles occur with VEEV, the enzootic cycle and the epizootic cycle. The mosquitoes that serve as the primary vectors for the bird- or rodent-mosquito life cycle are members of the subgenus *Melanoconion (Cedecei)*. Epizootics are associated with a mutation to a subtype I (AB, C, and possibly E), a change in mammalian pathogenesis, and a change to several bridge vectors. The enzootic cycle centers around sylvatic rodents such as spiny and cotton rats, which have high natural infection rates and can develop viremia high enough to transmit VEEV to mosquitoes. Opossums, bats, and shore birds likely contribute to dispersal of the enzootic virus so that constant cycling occurs. When epizootics occur with mutation of the virus and this change in mosquito vectors, equine infection becomes

a predominant feature in the maintenance of epizootic VEE. All mammalian hosts are capable of developing a high-titer viremia of ~10⁶ plaque-forming units/mL for up to 5 days, but the horse is likely to be the most important mammalian host in terms of vector capacity.

Flaviviruses: In general, viruses belonging to the Flaviviridae and Bunyaviridae families are less pathogenic than the Togaviridae; however, viral encephalomyelitis caused by any of these pathogens is a potentially catastrophic illness for any vertebrate host. There are 53 species of flaviviruses, and many are clinical pathogens for horses, including Japanese encephalitis, West Nile virus (WNV) encephalitis, Kunjin virus (KUN), and Murray Valley encephalitis virus. Overall, the diseases caused by the Japanese encephalitis serogroup are similar (see TABLE 3). All of these viruses are transmitted by a mosquito vector, with *Culex* spp usually the most efficient transmitter. KUN is actually a strain of WNV and is found in Australia, some southeast Asia countries, and New Guinea. Disease in horses caused by Murray Valley fever is geographically restricted to the South Pacific and is sporadic in occurrence.

WNV has the widest geographic distribution of all of the flaviviruses. Prior to 1999, WNV was recognized in Africa, the Middle East, Asia, and occasionally in European countries. In 1999, WNV infection was first recognized in North America. Since then, the virus has spread throughout the USA and parts of Canada and Mexico. WNV isolated from the outbreak in New York in 1999 appears to be closely related to an isolate recovered from geese in Israel in 1998.

Since 2010, continued worldwide spread and reemergence of many flaviviruses, especially WNV, has occurred. As of 2014, WNV is recognized as having seven lineages, with lineage 1 (sublineage 1a, 1b, and 1c) and lineage 2 affecting people and horses. Lineage 1a activity in the USA and Europe dominated much of the end of the 1990s until the mid-2000s, causing neuroinvasive infections in people and horses in Africa, Europe, Australia, Asia, North and Central America, and the Middle East. In 2012, a very large epizootic occurred in the USA, with 5,674 human and 690 equine cases reported. New emergences have occurred in Greece and Serbia, and the first lineage 1a case in India was detected in 2012. Lineage 1b viruses are primarily represented by KUN, with Australia undergoing the largest epizootic of arboviral disease in 2011,

involving 900 horses. Although multiple pathogens were detected, including KUN, Murray Valley encephalitis virus, and Ross River virus, there was emergence of a new strain of KUN. The 1c viruses are fairly nonpathogenic and found in India. (This sublineage may soon be designated as lineage 5.) Lineage 2 strains, long considered African based and inducing mild disease in horses, is also expanding globally with increased neuroinvasive activity. Neuroinvasive disease due to lineage 2 has emerged across Europe in Hungary, Austria, Italy, and Greece, which had at least four epizootic cycles with cases of neuroinvasive disease identified in horses.

Both wetland and terrestrial birds may be involved in the natural cycle of WNV, with migratory birds thought to introduce the virus into a geographic region. However, a wide range of infected birds (~326) have high, sustained viremia and little or no clinical disease (passerines). Fatal infections among corvids (eg, crows, blue jays, and magpies) have been the hallmark of WNV infection in the USA. Ticks have been demonstrated to be infected with WNV, but their role in natural transmission is unknown. Experimentally, transmission has been documented between cohabitating birds and from oral exposure to WNV in drinking water in birds. Oral transmission has been demonstrated experimentally in several types of raptors.

In people, other important routes of infection include blood transfusions, organ donation, breast milk, and across the placenta. Sporadic infections and illness have also occurred in several other mammalian species, including dogs, cats, camels, sheep, and squirrels. Oral transmission has been demonstrated experimentally in cats. Farmed alligators have demonstrated disease and mortality due to WNV, and there has also been a report of WNV-induced disease in crocodiles. Alligators are susceptible to oral infection. In addition to birds, only alligators have consistently demonstrated high enough viremia (10⁴–10⁵ plaque-forming units) to amplify virus, serve as reservoir hosts, and transmit virus back to mosquitoes.

Most equine-associated flaviviruses are maintained in an enzootic transmission cycle between wild birds and mosquitoes, although tickborne encephalitis found in Eurasia can cause disease in horses. Many species of mosquitoes can transmit the equine virulent viruses, although *Culex* spp are principal vectors to maintain enzootic activity. *C pipiens* complex and *C tarsalis*

are thought to play the largest role in natural transmission in North America. In the eastern and Midwestern regions of the USA, *C. pipiens* is one of the major vectors, whereas in the western regions of the USA, *C. tarsalis* is thought to be one of the most efficient vectors.

Bunyaviruses: Cache Valley virus (transmitted by mosquitoes and *Culicoides* sp among rabbits), Main Drain virus (transmitted by *Culicoides varipennis* among hares and rodents in the western USA), and snowshoe hare virus (transmitted by *Culiseta* and *Aedes* mosquitoes among rabbits in southern Canada and northern USA) have all been identified, although infrequently, as the cause of encephalitis in horses.

Clinical Findings of Viral Encephalomyelitis in Equids: The initial clinical signs are similar for the arboviruses; progression of clinical signs and severity of disease are the differentiating features. Initially, horses are quiet and depressed, with clinical neurologic signs generally occurring 9–11 days after infection. Compared with WEE and WNV disease, clinical signs of EEEV (and VEEV) encephalomyelitis more frequently include altered mentation, impaired vision, aimless wandering, head pressing, circling, inability to swallow, irregular ataxic gait, paresis and paralysis, seizures, and death. Spinal signs are often symmetric with ataxia in all limbs, rapidly progressing to quadriparesis, along with intensification of forebrain signs. Many horses progress to recumbence within 12–18 hr of onset of neurologic abnormalities. Most deaths occur within 2–3 days after the onset of signs.

The clinical signs and course of disease are highly variable in WNV disease and other flavivirus encephalomyelitis. Presenting complaints most often include neurologic abnormalities; other common initial complaints include colic, lameness, anorexia, and fever. Initial systemic signs include a mild fever, feed refusal, and depression. Neurologic signs are highly variable, but spinal cord disease and moderate mental aberrations are most consistent. Spinal cord disease manifests as asymmetric, multifocal or diffuse ataxia and paresis. Severe manifestations of WNV may occur independently in the fore- or hindlimbs, unilaterally, or in a single limb. In all clinical studies published to date, for WNV, >90% of affected horses developed some type of spinal cord signs, whereas 40%–60% developed behavioral changes

characterized by periods of hyperesthesia, ranging from mild apprehension to overt hyperexcitability, with fractious reactions to aural, visual, and tactile stimuli. Fine and coarse tremors of the face and neck muscles are common, described in 60%–90% of horses. Some horses have periods of cataplexy or narcolepsy that may render them temporarily or permanently recumbent.

Cranial nerve deficits can be seen in all arbovirus infections of horses; these include most cranial nerves with cell bodies located in the mid- and hindbrains. Weakness and/or paralysis of the face and tongue are most frequent. Horses with facial and tongue paresis can be dysphagic, and overt signs of quidding or even esophageal choke can develop. Many horses with severe mental depression and facial paresis will keep their heads low, resulting in severe facial edema. Occasionally, head tilt may be seen. Infrequently in WNV disease, urinary dysfunction ranging from mild straining to stranguria has been reported, making differentiation from equine herpesvirus 1 (EHV-1) more challenging.

During the neurologic phase, horses frequently thrash and injure themselves. Sepsis from trauma in recumbent horses also occurs. Prolonged recumbency leads to pulmonary infections, especially in foals, in which a long duration of slinging and treatment may be pursued more frequently than in large, recumbent animals. Dysphagia leads to decreased water and food intake, with renal damage due to concurrent use of anti-inflammatory drugs. Skin and muscle necrosis are common in recumbent horses. Life-threatening trauma can also occur, including a ruptured diaphragm and fractures.

Lesions: All necropsies on horses suspected of viral encephalitis should be performed with all participants wearing personal protective gear (ie, waterproof gown, boots, gloves, N-95 or N-99 mask, face shield, and hair covering). Gross lesions are most common with EEEV and severe VEEV disease and are characterized by widespread and prominent congestion of the meninges. In other infections, gross lesions are rarer and are limited to small multifocal areas of discoloration and hemorrhage throughout the brain and spinal cord. The brain should be examined microscopically for the presence of meningoencephalitis. In EEEV infection, a severe gliosis with necrosis of the neuropil is seen in the cerebrum and extending through the corona radiata through the hindbrain and cervical spinal cord.

Although mononuclear cells are present, neutrophils are widespread and diffusely distributed. The gliosis is less nodular than in WNV, and when there are accumulations of cells, there is extensive necrosis and often frank microscopic hemorrhage within and around lesions. In milder cases and in WNV infections, microscopically there is a non-necrotizing lymphohistiocytic poliomeningoencephalitis. Slight to severe inflammation, characterized by perivascular cuffing of lymphocytes and monocytes, is usually present. In more severe cases, there can be extravasation of fluid and red blood cells from vessels. Often the distribution of lesions is multifocal, with more severe lesions present in grey matter. In the neuropil, dying neurons often are surrounded by microglial cells. The most severe gliosis and perivascular cuffing is often in the midbrain (thalamus, hypothalamus) and hindbrain (pons and medulla), extending into the cerebellum. Lesions can be multifocal in the spinal cord and can be more severe in the lumbar cord.

Diagnosis: No consistent changes in clinical pathology have been found in equine viral encephalitis. With EEEV and WNV in horses, peripheral lymphopenia is common. Horses are frequently azotemic, likely from decreased food and water intake.

In general, no pathognomonic signs distinguish flavivirus infection in horses from other CNS diseases, and a full diagnostic evaluation should be performed. Confirmation of flavivirus infection with encephalitis in horses begins with assessment of 1) whether the horse meets the case definition based on clinical signs; (2) whether the horse resides in an area in which flavivirus has been confirmed in the current calendar year in mosquitoes, birds, people, or horses; and (3) lack of appropriate vaccination.

In terms of antemortem diagnostic testing, analysis of CSF can be a valuable adjunct to presumptive clinical assessment. CSF analyzed from horses with acute EEEV infection typically shows a neutrophilic pleocytosis with markedly increased total solids. Horses infected with EEEV that are partially immune may have predominantly mononuclear cells, but nondegenerate neutrophils are still present. Although WNV-infected horses can have normal CSF, if the CSF is abnormal, there is a mononuclear pleocytosis with moderately to markedly increased total solids. In a few horses with acute infections, virus may be isolated from the CSF. By the time

neurologic signs are seen, viremia has ended and detection of virus in the plasma of clinically affected horses is of no value.

Serology is the key to antemortem diagnosis of recent alphavirus and flavivirus infection in horses showing clinical signs. IgM antibody rises sharply and is increased in 85%–90% of horses with clinical arboviral encephalitis. Thus, the IgM capture ELISA is the test of choice to detect recent exposure to these viruses. Neutralizing antibody titers (primarily IgG) develop slowly during this time and stay increased for several months. Although neutralizing antibody tests will differentiate between subtypes of these viruses, and are thus considered the gold standard for confirmatory serology, paired serum samples are essential to detect recent exposure and to differentiate antibody response due to field infection from vaccine responses for any of these viruses. Because virus-neutralizing antibodies appear at the end of viremia and may precede appearance of neurologic signs, paired samples may not show a 4-fold increase in horses while demonstrating neurologic signs. In horses that succumb without premortem and postmortem testing, paired samples from febrile herdmates may be necessary to confirm presence of arbovirus activity within a locale. Maternal antibodies may interfere with neutralizing responses in young foals. This response is confounded by recent vaccination. The most common neutralizing antibody test formats are the classic plaque reduction neutralization test (PRNT) and a microwell format test. Practical application of the microwell vs the PRNT indicates that the endpoint titer in the microwell test can be several logs higher than in the PRNT, so results cannot be compared between samples.

Several postmortem diagnostic assays are available and, although specific, they vary in sensitivity, depending on the virus. The midbrain and brain stem have the highest concentrations of encephalitic viruses, including rabies virus. Immunohistochemistry and PCR testing for EEEV and EHV-1 are relatively straightforward compared with that for WNV. Diagnostic testing continues to confirm the unreliability of detection of virus, even by PCR, because of the low viral load in WNV infection. Often, only a single neuron in one or two sections may yield positive virus staining in the horse by immunohistochemistry. When tested by PCR, the limited viral load dictates accurate testing of appropriate tissues consisting of several locations, including thalamus, hypothalamus, rostral

colliculus, pons, medulla, and anatomically identified spinal cord. Viral isolation is still important for molecular epidemiology.

Infectious and noninfectious causes of brain and spinal cord diseases should be considered as differential diagnoses. Infectious causes include alphaviruses, rabies, equine protozoal myeloencephalitis (see p 1309), and EHV1; less likely causes are botulism and verminous meningoencephalomyelitis (eg, *Halickephalobus gingivalis*, *Setaria* spp, *Strongylus vulgaris*). Noninfectious causes include hypocalcemia, tremorigenic toxicities, hepatoencephalopathy, and leukoencephalomalacia.

Treatment: Treatment of viral encephalitis is supportive, because there are no specific antiviral therapies. Management is focused on controlling pain and inflammation, preventing injuries associated with ataxia or recumbency, and providing supportive care. Intervention does not appear to significantly affect the outcome of most fulminate EEEV infections. For WNV, flunixin meglumine (1.1 mg/kg, IV, bid) early in the course of the disease decreases the severity of muscle tremors and fasciculations within a few hours of administration.

Recumbent horses that are mentally alert frequently thrash, causing self-inflicted wounds and posing a risk to personnel. Responses to tranquilizers and anticonvulsant medications are variable, depending on the virus and severity of disease. A sling and hoist may be used to assist horses that are recumbent and have difficulty rising; however, recumbent horses with EEEV generally are too comatose to sling. Dysphagic horses require fluid and nutritional support.

Until equine protozoal myeloencephalitis is excluded, prophylactic antiprotozoal medications may be instituted. Other supportive measures (eg, oral and parental fluids and nutrition for dehydrated and dysphagic horses) are also important. Broad-spectrum antibiotics should be given for treatment of wounds, cellulitis, and pneumonia. Horses with intermittent or focal neuropathies have a better prognosis than those with complete flaccid paralysis or that appear comatose. Efficacy of specific antiviral agents for treatment of naturally occurring WNV or EEEV infection is unknown, even in people. Recent work with passive immunotherapy indicates possible benefit after the onset of clinical signs in WNV models.

Prognosis: Mortality of horses showing clinical signs from EEEV is 50%–90%, from

WEEV 20%–50%, from VEEV 50%–75%, and from flavivirus infections 35%–45%. Horses with clinical neurologic signs from alphavirus infection that recover have a high incidence of residual neurologic deficits, whereas many horses that recover from WNV disease have been reported to have no residual neurologic deficits. In EEEV infection, death is frequently spontaneous. With WNV disease, horses are euthanized for humane reasons, but spontaneous death does occur. In EEEV, most surviving horses exhibit longterm neurologic signs. In WNV disease, overt clinical signs in horses that recover can last from 1 day to several weeks; improvement usually occurs within 7 days of onset of clinical signs. Although 80%–90% of owners report that the horse returns to normal function 1–6 mo after disease, at least 10% of owners report longterm deficits that limit athletic potential and resale value. Deficits include residual weakness or ataxia in one or more limbs, fatigue with exercise, focal or generalized muscle atrophy, and changes in personality and behavioral aberrations.

Prevention: Vaccination against alphaviruses and flaviviruses as core annual vaccines are considered the standard of care for all horses in the USA as endorsed by the American Association of Equine Practitioners. Formalin-inactivated whole viral vaccines for EEEV, WEEV, and VEEV are commercially available in bi- and trivalent forms, usually formulated with tetanus toxoid; several now include WNV. Nonvaccinated adult horses require the label priming two injections. For adult horses in temperate climates, an annual vaccine within 1 mo before the start of the arbovirus season is recommended. However, for horses that travel between northern and southern areas affected by the virus, injections should be given two or even three times yearly in active arbovirus seasons. Mares should be vaccinated 1 mo before foaling to induce colostral antibody. If a pregnant mare is naive, the full priming series starting 2 mo before foaling is recommended. However, some mares do not produce colostral antibody if vaccinated for the first time during gestation.

In foals that have received adequate colostrum from vaccinated dams, vaccination should begin at 5–6 mo of age; foals should receive two additional vaccinations at 30 and 90 days after the first one. It is unclear whether maternal antibody interferes with vaccine responses in foals; however, epidemiologic evidence strongly indicates that horses between 4 mo

and 4 yr old are highly susceptible to EEEV. If there is early spring (March) activity in the southeastern USA, horses may require three injections throughout the year, especially in horses <5 yr old and in horses that have recently arrived in the southeastern USA. In foals born to nonvaccinated or minimally vaccinated mares, maternal immunity may wane, and vaccination should be performed at 4, 5, and 6 mo of age. In Florida, where the highest numbers of EEEV cases occur, horses of all ages should be vaccinated in January and again in April before the peak of the season. A third vaccination should be administered late in the summer if the season is particularly active. The frequency of vaccination may be minimized to once or twice per year in climates that have short mosquito seasons and in which limited activity has historically been reported.

Currently, several whole inactivated virion vaccines, one recombinant inactivated vaccine, and a canarypox-vectored vaccine are licensed for prevention of WNV viremia in most of the Americas, including the USA and Canada, and Europe. An inactivated virus vaccine is readily available against Japanese encephalitis virus. There is experimental evidence that the canarypox WNV lineage 1 vaccine provides cross-protection against WNV lineage 2 infection. WNV challenge studies indicate that ~10% of properly immunized horses do not produce neutralizing antibodies to WNV and that 2.3%-3% of equine WNV cases seen in the field are in fully vaccinated horses. The duration of immunity from vaccination with the killed, adjuvanted WNV vaccine is unknown.

Protection of horses from arboviruses must also include efforts to minimize exposure to infected mosquitoes. Mosquito mitigation includes applying an insect repellent that contains permethrin on the horses at least daily during vector season, especially at times of day when mosquitoes may be most active. Environmental management is also essential and includes keeping the barn area, paddocks, and pastures cleared of weeds and organic material, such as feces, that might harbor adult mosquitoes. Cleaning water tanks and buckets at least weekly will reduce mosquito breeding areas. Removal of other containers such as flower pots and used tires that may hold stagnant water is essential for reducing the number of mosquitoes in the area.

Options for control of arbovirus infection in other animals emphasize reduction of exposure. Few arbovirus infections have been documented in dogs and cats;

however, exposure to EEEV and WNV is detected in both species during arbovirus seasons. In active years, young dogs have been reported to be susceptible to EEEV infection.

Keeping dogs and cats indoors or in a screened area, especially during the time when mosquitoes are most active, reduces exposure. Disposal of dead birds or other small prey that might be eaten may reduce oral exposure.

Clinical cases of both of these diseases have also been recorded in other domestic and exotic animals during active seasons. Emus are exceptionally susceptible to EEEV. These animals are used for the commercial food industry, and infection results in high viremia and high amounts of virus shedding rectally, orally, and in regurgitated material. Vaccination will prevent viremia, shedding, and disease. Camelids are susceptible to WNV, and numerous reports of disease and pathology were recorded as the virus spread across North America. The killed, adjuvanted vaccine marketed for use in horses has been used in camelids without any reports of major adverse effects, and animals have demonstrated production of neutralizing antibody.

Zoonotic Risk: The reporting of these diseases (or suspicion of such) on an international and national basis is a basic duty of all veterinarians to ensure the health and safety of horses and people. As such, a thorough diagnostic investigation to confirm these infections is imperative, irrespective of state resources available for subsidized testing.

People may be infected by most of the arboviruses that commonly cause viral encephalitis in horses. Clinical signs in people vary from mild flu-like symptoms to death. Children, the elderly, and those who are immunosuppressed are the most susceptible. People with neurologic disease due to arboviruses usually have permanent neurologic impairment after recovery. Human disease is reported infrequently and generally follows equine infections by ~2 wk. Veterinarians should be aware of the possibility of human infection and use repellents and other procedures to protect themselves from hematophagous insects when working in sylvatic virus habitats or handling viremic horses. In addition, waterproof clothing (gown, boots, gloves), respirator (N-95 or N-99 mask), face shield, and hair covering are recommended during all necropsies performed on horses suspected of having encephalomyelitis.

LOUPING ILL

(Ovine encephalomyelitis)

Louping ill is an acute, tick-transmitted viral disease of the CNS that primarily affects sheep, but cattle, goats, horses, dogs, pigs, South American camelids, red grouse, and people also can be affected; people can be infected by tick bites or exposure to tissues or instruments contaminated with virus. The disease is seen throughout the rough hill grazings of the British Isles wherever the vector tick, *Ixodes ricinus*, is prevalent. Diseases of sheep indistinguishable from louping ill and caused by similar viruses have been reported in Norway, Spain, Turkey, and Bulgaria, which suggests that the condition may not be restricted to the British Isles.

Etiology and Transmission: The virus belongs to the Flaviviridae family and is part of an antigenically closely related complex of viruses known as the tickborne encephalitides, which are primarily associated with disease in people and distributed throughout the northern temperate regions. Infection is transmitted transstadially by the tick vector; transovarial transmission of louping ill virus does not appear to occur. In sheep flocks, mortality ranges from 60% in newly introduced stock to 5%–10% in sheep acclimatized to the pasture. On farms where the disease is endemic, losses are mainly confined to animals <2 yr old; adults tend to be immune as a result of previous infection, and lambs are protected in their first season by colostral antibody. However, when the disease appears for the first time, or after a lapse of several years, all ages of sheep are susceptible. Mortality is variable in other species but tends to be high in red grouse. All species of vertebrates that come in contact with questing ticks may become parasitized and infected with louping ill virus, but only sheep and grouse develop titers of viremia sufficient to pass the infection to the vector tick. Infection also can be spread through contact with contaminated instruments or tissues. Infected lactating goats can excrete high titers of virus in their milk, which may cause fatal infection of their kids and be a potential human health hazard.

Pathogenesis, Clinical Findings, and Lesions: The course of infection in all species is similar, and varies only in the

intensity of viremia and frequency with which clinical signs develop. After inoculation by an infected tick, virus initially replicates in lymphoid tissues, which gives rise to viremia that lasts 1–5 days. Only animals that develop high titers can transfer the virus to ticks. During viremia, a febrile reaction may be present, but overt clinical signs are generally absent until the virus enters the CNS and begins replication, even though the immune response has eliminated the virus from the extraneuronal tissues. The extent of neuronal damage consequent to viral replication determines the severity of signs, from none (subclinical) through varying degrees of neurologic dysfunction to sudden death. Histologic lesions may be present whether or not signs develop. Signs include fine muscular tremors, nervous nibbling, ataxia (particularly of the hindlimbs), weakness, and collapse; death may occur 1–3 days after onset of signs. Peracute deaths may also occur. In some recovered animals, residual paresis or torticollis may persist. All recovered animals are solidly immune for life.

The severity of clinical disease in animals recently infected with *Anaplasma phagocytophilum* (the cause of tickborne fever [see p 772]) is markedly increased, presumably because of the immunosuppressive effect of this organism. The accompanying pathology may be complex and associated with secondary bacterial and mycotic infection, accounting for the high mortality experienced when naive flocks are introduced to tick-infested pasture.

No specific gross lesions are present, although secondary pneumonia may develop. Histologic examination of the CNS usually shows a nonsuppurative polioencephalomyelitis with lesions predominantly in the brain stem.

Diagnosis: The disease normally is seen only in animals that have had access to tick-infested pasture; however, the variable clinical picture necessitates differentiation from other conditions that cause locomotor or neurologic dysfunction. Confirmation is by histologic examination of the brain, virus detection in CNS tissue, and serology. As much of

the brain and brain stem as possible should be fixed in formaldehyde solution (10% in saline), and sections examined for the characteristic lesions, which can be useful in reaching a presumptive diagnosis. Diagnosis is confirmed by immunohistochemistry using an appropriate monoclonal antibody. For routine diagnosis, virus isolation is now seldom undertaken and has been replaced by reverse transcriptase PCR. This requires a piece of brain stem to be collected into virus transport medium and dispatched to a suitable diagnostic laboratory. Measurement of serum neutralizing and hemagglutination inhibition antibodies also can help reach a diagnosis and for surveys. The presence of IgM antibody in cattle and sheep serum, detected by the hemagglutination inhibition test, provides good evidence that the animal was infected within the preceding 10 days.

Treatment and Control: No specific treatment is available, but nursing, hand-feeding, and sedation may be helpful. An inactivated, tissue culture-propagated vaccine is available and has successfully protected sheep, cattle, and goats. A single injection induces an antibody response that

provides protection for <2 yr. Colostrum from the vaccinated ewe prevents infection of lambs in their first months. Generally, all animals to be retained for breeding are vaccinated at 6–12 mo of age. Use of insecticidal dips to protect against exposure to ticks generally is inadequate, although pour-on preparations reduce exposure, and their systematic use may effectively reduce the abundance of ticks and prevalence of virus infection.

Zoonotic Risk: Louping ill virus infection of people can cause severe encephalomyelitis. Symptoms are biphasic; the initial, flu-like symptoms are replaced 4–5 days later with signs of encephalitis. People become infected through the bite of infected ticks or through contact with infected carcasses, sharp instruments, or aerosol. Only a few cases of natural transmission have been reported, most occurring in laboratory workers. Those engaged in the diagnosis or research of this virus should be vaccinated with a human vaccine against tickborne encephalitis virus. Because goats can excrete high titers of virus in their milk, goats kept for milk production in endemic areas must be vaccinated.

PSEUDORABIES

(Aujeszky disease, Mad itch)

Pseudorabies is an acute, frequently fatal disease with a worldwide distribution that affects swine primarily and other domestic and wild animals incidentally. The pseudorabies virus has emerged as a significant pathogen in the USA since the 1960s, probably because of the increase in confinement swine housing or perhaps because of the emergence of more virulent strains. Clinical signs in nonporcine animals are similar to those of rabies, hence the name “mad itch” (pigs do not display this sign). Pseudorabies is a reportable disease and has been successfully eradicated from the vast majority of the USA.

Etiology: Pseudorabies virus is a DNA herpesvirus. The pig is the only reservoir host, but the virus can infect cattle, sheep, cats, dogs, and goats as well as wildlife, including raccoons, opossums, skunks, and

rodents. Experimental studies in nonhuman primates indicate that rhesus monkeys and marmosets are susceptible but chimpanzees are not. Reports of human infection are limited and are based on seroconversion rather than virus isolation. Infections in horses are rare. Only one serotype of pseudorabies virus is recognized, but strain differences have been identified using monoclonal antibody preparations, restriction endonuclease assays, and heat and trypsin inactivation markers.

Epidemiology: The virus can be transmitted via nose-to-nose or fecal-oral contact. Indirect transmission commonly occurs via inhalation of aerosolized virus. Infectious virus can persist for up to 7 hr in air with a relative humidity of ≥55%. Data from England indicate that virus may travel via aerosols for up to 2 km in certain weather

conditions. Other studies have demonstrated that the virus can survive for up to 7 hr in nonchlorinated well water; for 2 days in anaerobic lagoon effluent and in green grass, soil, feces, and shelled corn; for 3 days in nasal washings on plastic and pelleted hog feed; and for 4 days in straw bedding. The virus is enveloped and, therefore, inactivated by drying, sunlight, and high temperatures ($\geq 37^{\circ}\text{C}$ [98.6°F]). Dead-end hosts, such as dogs, cats, or wildlife, can transmit the virus between farms, but these animals survive only 2–3 days after becoming infected. The potential role of insects as vectors is being investigated. Birds do not seem to play a role in transmission.

Clinical Findings and Pathogenesis:

The clinical signs in pigs depend on the age of the affected animal. Young swine are highly susceptible, and losses may reach 100% in piglets <7 days old. In general, signs of CNS disease (eg, tremors and paddling) are seen. If weaned pigs are infected, respiratory disease is the primary clinical problem, especially if complicated by secondary bacterial pathogens. Pseudorabies virus has been reported to inhibit the function of alveolar macrophages, thereby reducing the ability of these cells to process and destroy bacteria. A generalized febrile response (41° – 42°C [105.8° – 107.6°F]), anorexia, and weight loss are seen in infected pigs of all ages. Mortality can be very low (1%–2%) in grower and finisher pigs but may reach 50% in nursery pigs. Sneezing and dyspnea are frequently seen, and CNS involvement is reported occasionally. Clinical signs in nonporcine species, such as cats, dogs, cattle, and small ruminants, include sudden death, intense local pruritus, CNS signs (circling, maniacal behavior, paralysis), fever, and respiratory distress.

After natural infection, the primary site of viral replication is nasal, pharyngeal, or tonsillar epithelium. The virus spreads via the lymphatics to regional lymph nodes, where replication continues. Virus also spreads via nervous tissue to the brain, where it replicates, preferentially in neurons of the pons and medulla. In addition, virus has been isolated from alveolar macrophages, bronchial epithelium, spleen, lymph nodes, trophoblasts, embryos, and luteal cells.

Viral excretion begins ~2–5 days after infection, and virus can be recovered from nasal secretions, tonsillar epithelium, vaginal and preputial secretions, milk, or urine for >2 wk. A latent state, in which

virus is harbored in the trigeminal ganglia, may exist. In swine with latent infections, shedding may resume after periods of stress such as farrowing, crowding, or transport. Experimentally, corticosteroid injections (dexamethasone, 2 mg/kg, IM) for 5 consecutive days have induced recrudescence.

Lesions: Gross lesions of pseudorabies virus infection are often undetectable. Serous rhinitis, necrotic tonsillitis, or hemorrhagic pulmonary lymph nodes may be seen. Pulmonary edema, as well as pneumonic lesions of secondary bacterial pathogens, may be present. Necrotic foci (2–3 mm in diameter) may be scattered throughout the liver. Such lesions are typically found in young (<7 days old) piglets.

Microscopically, nonsuppurative meningoencephalitis is a characteristic lesion that can be present in gray and white matter. Mononuclear perivascular cuffing and neuronal necrosis may also be present. The meninges are thickened as a result of mononuclear cell infiltration. Necrotic tonsillitis with the presence of intranuclear inclusion bodies, as well as necrotic bronchitis, bronchiolitis, and alveolitis, are commonly seen. Focal areas of necrosis are often found in the liver, spleen, lymph nodes, and adrenal glands of macerated fetuses.

Diagnosis: In addition to the gross and microscopic lesions, other diagnostic aids include virus isolation, fluorescent antibody testing, and serologic testing. Brain, spleen, and lung are the organs of choice for virus isolation. Nasal swabs can be used for isolation of virus from acutely infected animals. The nasal specimens must be stored and transported in cold, sterile saline with antibiotics to suppress bacterial growth. The fluorescent antibody test can be performed using tonsil or brain.

Many serologic tests are now available, including serum neutralization, ELISA, and latex agglutination. Serum neutralization, which is the standard test, requires 48 hr to complete. An ELISA has been developed as a screening assay for large volumes of sera; however, specificity may be poor. False-positive results are typically reassessed using the serum neutralization test. The latex agglutination test, although highly sensitive and rapid, may also have poor specificity. After infection, antibodies can be detected within 6–7 days using the latex agglutination test, within 7–8 days using the ELISA, and within 8–10 days using the serum neutralization test.

A differential ELISA has been used to differentiate antibodies produced as a result of vaccination from those produced as a result of natural infection. The vaccines used in swine are based on the deletion of certain genes (gI, gII, or gX) from the vaccine virus. Swine vaccinated with a gene-deleted vaccine do not mount an antibody response to the protein coded for by the deleted gene. In contrast, infection with field virus results in antibodies against these proteins.

Colostrum antibodies to pseudorabies virus may be present until pigs are 4 mo old (similar to porcine parvovirus). Therefore, paired samples or serologic profiles may be necessary in grower and finisher pigs to assess decreasing levels of maternal antibody and to ensure that pigs are vaccinated at the appropriate time.

Treatment and Control: Although there is no specific treatment for acute infection with pseudorabies virus, vaccination can alleviate clinical signs in pigs of certain ages. Typically, mass vaccination of all pigs on the farm with a modified-live virus vaccine is recommended. Intranasal vaccination of sows and neonatal piglets 1–7 days old, followed by IM vaccination of all other swine on the premises, helps reduce viral shedding and improve survival. The modified-live virus replicates at the site of injection and in regional lymph nodes. Vaccine virus is shed in such low levels that mucous transmission to other animals is minimal. In gene-deleted vaccines, the thymidine kinase gene has also been deleted; thus, the virus cannot infect and replicate in neurons. It is recommended that breeding herds be vaccinated quarterly and that finisher pigs be vaccinated after levels of maternal antibody decrease. Regular vaccination results in excellent control of the disease. Concurrent antibiotic therapy

via feed and IM injection is recommended to control secondary bacterial pathogens.

Numerous programs have been developed for eradication of pseudorabies virus. As of 2014, all 50 states in the USA are considered free of the disease in commercial pigs; however, the virus appears to be endemic in feral pig populations and has been identified on game ranches. Effective strategies for eradication of pseudorabies include whole-herd depopulation, a test and removal strategy, and offspring segregation. Although effective, whole-herd depopulation is costly and time consuming. Usually, problems other than pseudorabies virus (eg, genetic improvement) need to be resolved before whole-herd depopulation can be cost effective.

The test and removal strategy consists of blood testing all breeding swine, culling all positive animals, and repeating this procedure until the population tests negative. Naturally infected animals can be culled when such a strategy is used in conjunction with a differential vaccination program. A test and removal strategy can be effective, but it is laborious, and latently infected animals that do not exhibit an antibody response on serologic testing may potentially resume shedding the virus at a later time.

In an offspring segregation program, young piglets (18–21 days old) are removed from vaccinated sows and raised to adulthood at another site. If enough gilts and boars are raised in this manner, the original breeding herd may be depopulated and subsequently repopulated with seronegative replacements. This method also allows seedstock producers to sell animals, even though the breeding herd is infected. In this case, however, all offspring must be individually tested using the serum neutralization test and have negative results before being sold.

RABIES

Rabies is an acute, progressive viral encephalomyelitis that principally affects carnivores and bats, although any mammal can be affected. The disease is fatal once clinical signs appear. Rabies is found throughout the world, but a few countries claim to be free of the disease because of

either successful elimination programs or their island status and enforcement of rigorous quarantine regulations. Globally, the dog is the most important reservoir, particularly in developing countries. Integrated veterinary management of local animal populations, by mass vaccination of

dogs and community promotion of responsible pet ownership, is the most cost-effective, humane, long-term solution toward eliminating regional canine rabies in a One Health context.

Etiology and Epidemiology: Rabies is caused by lyssaviruses in the Rhabdovirus family. Lyssaviruses are usually confined to one major reservoir species in a given geographic area, although spillover to other species is common. Identification of different virus variants by laboratory procedures such as monoclonal antibody analysis or genetic sequencing has greatly enhanced understanding of rabies epidemiology. Generally, each virus variant is responsible for virus transmission between members of the same species in a given geographic area. To date, >15 different lyssaviruses have been described. Globally, rabies virus is the most important member of the genus.

From an epidemiologic perspective, the name of the mammalian species acting as the reservoir and vector is used as an adjective to describe involvement in the infection process. For example, rabies maintained by dog-to-dog transmission is termed canine rabies, whereas rabies in a dog as a result of infection with a variant from a different reservoir mammal, eg, skunk (or raccoon or fox), would be referred to as skunk (or raccoon or fox, etc) rabies in a dog.

In North America, distinct virus variants are responsible for rabies perpetuation in red and Arctic foxes in Canada and Alaska, raccoons along the eastern seaboard from Maine to Florida, and gray foxes in the southwest, including Arizona, Colorado, and Texas. Two different variants are responsible for rabies in striped skunks, one in the south central states and the other in the north central states, which often extends into the Canadian prairies. Another skunk rabies virus variant is found in California. By comparison, the epidemiology of rabies in bats is complex. In general, each variant found in bats may be characterized with a predominant bat species. Spillover from bats to terrestrial animals is seen infrequently. Most human cases of rabies in the USA in the past decade have been caused by bat rabies virus variants (especially viruses associated with *Lasiurus noctivagans*, the silver-haired bat, and *Perimyotis subflavus*, the tricolored bat).

Rabies emergence may be affected by changes in virus-host dynamics or human translocation of infected species. For many

years, skunks were the most commonly reported rabid animal in the USA, but since 1990, rabid raccoons have been the most numerous. Canine rabies became established in dogs and coyotes (*Canis latrans*) in southern Texas but was eliminated by the end of the 20th century. Canine rabies exists in Mexico, with the potential to spread throughout the USA if reintroduced. Skunk, raccoon, and fox rabies are each found in fairly distinct geographic regions of North America, although some overlap occurs. Bat rabies is distributed throughout the Americas. The vampire bat is an important reservoir in Latin America and is the source of multiple outbreaks in cattle, as well as in people, particularly in parts of Amazonia.

In western Europe, red fox rabies predominated before its elimination by oral vaccination. In parts of eastern Europe, rabies in raccoon dogs is of increasing concern. Bat rabies, maintained by several different lyssaviruses in insectivorous Chiroptera, appears to be widely distributed throughout Europe.

Other wildlife play an important role in the transmission of rabies in certain areas, including different species of mongooses in the Caribbean, southern Africa, and parts of Asia; jackals in parts of Africa; wolves in parts of northern Europe; marmosets in Brazil; and ferret badgers in China.

All rabies reservoirs are also vectors of the virus, but not all vectors are reservoirs. For example, cats can effectively transmit the virus, but no cat-to-cat transmission of rabies perpetuates in lieu of a predominant reservoir (such as infected dogs), and no unique feline rabies virus variant has been documented. However, cats are the most commonly reported rabid domestic animal in the USA. Virus is present in the saliva of rabid cats, and people have developed rabies after being bitten by rabid cats. Reported cases in domestic cats have outnumbered those in dogs in the USA every year since 1990.

Transmission and Pathogenesis: Lyssaviruses are highly neurotropic. Transmission almost always occurs via introduction of virus-laden saliva into tissues, usually by the bite of a rabid animal. Although much less likely, virus from saliva, salivary glands, or brain can cause infection by entering the body through fresh wounds or intact mucous membranes. Usually, saliva is infectious at the time clinical signs occur, but domestic dogs, cats, and ferrets may shed virus for several days before onset of clinical signs. Viral shedding in skunks has been reported for up to 8 days before onset

of signs. Rabies virus has not been isolated from skunk musk (spray).

The incubation period is both prolonged and variable. Typically, the virus remains at the inoculation site for a considerable time. The unusual length of the incubation period helps to explain the effective action of local infiltration of rabies immune globulin during human postexposure prophylaxis, even days after exposure. Most rabies cases in dogs develop within 21–80 days after exposure, but the incubation period may be shorter or considerably longer. One recorded case of rabies in a person in the USA had an incubation period estimated reliably of >8 yr.

The virus travels via the peripheral nerves to the spinal cord and ascends to the brain. After reaching the brain, the virus travels via peripheral nerves to the salivary glands. If an animal is capable of transmitting rabies via its saliva, virus will be detectable in the brain. Virus is shed intermittently in the saliva.

Hematogenous spread does not occur. Under most circumstances, there is no danger of aerosol transmission of rabies virus. However, aerosol transmission has occurred under very specialized conditions in which the air contained a high concentration of suspended particles or droplets carrying viral particles. Such conditions have been responsible for laboratory transmission under less than ideal containment situations. There has been a suggestion of rare natural aerosol transmission in a cave inhabited by millions of bats. Oral and nasal secretions containing virus were probably aerosolized from tens of thousands of rabid bats. Aerosol infection may occur via direct attachment of the virus to olfactory nerve endings.

Near the end of the clinical phase, after replication in the CNS, virus may be found in nearly every innervated organ. Rabies has been transmitted by transplantation of tissues and organs from infected people.

Clinical Findings: Clinical signs of rabies are rarely definitive. Rabid animals of all species usually exhibit typical signs of CNS disturbance, with minor variations among species. The most reliable signs, regardless of species, are acute behavioral changes and unexplained progressive paralysis. Behavioral changes may include sudden anorexia, signs of apprehension or nervousness, irritability, and hyperexcitability (including priapism). The animal may seek solitude. Ataxia, altered phonation, and changes in temperament are apparent. Uncharacteristic aggressiveness may develop—a normally docile animal may suddenly become vicious. Commonly, rabid

wild animals may lose their fear of people, and normally nocturnal species may be seen wandering about during the daytime.

The clinical course may be divided into three general phases—prodromal, acute excitative, and paralytic/endstage. However, this division is of limited practical value because of the variability of signs and the irregular lengths of the phases. During the prodromal period, which lasts ~1–3 days, animals show only vague nonspecific signs, which intensify rapidly. The disease progresses rapidly after the onset of paralysis, and death is virtually certain a few days thereafter. Some animals die rapidly without marked clinical signs.

The term “furious rabies” refers to animals in which aggression (the acute neural excitative phase) is pronounced. “Dumb or paralytic rabies” refers to animals in which the behavioral changes are minimal, and the disease is manifest principally by paralysis.

Furious Form: This is the classic “mad-dog syndrome,” although it may be seen in all species. There is rarely evidence of paralysis during this stage. The animal becomes irritable and, with the slightest provocation, may viciously and aggressively use its teeth, claws, horns, or hooves. The posture and expression is one of alertness and anxiety, with pupils dilated. Noise may invite attack. Such animals lose caution and fear of people and other animals. Carnivores with this form of rabies frequently roam extensively, attacking other animals, including people, and any moving object. They commonly swallow foreign objects, eg, feces, straw, sticks, and stones. Rabid dogs may chew the wire and frame of their cages, breaking their teeth, and will follow a hand moved in front of the cage, attempting to bite. Young pups can seek human companionship and are overly playful, but bite even when petted, usually becoming vicious in a few hours. Rabid skunks may seek out and attack litters of puppies or kittens. Rabid domestic cats and bobcats can attack suddenly, biting and scratching viciously. As the disease progresses, muscular incoordination and seizures are common. Death results from progressive paralysis.

Paralytic Form: This is manifest by ataxia and paralysis of the throat and masseter muscles, often with profuse salivation and the inability to swallow. Dropping of the lower jaw is common in dogs. Owners frequently examine the mouth of dogs and livestock searching for a foreign body or administer medication with their

bare hands, thereby exposing themselves to rabies. These animals may not be vicious and rarely attempt to bite. The paralysis progresses rapidly to all parts of the body, and coma and death follow in a few hours.

Species Variations: Cattle with furious rabies can be dangerous, attacking and pursuing people and other animals. Lactation ceases abruptly in dairy cattle. The usual placid expression is replaced by one of alertness. The eyes and ears follow sounds and movement. A common clinical sign is a characteristic abnormal bellowing, which may continue intermittently until shortly before death.

Horses and mules frequently show evidence of distress and extreme agitation. These signs, especially when accompanied by rolling, may be interpreted as evidence of colic. As in other species, horses may bite or strike viciously and, because of their size and strength, become unmanageable in a few hours. People have been killed outright by such animals. These animals frequently have self-inflicted wounds.

Rabid foxes and coyotes often invade yards or even houses, attacking dogs and people. One abnormal behavior that can occur is demonstrated by an animal that attacks a porcupine; finding a fox, or another animal, with porcupine quills can, in many cases, support a diagnosis of rabies.

Rabid raccoons, foxes, and skunks typically show no fear of people and are ataxic, frequently aggressive, and active during the day, despite their often crepuscular nature. In urban areas, they may attack domestic pets.

In general, rabies should be suspected in terrestrial wildlife acting abnormally. The same is true of bats that can be seen flying in the daytime, resting on the ground, paralyzed and unable to fly, attacking people or other animals, or fighting.

Rodents and lagomorphs rarely constitute a risk of exposure to rabies virus. However, each incident should be evaluated individually. Reports of laboratory-confirmed rabies in woodchucks are not uncommon in association with the raccoon rabies epizootic in the eastern USA.

Diagnosis: Clinical diagnosis is difficult, especially in areas where rabies is uncommon, and should not be relied on when making public health decisions. In the early stages, rabies can easily be confused with other diseases or with normal aggressive tendencies. Therefore, when rabies is suspected and definitive diagnosis is required, laboratory confirmation is

indicated. Suspect animals should be euthanized, and the head removed for laboratory shipment.

Rabies diagnosis should be done by a qualified laboratory, designated by the local or state health department in accordance with established standardized national protocols for rabies testing. Immunofluorescence microscopy on fresh brain tissue, which allows direct visual observation of a specific antigen-antibody reaction, is the current test of choice. When properly used, it can establish a highly specific diagnosis within a few hours. Brain tissues examined must include medulla oblongata and cerebellum (and should be preserved by refrigeration with wet ice or cold packs). Virus isolation by the mouse inoculation test or tissue culture techniques using mouse neuroblastoma cells may be used for confirmation of indeterminate fluorescent antibody results, but it is no longer in common use in the USA.

Prevention and Control: Comprehensive guidelines for control in dogs have been prepared internationally by the World Health Organization and in the USA by the National Association of State Public Health Veterinarians (NASPHV). They include the following: 1) notification of suspected cases, and euthanasia of dogs with clinical signs and dogs bitten by a suspected rabid animal; 2) reduction of contact rates between susceptible dogs by leash laws, dog movement control, and quarantine; 3) mass immunization of dogs by campaigns and by continuing vaccination of young dogs; 4) stray dog control and euthanasia of unvaccinated dogs with low levels of dependency on, or restriction by, people; and 5) dog registration.

The Compendium of Animal Rabies Control, compiled and updated regularly by the NASPHV, summarizes the most current recommendations for the USA and lists all USDA-licensed animal rabies vaccines marketed in the USA. Many effective vaccines, such as modified-live virus, recombinant, and inactivated types, are available for use throughout the world; in the USA, no modified-live rabies virus vaccines are currently marketed (for any species). Recommended vaccination frequency is every 3 yr, after an initial series of two vaccines 1 yr apart. Several vaccines are also available for use in cats, and a few for use in ferrets, horses, cattle, and sheep. Because of the increasing importance of rabies in cats, vaccination of cats is critical. No parenteral vaccine is approved for use in wildlife. Protective immunity from the

commercially available vaccines for domestic species has not been definitively demonstrated in wildlife species.

Until recently, the control of rabies in wildlife populations relied on population reduction of wildlife in an attempt to reduce the contact rate between susceptible animals; however, this proved difficult and often not publicly acceptable, ecologically sound, economically warranted, or programmatically effective. In Europe and Canada, use of oral vaccines distributed in baits to control fox rabies has been widespread and effective. The disease in foxes has been eliminated from most of western Europe and curtailed significantly in Ontario. Use of a vaccinia-rabies glycoprotein recombinant virus vaccine in the USA has successfully eliminated coyote rabies in southern Texas and has limited the western expansion of raccoon rabies from the eastern USA. The license limits use of the vaccine to state or federal rabies programs; it is not available to private veterinarians or for individual animal use. Together with other vaccines, it is also being used to assist in the control of dog rabies in developing countries.

Management of Suspected Rabies

Cases—Exposure of Pets: Where terrestrial wildlife or bat rabies is known to occur, any animal bitten or otherwise exposed by a wild, carnivorous mammal (or a bat) not available for testing should be regarded as having been exposed to rabies. The NASPHV recommends that any unvaccinated dog, cat, or ferret exposed to rabies be euthanized immediately. If the owner is unwilling to do this, the animal should be placed in strict isolation (ie, no human or animal contact) for 6 mo and vaccinated against rabies 1 mo before release. If an exposed domestic animal is currently vaccinated, it should be revaccinated immediately and closely observed for 45 days.

Zoonotic Risk: Rabies has the highest case fatality of any infectious disease. When a person is exposed to an animal suspected of having rabies, the risk of rabies virus transmission should be evaluated carefully. Risk assessment should include consideration of the species of animal involved, the prevalence of rabies in the area, whether exposure sufficient to transmit rabies virus occurred, and the current status of the animal and its availability for diagnostic testing. Wild carnivores and bats present a considerable risk where the disease is found, regardless of whether abnormal behavior has been observed. Insectivorous

bats, though small, can inflict wounds with their teeth and should never be caught or handled with bare hands. Bat bites may be ignored or go unnoticed, so direct contact with bats could be considered a risk of virus exposure. Any wild carnivore or bat suspected of exposing a person to rabies should be considered rabid unless proved otherwise by laboratory diagnosis; ideally, this includes bats in direct contact with people, such as those found in rooms with sleeping or otherwise unaware persons. Wildlife, including wolf hybrids, should never be kept as pets; if one of those animals exposes a person or domestic animal, the wild animal should be managed like free-ranging wildlife.

Any healthy domestic dog, cat, or ferret, whether vaccinated against rabies or not, that exposes (bites or deposits saliva in a fresh wound or on a mucous membrane) a person should be confined for 10 days; if the animal develops any signs of rabies during that period, it should be euthanized and its brain promptly submitted for rabies diagnosis. If the dog, cat, or ferret responsible for the exposure is stray or unwanted, it may be euthanized as soon as possible and submitted for rabies diagnosis. Since the advent of testing by immunofluorescence microscopy, there is no value in holding such animals to "let the disease progress" as an aid to diagnosis.

Internationally, the World Health Organization recommends several types of cell-culture vaccines for human groups at risk. In the USA, guidelines for human rabies prevention follow recommendations prepared by the Advisory Council on Immunization Practices. Preexposure immunization is strongly recommended for people in high-risk groups, such as veterinary staff, animal control officers, rabies and diagnostic laboratory workers, and, under certain circumstances, some travelers working in countries in which canine rabies is enzootic. Preexposure vaccine is administered on days 0, 7, and 21 or 28. However, preexposure prophylaxis alone cannot be relied on in the event of subsequent rabies virus exposure and must be supplemented by a limited postexposure regimen (two doses of vaccine, IM, on days 0 and 3). For healthy, unvaccinated patients bitten by a rabid animal, postexposure prophylaxis consists of wound care, local infiltration of rabies immune globulin, and vaccine administration on days 0, 3, 7, and 14. When provided in a timely and appropriate manner, modern postexposure prophylaxis virtually assures human survival.

TESCHOVIRUS ENCEPHALOMYELITIS

(Porcine polioencephalomyelitis, Teschen disease, Talfan disease)

Teschovirus encephalomyelitis (formerly known as porcine enteroviral encephalomyelitis) is analogous to human poliomyelitis. Severe disease is now rare; it is seen in eastern Europe and Madagascar but was last reported in western Europe from Austria in 1980. In other countries, sporadic mild disease is reported, or the disease is unrecognized.

Etiology, Epidemiology, and Pathogenesis:

Until 1999, viruses causing this disease were classified within the genus *Enterovirus* (family *Picornaviridae*). However, analyses of their complete genome sequences revealed them to be very different from the enteroviruses, and they were reclassified in a new genus, *Teschovirus*, as the species *Porcine teschovirus* (the name was derived from Teschen disease). In 2015, the species was renamed to *Teschovirus A* to remove reference to the host species; however, the virus common name remains porcine teschovirus (PTV). Originally, 11 porcine enterovirus (PEV) serotypes were defined by virus neutralization. Of these, PEV 1–7 and 11–13 have been renamed PTV 1–10. Additional serotypes (PTV 11–13) have also recently been described, and it is likely more serotypes will be discovered in the future. PEV-8 has been reclassified as a member of a new picornavirus genus, *Sapelovirus*. PEV types 9 and 10, which have not been associated with neurologic disease, are distinct from the teschoviruses and remain in the *Enterovirus* genus. PTVs are ubiquitous in swine populations throughout the world. Many strains are nonpathogenic, but most neurotropic strains belong to one of the first three serotypes; serotype 1 includes not only the highly virulent but also many of the less virulent neurotropic strains. Although antigenic subtypes are recognized, they do not distinguish between more or less virulent strains of virus. PTV can survive in the environment for months.

Transmission is by direct or indirect contact with infected pigs. The virulent serotype 1 strain of classical Teschen disease results in high morbidity and mortality in all ages of pigs but apparently has remained confined to certain geographic areas. Mild, sporadic disease is seen

elsewhere. Conventional herds are usually endemically infected, and exclusion of teschoviruses from SPF herds is difficult to maintain. Infection is mainly inapparent, and pigs usually become infected at weaning with the decline of passive maternal immunity and mixing of groups. Sporadic clinical cases of nervous disease are seen mainly around this time, although disease is more common in unweaned piglets after introduction of a serotype to which the herd has not been exposed.

Ingested virus replicates in the GI tract and associated lymphoid tissue. There is no destruction of gut epithelium, but virus is shed from multiplication sites into the feces for several weeks. In some pigs, especially those infected with virulent strains, viremia ensues and results in spread of infection to the CNS.

Clinical Findings: In acute virulent infection, clinical signs appear 1–4 wk after exposure in pigs of all ages. Ataxia is often seen first, followed by fever, lassitude, and anorexia. Seizures, nystagmus, opisthotonos, and coma may occur. Paralysis, initially evident as paraplegia but progressing to quadriplegia, is frequent in severe cases. Death is common within 3–4 days of onset of signs.

In mild disease, signs are essentially ataxia and paresis, the latter more rarely progressing to paralysis. Only young pigs (unweaned or weaned) are susceptible, and recovery is frequent.

Lesions: There are no gross lesions.

Microscopic changes are most prominent in the gray matter of the brainstem, cerebellum, and spinal cord. The nonsuppurative encephalitis is characterized by neuronal necrosis, neuronophagia, glial foci, and perivascular lymphocytic cuffing. Meningitis is often present over the cerebellum.

Diagnosis: The clinical signs (especially those of locomotor disturbance), epidemiology, and absence of specific gross necropsy findings offer a presumptive diagnosis. The nature and distribution of histologic lesions provide supportive evidence. Acute and convalescent serum samples, taken ≥ 2 wk apart, may demonstrate a rise in neutralizing or complement-fixing antibodies. Virus

isolation from the CNS is required to confirm the diagnosis. Differentiation of severe and milder forms of the disease can be based only on serologic, clinical, and epidemiologic evidence.

Differential diagnoses include the many other viral encephalitis of pigs, particularly classical swine fever, African swine fever, pseudorabies, rabies, and the encephalopathies of edema disease and water deprivation/salt intoxication. The prominent locomotor signs in teschovirus encephalomyelitis also can be confused with several toxic and nutritional neuropathies.

The different serotypes are identified either by virus neutralization, complement fixation, or ELISA using specific antisera. Genome sequence data is available for all

the PTV serotypes, and molecular diagnosis by reverse transcriptase-PCR (RT-PCR) and real-time RT-PCR has been described.

Treatment and Control: There is no treatment. Live attenuated vaccine is used for control in areas experiencing severe endemic disease. In the past, eradication measures in central Europe involved ring vaccination and slaughter and also restrictions on importation of pigs and pork products. In many countries, suspected disease must be reported to regulatory authorities. In herds with endemic mild clinical disease, introduction of new breeding stock ≥ 1 mo before breeding should enhance passive immunity in offspring.

SPORADIC BOVINE ENCEPHALOMYELITIS

(Chlamydial encephalomyelitis, Buss disease, Transmissible serositis)

Sporadic bovine encephalomyelitis (SBE) is reported in various parts of the world. The disease affects cattle and buffalo, resulting in neurologic signs and polyserositis.

Etiology and Epidemiology: SBE is caused by *Chlamydia pecorum* biotype 2. Genetically identical *C. pecorum* isolates have been identified from clinical cases in geographically different areas. The *C. pecorum* isolates from clinical cases are distinct from those found in the GI tract of asymptomatic animals. Based on these findings, subclinical intestinal infections in cattle and other animals may not be the source of infection in SBE. The disease is most often seen in calves < 6 mo old and less commonly in older cattle. Sporadic cases and outbreaks can occur within individual herds. Morbidity rates are most commonly $< 25\%$, but can reach 50% . The mortality rate can approach 30% and is highest in calves. Many sick animals die if not treated at an early stage.

Clinical Findings: The incubation period in experimentally infected calves is 6–30 days. The first sign in natural and experimental cases is fever (104° – 107° F [40° – 41.7° C]). Appetite remains good for the first 2–3 days despite the fever. Afterward, depression, excess salivation,

diarrhea, anorexia, and weight loss occur. Nasal discharge and respiratory disease signs due to pleuritis may be seen. Early neurologic signs include stiffness and knuckling at the fetlocks. Calves become uncoordinated and stagger, circle, or fall over objects. Head pressing and blindness are not seen. In the terminal stage, calves are frequently recumbent and may develop opisthotonos. The course of the disease is usually 10–14 days.

Lesions: Lesions are not limited to the brain; vascular damage can be seen in several organs. Serofibrinous peritonitis, pleuritis, and pericarditis are common and are especially pronounced in more chronic cases. Microscopic lesions in the brain consist of perivascular cuffs and inflammatory foci in the parenchyma composed primarily of mononuclear cells.

Diagnosis: A tentative diagnosis can be based on clinical signs and particularly on the presence of serofibrinous peritonitis in the absence of other causes of peritonitis such as intestinal volvulus, intussusception, traumatic perforation of the reticulum, perforated abomasal ulcer, or displaced organs. Differential diagnoses also include rabies, infectious bovine rhinotracheitis with encephalitis, listeriosis, thromboembolic encephalo-

myelitis, polioencephalomalacia, pseudorabies, paramyxovirus encephalomyelitis, and malignant catarrhal fever. SBE can be diagnosed by PCR detection of *C. pecorum* DNA in brain tissue, pleural fluid, pericardial fluid, or peritoneal fluid of affected animals. Diagnosis can also be confirmed by culture in either developing chicken embryos or cell cultures, by histologic changes in brain sections, or by evaluation of tissue impression smears

after Giemsa or immunofluorescent staining.

Treatment: The antibiotics of choice are tetracyclines, oxytetracyclines, and tylosin. For treatment to be effective, it must be given as early as possible in high doses (eg, oxytetracyclines at 10–20 mg/kg/day) and for ≥ 1 wk. If treatment is effective, the fever should drop significantly within 24 hr. No vaccines are available.

EQUINE PROTOZOAL MYELOENCEPHALITIS

Equine protozoal myeloencephalitis (EPM) is a common neurologic disease of horses in the Americas; it has been reported in most of the contiguous 48 states of the USA, southern Canada, Mexico, and several countries in Central and South America. In other countries, EPM is seen sporadically in horses that previously have spent time in the Americas.

Etiology and Epidemiology: Most cases of EPM are caused by an Apicomplexan protozoan, *Sarcocystis neurona*. Horses are infected by ingestion of *S. neurona* sporocysts in contaminated feed or water. The organism undergoes early asexual multiplication (schizogony) in extraneural tissues before parasitizing the CNS. Because infectious sarcocysts are only rarely formed, the horse is considered an aberrant, dead-end host for *S. neurona*. Like other *Sarcocystis* spp, *S. neurona* has an obligate predator-prey life cycle. The definitive (predator) host for *S. neurona* in the USA is the opossum (*Didelphis virginiana*). Opossums are infected by eating sarcocyst-containing muscle tissue from an infected intermediate (prey) host and, after a brief prepatent period (probably 2–4 wk), infectious sporocysts are passed in the feces. Nine-banded armadillos, striped skunks, raccoons, sea otters, Pacific harbor seals, and domestic cats have all been implicated as intermediate hosts; however, the importance in nature of each of these species is unknown. Sporadic cases of EPM are associated with *Neospora hughesi*, an organism closely related to *S. neurona*. The natural host(s) of this organism have not yet been identified.

Clinical Findings: Because the protozoa may infect any part of the CNS, almost any

neurologic sign is possible. The disease usually begins insidiously but may present acutely and be severe at onset. Signs of spinal cord involvement are more common than signs of brain disease. Horses with EPM involving the spinal cord have asymmetric or symmetric weakness and ataxia of one to all limbs, sometimes with obvious muscle atrophy. When the sacrocaudal spinal cord is involved, there are signs of cauda equina syndrome. EPM lesions in the spinal cord also may result in demarcated areas of spontaneous sweating or loss of reflexes and cutaneous sensation. The most common signs of brain disease in horses with EPM are depression, head tilt, and facial paralysis. Any cranial nerve nucleus may be involved, and there may be seizures, visual deficits including abnormal menace responses, or behavioral abnormalities. Without treatment, EPM may progress to cause recumbency and death. Progression to recumbency occurs over hours to years and may occur steadily or in a stop-start fashion.

Lesions: There is focal discoloration, hemorrhage, and/or malacia of CNS tissue. Histologically, protozoa may be found in association with a mixed inflammatory cellular response and neuronal destruction. Schizonts, in various stages of maturation, or free merozoites commonly are seen in the cytoplasm of neurons or mononuclear phagocytes. Also parasitized are intravascular and tissue neutrophils and eosinophils and, more rarely, capillary endothelial cells and myelinated axons. Merozoites may be found extracellularly, especially in areas of necrosis. In at least 75% of clinical cases, protozoa are not seen on H&E-stained sections.

Diagnosis: Postmortem diagnosis is confirmed by demonstration of protozoa in CNS lesions on the basis of distinctive morphology or by immunohistochemical staining. Testing for *S. neurona*-specific antibody is the basis for presumptive antemortem diagnosis of EPM. Serologic tests for specific antibodies against whole *S. neurona* (eg, indirect fluorescent antibody test) or *S. neurona* surface antigens (snSAGs) provide evidence of current or recent exposure to the organism; thus, low or negative serum titers tend to exclude the diagnosis of EPM. Conversely, positive or high serum *S. neurona* titers have limited diagnostic utility in that such titers do not clearly distinguish horses with subclinical extraneural infections from those with EPM. In horses with neurologic signs, serum:CSF antibody titer ratios of $<1:100$ or C-ratios >1 are indicative of production of *S. neurona* antibody in the CNS and are highly supportive of the diagnosis of EPM. In a few horses with EPM, CSF analysis reveals abnormalities such as mononuclear pleocytosis and increased protein concentration.

Depending on the clinical signs, differential diagnoses may include cervical vertebral stenotic myelopathy, trauma, aberrant parasite migration, equine degenerative myeloencephalopathy, equine herpesvirus 1 myeloencephalopathy, equine motor neuron disease, cauda equina neuritis, arboviral (Eastern or Western equine, West Nile) encephalomyelitis, rabies, bacterial meningitis, hepatoencephalopathy, and leukoencephalomalacia.

Treatment: The FDA-approved treatments for EPM are ponazuril (5 mg/kg/day, PO, for 28 days), diclazuril (1 mg/kg/day, PO, for 28 days), and a combination of sulfadiazine and pyrimethamine (20 mg/kg and 1 mg/kg, respectively, for at least 90

days). The bioavailabilities of ponazuril and diclazuril are improved by concurrent PO administration of corn oil or DMSO. A loading dose of ponazuril (15 mg/kg, PO) may be given on the first day of treatment to rapidly attain therapeutic blood levels. The sulfadiazine/pyrimethamine product must be given at least 1 hr before or after hay is fed. Anemia may develop after prolonged treatment with sulfadiazine/pyrimethamine and is best prevented by providing folate-rich green forage such as alfalfa hay or green pasture. Approximately 60% of horses improve with each type of treatment, but $<25\%$ recover completely. Relapses occur commonly up to 2 yr after discontinuation of antiprotozoal therapy. Because immunosuppression/immuno-deficiency may be a risk factor for EPM, immunomodulators (eg, mycobacterial cell-wall derivative, levamisole, killed parapox ovis, or transfer factor) are sometimes given as ancillary therapy.

Prevention and Control: No proven preventive is available. A conditionally approved vaccine was marketed, but the license lapsed in 2008 and it is no longer offered. There is interest in using antiprotozoal drugs for prevention; however, evidence-based protocols are not yet available. The source of infective sporocysts is opossum feces, so it is prudent to prevent access of opossums to horse-feeding areas. Horse and pet feed should not be left out; open feed bags and garbage should be kept in closed galvanized metal containers, bird feeders should be eliminated, and fallen fruit should be removed. Opossums can be trapped and relocated. Because putative intermediate hosts cannot be directly infective for horses, it is unlikely that control of these populations will be useful in EPM prevention.

CNS DISEASES CAUSED BY HELMINTHS AND ARTHROPODS

A number of metazoan parasites (helminths and arthropods) are associated with pathology in the CNS and may be categorized as described below.

Immature (Larval) Stages of Parasites of Carnivorous Animals: These developmental stages may induce behavioral changes in the intermediate host that are

likely to enhance transmission to the definitive host by means of predation. For example, *Taenia multiceps multiceps* is acquired by the canine definitive host when the dog ingests the infective larval stages of the tapeworm *Coenurus cerebralis* in the brain and spinal cord of the ovine intermediate host. In sheep, *C. cerebralis* causes

ataxia, which allows the dog (a carnivore) to more easily prey upon the infected sheep.

Immature Stages of Parasites

Exhibiting a Neurotropic Affinity: These developmental stages require conditions provided by the host's CNS for their growth and development. For example, *Hypoderma bovis* in cattle can migrate through the spinal cord and adjacent tissues to reach its predilection site, the dorsum of the back.

Erratic or Aberrant Parasites: These parasites are normally found in non-neurologic, predilection sites within the definitive host but, on occasion, may wander erratically into some portion of the CNS. For example, larvae of *Cuterebra* spp are normally found in subcutaneous sites in dogs or cats but may also aberrantly wander into the CNS and localize on the cerebrum or cerebellum.

Incidental Parasites: These parasites are found in a different host than that in which they normally are found. For example, *Parelaphostrongylus tenuis* normally is found in neurologic sites within the definitive host, white-tailed deer, in which the parasite is nonpathogenic. However, in an incidental host, such as moose, elk, or llama, the parasite migrates through portions of the CNS and produces an often fatal neurologic disease.

Facultative Parasites: These parasites are normally free-living within the animal's environment but, on occasion, can develop into a parasitic existence. For example, *Halicephalobus deletrix*, a saprophytic soil nematode that is found free-living in nature, has been reported to produce pathology in the CNS of horses.

Successful chemotherapeutic treatment for cerebrospinal nematodiasis has been reported with diethylcarbamazine at 100 mg/kg (45 mg/lb). Ivermectin and organophosphates kill larval bots and at least some nematodes, but killing parasites in situ within the CNS may provoke additional tissue damage.

Before implementing therapy for a pathogenic helminth or arthropod, other possible causes of neuropathology should be carefully considered. In particular, rabies (see p 1302) should always be included in the differential diagnoses. The animal's age, vaccination status, exposure status, and history are factors that should be considered when rendering a diagnosis.

CESTODES

Coenurosis: *Taenia multiceps multiceps* is an intestinal parasite of canids (especially

dogs, foxes, and jackals) and occasionally people. Its intermediate hosts include sheep, goats, deer, antelope, chamois, rabbits, hares, horses, and less commonly cattle, which acquire this tapeworm's eggs while grazing. After ingestion, some oncospheres hatch and reach the brain, developing by endogenous budding into a metacestode (larval) stage known as *Coenurus cerebralis*. Initial invasion and development of the oncospheres may be responsible for acute suppurative meningoencephalitis. The fully developed coenurus may be 5–6 cm in diameter and cause increased intracranial pressure, which results in ataxia, hypermetria, blindness, head deviation, stumbling, and paralysis. This clinical condition is colloquially known as gid, sturdy, or staggers. In sheep, palpation of the skull caudal to the horn buds may reveal refraction; surgery to remove the cyst, including its wall, has a reasonable chance of success and is justified in valuable animals. Dogs associated with sheep and other livestock should not be fed the brain or spinal cord from infected animals and should be dewormed regularly.

Cysticercosis: *Taenia solium* is a tapeworm found in the small intestine of people. Its metacestode (larval) stage, a cysticercus, is a large fluid-filled cavity or vesicle or bladder found in the musculature of pigs. This larval stage was once regarded as a separate parasite, and it still retains the scientific name *Cysticercus cellulosae*. In people, this larval stage usually develops in subcutaneous sites and musculature but may be found in nervous tissues, eg, the brain and ocular tissues. Infection in people stems from ingestion of tapeworm eggs in contaminated foods or from dirty hands. In the brain, the parasite usually develops in the ventricles. Infection causes pain, paralysis, epileptiform seizures, locomotor disturbances, and possibly death. The larval cysticerci commonly localize on the meninges and in the neuropil. Treatment of human cysticercosis is by surgical removal of the lesion; however, the prognosis is poor.

Echinococcosis: *Echinococcus granulosus* is a tapeworm found in the small intestine of the canid definitive host. Its eggs are ingested by the intermediate hosts, wild and domestic herbivores, eg, sheep, cattle, and moose. People can also serve as intermediate hosts. After hatching in the intestine of the intermediate host, the oncospheres invade the circulatory system

and lodge in various organs (the liver and lungs), where they develop into large, thick-walled, unilocular hydatid cysts that bud protoscolices endogenously. Hydatids have been rarely reported in the CNS of domestic animals and are rare in people, in which they produce symptoms similar to those of a brain tumor.

Foxes are the definitive host for a related species, *Echinococcus multilocularis*. Microtine rodents (such as voles) are the intermediate hosts. This parasite has been rarely found in the brain of people, in which the invasive, thin-walled multilocular hydatid cysts produce innumerable exogenous daughter cysts that bud protoscolices. Surgical intervention is more successful in removing unilocular hydatid cysts of *E. granulosus*.

TREMATODES

Paragonimiasis: *Paragonimus westermani* and *P. kellicotti*, the lung flukes, have been reported to migrate aberrantly and produce cysts in the brain and spinal cord of pigs, dogs, cats, rats, and people. Flukes in these extrapulmonic sites in dead-end hosts do not produce patent infections.

Schistosomiasis: Schistosomes, or blood flukes, normally deposit their eggs in the small vessels of the gut and urinary bladder, from which they pass into the external environment via the feces or urine. Some eggs, however, may get into the general circulation and reach the CNS, where they become encapsulated. This condition has been noted in people and domestic animals.

Troglotremaniasis: *Troglotrema acutum* inhabits the frontal and ethmoidal sinuses of foxes and mustelids in Europe. Flukes live in pairs in cysts in these sinuses. These parasites cause decalcification and atrophy of the bony walls of the sinuses and eventually result in perforation into the cranial cavity. Microorganisms enter the cranial vault, leading to fatal, purulent meningitis. No treatment is available.

NEMATODES

Ascarids

The larvae of some ascarid roundworms, including *Toxocara* spp of dogs and cats and *Baylisascaris* spp of mustelids, can cause CNS disease.

Nervous disorders, frequently associated with ascarid infection in young dogs, may be

due to focal lesions in the CNS caused by the death of aberrant arrested larvae of *T. canis*. *Toxocara* larvae may also invade the eye and cause ocular larva migrans in people.

Baylisascaris procyonis is the ascarid found in the small intestine of raccoons. It causes larva migrans in both wild and domestic animals in North America and is usually associated with the production of clinical CNS disease. More than 90 species of wild and domesticated animals have been identified as being capable of serving as paratenic (transport) hosts harboring *B. procyonis* larvae. Some species, including opossums, skunks, cats, pigs, sheep, and goats, appear to be marginally susceptible or resistant to the neurologic migration. The parasite has been associated with the production of cerebrospinal nematodiasis in people, particularly children; it also has been implicated as a cause of ocular larva migrans.

Filarids

Dirofilaria immitis is often referred to as the canine heartworm but can also infect cats and ferrets. As adults, these parasites usually infect the right ventricle and the pulmonary artery and its fine branches. *D. immitis* has been recovered from a variety of aberrant sites, including the CNS of its definitive hosts and the anterior chamber of the eye. (See also HEARTWORM DISEASE, p 127.)

Elaeophora schneideri, a filarid of the carotid arteries and its branches, is common in mule deer, primarily in western North America. Microfilariae accumulate in the skin of the head and face; intermediate hosts are tabanid horseflies. Larvae develop in arteries of the leptomeninges before migrating to the carotids. Infection is usually asymptomatic in normal definitive hosts. In wapiti, moose, white-tailed deer, sheep, and goats, worms in the arteries cause degeneration and loss of the endothelium and accumulation of plasma proteins and platelets on and within the intima. Thrombosis, infiltration of the intima, and fibroblastic proliferation may eventually result in occlusion and ischemic necrosis in associated tissues. Necrotic lesions associated with occlusion of leptomeningeal arteries are commonly found in the brain. Neurologic signs include blindness, head deviation, circling, ataxia, and paralysis (See also ELAEOPHOROSIS, p 904).

Setaria digitata is found in Asia and is a common parasite of the peritoneal cavity. Microfilariae are found in the blood; mosquitoes are intermediate hosts. Details

of development in the normal host are unknown. In cattle, clinical signs do not appear to develop. In horses, goats, and sheep, the developing worms invade the CNS and cause motor weakness, ataxia, lameness, drooping eyelids or ears, and lumbar paralysis. Lesions include focal malacia and degeneration of axis cylinders and myelin sheath in all regions of the CNS.

Setaria cervi has been reported on the leptomeninges of deer in Europe and in the former USSR, often in association with *Elaphostrongylus cervi*. *Setaria* spp have also been found in the CNS of horses. The significance of these findings is unclear.

Filarids may also parasitize avian species. *Splendidofilaria quiscua* is found in the cerebral hemispheres of grackles (*Quiscalus quiscua*) and other birds in North America. *Paronchocerca helicina* is found in the cranial leptomeninges of the snake bird (*Anhinga anhinga*) in the USA.

Metastrongyles

Angiostrongylus cantonensis is a common parasite of the pulmonary arteries of rats in southeast Asia and the south Pacific. Terrestrial, aquatic, and amphibious snails and slugs are intermediate hosts. Paratenic hosts are freshwater prawns, land crabs, coconut crabs, and planarians. Larvae invade the cerebrum and develop in the neural parenchyma for ~2 wk, then enter the subarachnoid space and migrate, ~1 mo after infection, to the pulmonary arteries via the venous system. Neurologic signs are rare in rats with light to moderate infections, but circling, cannibalism, and paraplegia may develop in heavy infections. In endemic areas, people frequently acquire infections by consuming raw or undercooked intermediate or paratenic hosts. In people, this parasite may produce a fatal eosinophilic meningoencephalitis. In Australia, *A. cantonensis* has produced an ascending paralysis in puppies. It may be an incidental parasite in dogs.

Gurlita paralyans is found in the spinal veins of cats and has reportedly produced a high incidence of paralysis. It may be an incidental parasite in cats.

Elaphostrongylus cervi is a common parasite of the skeletal musculature of *Rangifer* and *Cervus* spp (reindeer and elk) in the holarctic region, especially Eurasia. It is transmitted through terrestrial snails and slugs and apparently develops for a time in the CNS before migrating to the muscles. Infection is associated with lumbar weakness, paresis, and paralysis in cervids in Sweden and in the former USSR.

Parelaphostrongylus tenuis is found in the subdural space and venous sinuses of the cranium of white-tailed deer in eastern North America. Eggs reach the lungs in the venous blood and develop into larvae, which pass up the bronchial tree and out with the feces. Infective larvae, acquired from terrestrial snails and slugs as the deer feeds, invade the spinal cord and develop for several weeks in the dorsal horns of the gray matter; then, they invade and mature in the subdural space. The infection is usually asymptomatic in white-tailed deer. However, *P. tenuis* causes pathology in the CNS of various cervids (moose, caribou, wapiti) and antelope, llamas, sheep, and goats. In these hosts, the parasite produces considerable trauma in the CNS. In addition, eggs deposited in the neural tissue provoke marked inflammatory reactions. Clinical signs consist of lumbar weakness, ataxia, lameness, stiffness, circling, abnormal positions of the head, and paralysis. Signs vary in onset and character in individual animals. Temporary remissions are typical.

Skrjabinogylus nasicola and *S. chitwoodorum* are found in the frontal sinuses of mustelids, especially mink, weasels, and skunks. Larvae acquired from terrestrial snails and slugs develop for a time in the gut wall, then migrate to the spinal cord. They move on to the leptomeninges to the brain and along the olfactory tracts to the cribriform plate, which they penetrate to reach the frontal sinuses. Their presence on the leptomeninges elicits hemorrhage and leptomeningitis. In heavy infections, some subadult worms may invade the brain and cause neurologic signs, including paralysis.

Rhabdiorids

Halicephalobus deletrix is a free-living soil rhabditiform associated with soil and decaying vegetation in the host's environment. This nematode has been reported in the CNS of horses and people. It may reach the CNS through wounds contaminated by soil that contain these nematodes or through abscesses in the oral and nasal cavities. The nematode multiplies in the CNS and is highly destructive of neural tissues. Pathogenicity in the CNS can be attributed to trauma caused by activities of the parasites; the role of excretory and secretory products is unknown. Also, the parasites may transport pathogenic microorganisms to the CNS. Clinical signs are related to the location of and lesions produced by the parasite. Signs resemble viral encephalitis and include motor weakness, ataxia, head deviation, circling,

depression, blindness, drooping of the ear or eyelid, loss of the herding instinct, and paralysis. Lesions consist of vasculitis, hemorrhagic necrosis, and malacia.

Miscellaneous Nematodes

Migrating larvae of strongyles (perhaps *Strongylus vulgaris*) have been reported in the CNS of horses. Larvae of *Stephanurus dentatus* rarely invade the CNS of pigs. Larvae of *Trichinella spiralis* were found in the brain in a fatal case of trichinosis in a person. Larvae of *Strongyloides stercoralis* may invade the brain of experimentally infected animals. *Gnathostoma spinigerum* has been found rarely in the CNS of people. *Eustrongylides ignotus* implanted subcutaneously in rats and chickens migrated to the CNS and caused death of the host.

ARTHROPODS

Myiasis is the development of larval dipteran flies (bots and warbles) within the tissues or organs of people and other domestic or wild animals. Myiasis that involves the CNS is rather uncommon except for the larval stages of *Hypoderma bovis*, the cattle heel fly. Its larvae normally burrow between the periosteum and dura mater of the bovine spinal cord during migration to the subcutaneous tissues of the back. Neurologic signs, varying from a transient, stiff, unsteady gait to paralysis, may be seen in cattle given systemic insecticides when the larvae are present in the spinal canal. (See also CATTLE GRUBS, p 876.)

The larvae of *Oestrus ovis*, the nasal bot fly of sheep (see p 1473), are normally found

in the nostrils and paranasal sinuses. They rarely penetrate the ethmoid bone and reach the forebrain. However, it is possible that other factors facilitate entry of larvae into the brain. The bones of the skull may erode. If the brain is injured, clinical signs, such as a high-stepping gait and incoordination, may mimic infection with *Coenurus cerebralis*. This condition is often referred to as false gid. Surgical intervention may be useful but can prove difficult if the larvae are difficult to reach.

Larval *Cuterebra* spp, normally found in subcutaneous sites in dogs or cats, have been known to wander into the CNS and localize in the cerebrum or cerebellum (see p 879). Intracranial migrations by larvae of dipteran flies have been reported in people (*Dermatobia hominis*), cattle (*Hypoderma bovis*), and horses (*Hypoderma* spp).

Bots and warbles may move rapidly after death of the host and migrate into tissues far from the site of origin.

Treatment of intracranial myiasis is currently experimental. Surgical and medical therapies to alleviate intracranial myiasis have been considered. The efficacy of systemic organophosphates against migrating larvae of *Hypoderma* suggest that organophosphates may effectively eliminate certain dipteran larvae from the nervous system. Parenteral corticosteroids are also recommended to prevent additional inflammatory damage and intracranial pressure throughout the treatment period. Ivermectin (300 mcg/kg on alternate days) used in conjunction with corticosteroids should be considered experimental therapy for intracranial cuterebrosis in cats; it is not approved by the FDA for this use.

TICK PARALYSIS

Tick paralysis (toxicity) is an acute, progressive, symmetrical, ascending motor paralysis caused by salivary neurotoxin(s) produced by certain species of ticks. With some species, other signs of systemic "single organ" toxicity (eg, cardiac, airway, bladder, lung, esophagus, etc) may be seen separate to or within the classic paretic-paralysis presentation. People (usually children) and a wide variety of other mammals, birds, and reptiles may be affected. Human cases of tick paralysis caused by the genera *Ixodes*, *Dermacentor*,

and *Amblyomma* have been reported from Australia, North America, Europe, and South Africa; these three plus *Rhipicephalus*, *Haemaphysalis*, *Otobius*, and *Argas* have been associated with paralysis to varying degrees in animals.

This toxicity is unique, because it is a pulsed toxin flow associated with repeat tick feeding over a set period of time. Animals are generally affected by paralysis, but there are also very odd presentations of associated toxicity. Deterioration can be unpredictable and rapid in some cases, and

some animals may have prolonged and unexplainable recovery. Very severe cases require intensive care, including artificial ventilation, to maximize recovery rates, and generally, only tick removal and use of tick antitoxin serum (TAS) and antibiotics have a major effect on overall mortality.

Etiology, Epidemiology, and Pathogenesis: The potential to induce paralysis has been demonstrated, described, or suspected in 64 species of ticks belonging to 7 ixodid and 8 argasid genera. ● In the eastern coast of Australia, the paralysis tick *I holocyclus* (and to a lesser extent *I cornuatus* and *I hirstii*, in which morphologic classification has been shown to be unreliable) causes the most severe form of tick paralysis, with a mortality of as much as 10% in dogs (usually 4%–5%), irrespective of therapy.

In North America, *D andersoni* (the Rocky Mountain wood tick) and *D variabilis* (the American dog tick) are the most common causes. Sheep, cattle, and people may be affected, as well as dogs. *D albipictus*, *I scapularis*, *Amblyomma americanum*, *A maculatum*, *R sanguineus*, and ● *megnini* may cause paralysis. In fowl, *Argas radiatus* and *A persicus* have caused paralysis. In Africa, *I rubicundus* (Karoo tick paralysis) and *R punctatus* in South Africa, *R evertsi evertsi* and *Argas walkerae* in sub-Saharan Africa, and *R evertsi mimeticus* in Namibia can cause the disease. Cats appear to be resistant to the disease caused by these ticks but are affected by *I holocyclus*. Toxicity is usually less severe (than in dogs), does not include chest complications, and has a better prognosis.

I holocyclus in Australia causes a much more severe disease than that seen in North America and elsewhere. Dogs and cats are affected, as well as sheep, goats, calves, foals, horses, pigs, flying foxes, poultry, birds (ostrich), reptiles (snakes and lizards), and people. Both local (less common) and systemic paresis and paralysis are seen. The natural hosts (bandicoots) are rarely affected, presumably acquiring immunity at an early age. However, without exposure to toxin, they too become susceptible.

Host factors influencing epidemiology include species, sensitivity to toxin, age, acquired immunity, field behavior, concurrent work demands, reaction to environmental factors, skin reactivity, and population density. Antitoxin immunity, starting at least 2 wk after primary tick exposure and lasting a few weeks, can be boosted by further infestations, but chronic

tick exposure eventually is associated with a decline in immunity, possibly due to toxin-neutralizing effects by the host. Tick factors include age, toxin absorption and circulation dynamics, paralysis-inducing capability, other toxic effects, sexual activity, rate and volume of secretions, and the frequency of the sucking phase.

The maximal prevalence of tick paralysis is associated with seasonal activity of female ticks, mainly in spring and early summer, but in some areas ticks are active throughout the year. Environmental factors such as temperature and humidity also play a major role in tick morbidity and mortality (ie, ticks are easily killed by both hot/dry and wet conditions). Modern rapid transport of ticks attached to people, animals, or plant material can give rise to isolated cases of tick paralysis, far removed from the particular geographic area (or country) where the ticks are naturally found. The diagnosis may be delayed when such infested animals travel to areas where such paralysis associated with reduced levels of acetylcholine is not typically seen.

Toxicity does not relate directly to tick size, number, or duration of attachment. The clinical signs produced in various hosts depend on several variables, including toxin secretion rate, local site responsiveness, host immunity and susceptibility, and specific organ susceptibility.

Systemic toxicity follows injection of toxin(s) into the host, especially during periods of rapid engorgement, although large numbers of larval or nymphal ticks may also cause the same paralysis of the neuromuscular junction. The toxin is presumed to travel from the attachment site via the lymph to the systemic circulation and thus to all areas of the body, where it has a direct effect on cellular potassium channels and thus on intracellular calcium levels. However, primary hypoventilation is the main cause of death in most severe cases, in which alveolar disease may also be present.

Clinical Findings: In tick paralysis other than that caused by *I holocyclus*, clinical signs are generally seen ~5–9 days after tick attachment and progress over the next 24–72 hr. When *I holocyclus* is involved, clinical signs usually appear in 3–5 days (rarely longer, eg, up to 18 days, possibly with virginal ticks) after attachment and usually progress rapidly throughout the next 24–48 hr. Time periods can vary with *I holocyclus* because of tick factors, environmental humidity, temperature (microclimate), and host factors. Both “shorter onset to severe” signs and delayed

"quiet" attachments with minimal signs may be seen. Removal of *I holocyclus* ticks does not immediately halt progression of disease. In severe cases, death from respiratory muscle failure and other respiratory complications can occur within 1–2 days of the onset of signs.

Early signs may include change or loss of voice (due to laryngeal paresis); hindlimb incoordination (presumed to be due to weakness and not central CNS ataxia); change in breathing rhythm, rate, depth, and effort; gagging, grunting, or coughing; regurgitation or vomiting; and pupillary dilation. Dogs with a grunt are believed to have increased airway resistance.

Hindlimb paralysis begins as slight to pronounced incoordination and weakness, which is best observed with the animal turning or walking away from the observer (or when climbing stairs or jumping up). As paralysis progresses, the animal becomes unable to move its hindlimbs and forelimbs, to stand, to sit, to right, and finally to lift its head.

A four-stage classification system based on systemic limb activity may enable clinical predictability. In stage 1, the dog's voice is changed (usually noticed retrospectively), and the dog is weakened but can still walk and stand. In stage 2, the dog cannot walk but can stand. In stage 3, the dog cannot stand but can right. In stage 4, the dog cannot right. Stages 3 and 4 (~30% of cases) indicate a poor prognosis. However, some dogs show few signs because of low levels of toxin or high levels of protective skin or systemic immunology, and some show signs in only one organ (eg, esophageal paralysis). Sensation is usually preserved, but it is increasingly harder to detect the clinical responses to stimuli due to lower motor neuron paralysis. (Visual analog scale scoring is also performed for the neuromuscular junction, overall toxicity, and dyspnea, with highly predictive results).

Breathing abnormalities include choke, upper respiratory tract obstruction, bronchoconstriction (especially seen early in cats), progressive fatigue of respiratory muscles, and aspiration of esophageal and/or gastric contents (due to loss of pharyngeal and laryngeal function), leading to aspiration pneumonia. Aspiration can be significant, and the lung severely affected before any obvious signs. It is possible to have a silent (no crackles), severely pneumonic lung if there is poor airflow into the affected lobe. Some dogs have profound dyspnea, no crackles, and extensive pulmonary radiographic opacity (due to

aspiration pneumonia); such cases are usually terminal. Dogs with upper respiratory tract obstruction have a marked expiratory stridor (not the classic inspiratory stridor of primary laryngeal paralysis of large breeds), often with the head and forelegs extended to maximize air flow and exchange. If there is chest disease as well, the animal is usually very dyspneic. A thrill can be felt at or just below the larynx in association with the obstructed expiratory effort and stridor. The upper respiratory tract lesion can be easily missed, especially if the dog is paralyzed. Often the respiratory rate is high and forced. In cats, the doll test can be used to assess upper respiratory tract function. If finger/thumb compression of the chest induces a stridor, then this supports paresis or paralysis, irrespective of other respiratory tract defects. It is essential that any upper respiratory tract obstruction be diagnosed, because the associated workload, anxiety, and resultant fatigue can quickly become terminal.

Paralysis of esophageal muscles develops in most dogs (but not cats), with or without obvious esophageal dilation. Saliva and ingested food or fluid pool in the esophagus and may be regurgitated into the pharynx and mouth. Loss of pharyngeal function makes it difficult for the animal to clear material from the upper respiratory tract, which may then lead to aspiration pneumonia.

Vomiting (with evidence of bile) may occur in *I holocyclus* paralysis; a central action of toxin on the vomiting center has been suggested. Most cases of vomiting reported by owners are probably regurgitation, although drug-induced vomiting can be a complication. Dogs will gag and retch in an attempt to clear secretions and move their head and jaw in an odd way, associated with a characteristic groan, to further attempt clearance of materials.

Body temperature may be normal in the early stages; however, due to the toxin's effect on arteriovenous anastomoses (shunts), normal thermoregulation is lost. This can cause hyper- and hypothermia as animals are affected by local environmental factors. Shivering is also lost in severe cases. Profound hypo- and hyperthermia can occur suddenly and can be easily misdiagnosed; hypothermia clinically resembles tick paralysis in several ways. When body temperature is restored, the level of tick paralysis in some cases can be mild.

Rarely in dogs, acute congestive heart failure can present with extensive pulmonary edema due to diastolic

myocardial dysfunction (the myocardium is unable to correctly relax, reducing efficient chamber filling and therefore systolic cardiac output). Venous return may also be reduced, and systemic venous pressure is increased.

Some dogs have a prolonged QT interval on ECG, which can result in a lethal ventricular arrhythmia. The frequency of these unexplained deaths, which follow complete gross clinical recovery, is not known, but most veterinarians who treat many cases report such events.

Cats with moderate to severe toxicity can be anxious. It is essential not to interfere with these animals until they have settled in their cage. If procedures are forced on them, these animals can die from obstructive dyspnea and the (presumed) associated hypoxemia, acidosis, and hypercapnea. Animals can deteriorate if compromised by excessive hospital stress (eg, nursing attention, noise, smell).

Cats may present with an "asthma-like" airway constriction, usually when they are mildly paretic; expiratory wheeze on auscultation, forced abdominal expiratory effort, and very easily induced exercise intolerance are classic signs at this time. These cats often have a positive doll test and will, after a few steps, sit on their hindquarters with the chest in a more upright vertical position than normal, often with an increased respiratory focus or effort. Feline "asthma" can be easily misdiagnosed at this stage if a tick is not found or suspected.

Diagnosis: The presence of a tick in conjunction with the sudden appearance of limb weakness and/or respiratory impairment is diagnostic. The offending tick may no longer be attached, but a "skin crater" (a hole 1–2 mm deep and 1–3 mm wide, surrounded by a variably raised and inflamed area) confirms the diagnosis. Sometimes neither tick nor crater can be found (ticks attached deep in the ear, between toes, or in the mouth or anus may be missed). However, with the appropriate clinical signs, in a known tick area without another obvious cause of lower motor neuron or neuromuscular disease, TAS treatment is still indicated. Recovery after treatment subjectively confirms the provisional diagnosis.

Specific laboratory diagnostic techniques are not available, but procedures that may be generally helpful include a PCV, serum protein, and radiography to assess presence and degree of pulmonary edema, megaesophagus, and pneumonia due to aspiration.

Specific signs (eg, congestive heart failure, urethral obstruction) require routine evaluation and treatment of that body area or system.

Botulism, polyradiculoneuritis, acute peripheral neuropathies, snakebite, hypokalemia, and toadfish and ciguatera toxicity are some differential diagnoses. In regions where ticks are endemic, tick paralysis is usually high on the list of differential diagnoses for any flaccid, clinically ascending motor paralysis. It should also be considered in the differential diagnosis of megaesophagus, unexplained vomiting, acute left congestive heart failure (dogs), or "asthma" (cats). The tick season is usually well known for various areas (eg, a local creek) within the environment of a particular practice, and often most tick paralysis cases come from a few, well-defined, highly endemic areas.

Blood and serum values are unchanged in the early stages. Increased PCV (with normal serum protein) indicates a fluid shift into the lungs and a more guarded prognosis. Other changes may include increased levels of blood glucose, cholesterol, phosphate, and CK, and a decrease in blood potassium levels, but none of these changes are specific for tick paralysis or indicate severity or prognosis.

Echocardiography reveals both diastolic and secondary systolic myocardial dysfunction associated with reduced ventricular filling, possibly due to both peripheral venous pooling and poor diastolic myocardial relaxation. Nonstressful radiography gives the best available prognostic support, and pulse oximetry the best continuous assessment of oxygenation. Capnography helps assess the functional level of ventilation. Arterial blood gas analysis (although invasive) gives the best overall assessment of cardiopulmonary function. However, the stress of any such testing should be considered; positioning for chest radiographs (eg, dorsoventral to lateral) can tip animals into a terminal hypoventilatory decline associated with acute respiratory or cardiac arrest.

Treatment: In most infestations (except *I. holocyclus*), removal of all ticks usually results in improvement within 24 hr and complete recovery within 72 hr. If ticks are not removed, death may occur from respiratory paralysis in 1–5 days. Removal of *I. holocyclus* ticks does not immediately halt progression of disease. Clinical signs can deteriorate for ~24 hr and longer, but most dogs start to improve in 6–12 hr after TAS therapy. In any infestation, removal of

all ticks is absolutely necessary. The entire integument should be searched, diligently and repeatedly, especially on long-haired animals or those with thick coats. Most ticks (80%) are located around the head or neck, but they can be found anywhere on the body. Plucking the tick(s) yields the best result (in dogs) and does not induce anaphylaxis.

Therapy for tick toxicity must address primary tick toxemia and paralysis, secondary issues (eg, esophageal reflux, aspiration pneumonia), and potential tertiary factors (eg, chronic weakness, esophageal stricture).

TAS is an immune serum against the toxin (similar to tetanus antitoxin) and is the product of choice. It should be given as early in the disease as possible; subsequent "top up" doses are not effective, because they are too late. For dogs, a minimal dosage of 0.5–1 mL/kg, should be given slowly IV throughout at least 20 min to avoid any shock reaction. Rapid IV use can induce clinical reactions in >80% of dogs. Anaphylaxis can occur unpredictably (as with all products), necessitating the use of high-dose, soluble cortisol and rapid fluid loading, etc. Based on retrospective case studies, cats are believed to be somewhat more susceptible than dogs, presumably with a second dose, a few weeks (not days) after the first dose.

Animals with multiple ticks or in the early stages of paralysis should receive a higher dose, because these cases have the most unbound toxin to neutralize. However, there are no data for the exact dosage rates required, and batch and brand levels of protective immunoglobulin may vary. Severely affected dogs may have less remaining unbound circulating toxin for TAS to neutralize. However, debate persists about the required (possibly less) dose of TAS. It has been suggested that a standard dose should be given, based on the amount needed to neutralize the pulsed toxin flow from one tick rather than on a weight basis; a minimal dose of 10–20 mL is recommended for dogs (and 5–10 mL for cats). However, until the level of remaining unbound toxin in the affected animal and the level of specific protective immunoglobulin can be better assessed, a set dose rate cannot be established (the level of disease is reflective of the level of bound toxin, which is not affected by TAS).

TAS given IP is the best alternative in cats for which the IV route is an issue (eg, respiratory distress, restraint dangers, dyspnea). However, its clinically effective half-life is believed to be short (days not

weeks), and it will have no effect if the toxin is already tissue bound and the animal is severely ill or about to become so (with toxin in the perivascular space).

Minimization of stress and anxiety is essential. Acepromazine (0.03 mg/kg) may be given SC before any other medication or handling that may upset the animal. However, high doses should be avoided, especially if the animal is depressed, hypotensive, or hypothermic. (Overdosage may induce hypotension and hypothermia.) Opiates are an alternative (eg, methadone, 0.3–0.5 mg/kg, SC, IM). Oxygen therapy (nonstressful, usually nasal) is implemented (as indicated), but progressive disease requires more intensive therapy.

General anesthesia is indicated in animals that are severely fatigued and dyspneic, to allow for better administration of oxygen, esophageal drainage, and upper respiratory tract suction. Pentobarbitone can be used as a constant-rate infusion or given periodically IV to induce light anesthesia, with repeat doses as needed. Another potential benefit of pentobarbitone may be control of long QT syndrome. The chief benefits of some form of anesthesia (eg, propofol) are to reduce dyspnea, enable muscle rest, and help overcome primary muscle fatigue and general exhaustion. Periods of 6–8 hr of light anesthesia are best, with reassessment of clinical status after each period.

Mechanical or manual ventilation may be required but should be carefully assessed because recovery can be delayed, especially in brachycephalic animals. Longer-term ventilation cases can have a 70% recovery rate. It is essential to assess pulmonary (expired CO₂ levels) and alveolar (pulse oximetry) ventilatory capacity and to be aware of profound respiratory muscle fatigue. Alveolar disease (edema and/or pneumonia) has a poor prognosis in such cases.

Atropine (repeated every 6 hr, lowest dose) can be used if GI and respiratory secretions are excessive, but its effect on tear secretion (and the host's potential for eyelid paralysis, reduced blink reflex, and corneal drying) and cardiac rate and rhythm changes should be considered.

Antiemetic therapy should be used in animals that are vomiting, which is usually a poor prognostic sign. If the animal is regurgitating, the esophagus should be aspirated along with the upper respiratory tract. Correct drainage positioning then becomes a vital factor in helping to avoid aspiration. Care is needed with gastro-esophageal reflux cases regarding their chronicity and tissue damage.

Broad-spectrum bactericidal antibiotics are indicated (especially in severe cases) to help avoid development of aspiration pneumonia, but they must be given as soon as possible. Dogs with upper respiratory tract obstruction require either tracheotomy or anesthesia and intubation to overcome the potentially lethal effects of such obstruction.

Diuretics (eg, furosemide) with maximally appropriate oxygen treatment are indicated to treat congestive heart failure. Verapamil (0.1 mg/kg, IV bolus) has been used to help relieve the basic toxic myocardial effect of a failure to relax. The toxin does unbind, so if the animal can be kept free of terminal pulmonary edema (or arrhythmia), the cardiac failure will reverse over a few days, provided routine support is given. Esmolol has been used to treat affected animals that have a long QT interval and the potential for a lethal, unpredictable ventricular arrhythmia.

Fluid therapy should be used with great care, because pulmonary edema can be induced easily. Staying below maintenance levels and ensuring the animal is assessed for edema, both before and during IV fluid therapy, should be routine. Dehydration can occur in tick paralysis but not usually in routine cases until the second day of hospitalization, when increased PCV and protein values may be evident. In small patients, SC or IP fluids can be given if lung status is a concern. Exceptional cases may require extensive rehydration (eg, paralyzed in the sun with high humidity and temperature for a day before presentation), but the extent of the underlying organ dysfunction should be assessed before intensive fluids are given.

The asthma-like disease in cats is hard to reverse, because routine bronchodilators do not seem to be effective.

Muscle fatigue can be reduced (with recovery of some muscle strength) by short periods (6–8 hr) of anesthesia. The animals remain hypercapneic but, with endotracheal intubation and O_2 therapy, can establish reasonable hemoglobin saturation levels (>95%), provided there is no significant alveolar disease.

Intoxicated animals lose their ability to regulate body temperature. Animals that have fallen below 32°C (90°F) for a long period may be hard to resuscitate. Various heating mechanisms are used (hot water bottles, blankets, hot air flow blankets), but peripheral heat absorption cannot occur if arteriovenous anastomoses (shunts) are shut due to the effect of the toxin and the host's vasoconstrictive reaction to

hypothermia. Warmth applied at the lower limbs (especially the hindlimbs) will be of maximal benefit; direct application to the groin area may also potentially be useful. Some animals may need warmed fluids, IV or rectally, to reverse a very cold presentation (eg, $\leq 32^\circ\text{C}$). Sudden hyperthermia ($>42^\circ\text{C}$) can be seen in hospitalized dogs. They usually show exaggerated head and possibly foreleg movements and signs of anxiousness. With cooling (eg, wet towels, direct fan flow, high rate of air changes), these signs abate.

Because the animal's condition is expected to deteriorate after ticks are removed and TAS is given, hospitalization with minimally invasive monitoring and good nursing care is necessary. The animal should be kept in a quiet, dark, comfortable area of the hospital where it can be easily seen. It should be placed on the sternum to maximize lung function. Lateral recumbency, left side down with the shoulder (not the pharynx or neck) as the highest point, is the best position for drainage. If possible, slight "head down" is also advised. Animals should never be rotated unless it can be done frequently (every 1–2 hr), day and night.

Because the animal cannot void, catheterization is necessary, with the bladder expressed at least twice daily to avoid infection. As with other localized tick toxicity effects, this may persist beyond the period when the animal has generally recovered. Eye protectants should be used to prevent corneal ulceration or dryness (lid closure, artificial tears, contacts). Suction of the pharynx, larynx, and proximal esophagus minimizes upper respiratory tract distress caused by saliva pooling and regurgitation. An esophageal tube may be slowly inserted to remove any pooled material; in some cases, this is voluminous and the tube may possibly prevent choke (seen mostly in brachycephalic breeds with laryngeal blockage by foreign material). Fluid and oxygen therapy should be monitored to avoid overhydration or under-supply, respectively. Nutritional support should be performed carefully to ensure that GI and respiratory function can cope with any offered food and water.

Repeated tick searches should be performed during hospitalization, especially if the animal deteriorates unexpectedly or is slow to recover. Long or matted hair should be clipped, especially about the head and neck. Application of an acaricide may kill any ticks missed in searching. However, the stress of searching, clipping, or bathing can be detrimental in severely affected or

nervous animals, in which sedation is recommended.

Prognosis: Appropriate and timely treatment (TAS and antibiotics, especially in severe cases) saves ~95% of affected animals, but ~5% of animals are likely to die despite all treatment efforts, especially those with aspiration, or advanced respiratory paralysis and dyspnea. Most animals (>80%) have only one tick and a large attachment crater. Prolonged recovery and weight loss can be seen with various complications, and death can also occur due to choke, respiratory muscle fatigue, cardiac arrhythmias, congestive heart failure, and cardiopulmonary arrest. Older animals are at greater risk, as are very young pups. Proportionally more severe cases are seen at the start of the season, and a second (close to the first) infestation will be more severe. Dyspnea, crackles, and wheezes are poor prognostic signs, as are high neuromuscular junction scores (3 and 4) or high visual analog scale scores ($\geq 75\%$) for toxicity or respiratory distress.

Before discharge, the drop test can be used in cats to assess neuromuscular function and three-dimensional gravitational control. Cats should be able to correct a fall from 10–20 cm above the top of the table. Still-affected cats will not correct in time and land more heavily, with the chin hitting the padded table top. Recovered cats land lightly with good head control. Jumping up to and down from the cage can also be used to assess muscle strength in cats. In dogs, jumping down from a cage can induce stridor, indicating unresolved respiratory paresis with forced expiratory air flow, because the unsupported abdominal momentum affects the diaphragm and lung air flow, producing a high-volume expiration. Lifting a dog (with the holder's arms wrapped outside the

fore- and hindlegs) with unresolved tick paralysis often produces stridor, indicating abnormal laryngeal function. Animals should be able to eat, drink, and walk normally without any stridor before discharge.

Owners should be advised to continue searching recovered animals for ticks; use appropriate preventive methods to avoid reattachment of ticks; and avoid high temperatures, stress, or strenuous exercise for at least the first month. Smaller, more frequent meals may also be indicated if there was esophageal dysfunction. This rest period especially applies to working farm dogs, in which early overexercise may lead to permanent muscle damage.

Prevention and Control: Owners should not rely solely on chemical control to prevent tick infestation, because no product is totally effective, and a single attached tick can cause the disease. They should be advised about when and where their pets will be at risk; encouraged to thoroughly search the coat daily; keep the coat as short as possible (to aid searching); and understand the efficacy, appropriateness, safety, and limitations of available preventive products (sprays, topical spot-ons, tablets, and collars). Combination therapy (eg, spray and collar) may give better results by using two modes of action, but there are no published data to support this concept.

Attempts to produce an effective vaccine against the *I. holocyclus* toxin have so far been unsuccessful, as have been attempts at "in-field" tick control. Specific RNA studies show that ticks vary geographically, and such genetic differences may explain why clinical signs of tick paralysis and visual analog scale toxicity scores can vary between different areas at the same time of the year in the same season.

REPRODUCTIVE SYSTEM INTRODUCTION

The reproductive system provides the mechanism for the recombination of genetic material that allows for change and adaptation. Manipulation of this system in breeding management programs allows the rapid and dramatic alteration of the conformation and productivity of domestic animals. Theriogenology is the veterinary clinical specialty that deals with reproduction. The reproductive system is incredibly complex in both its anatomy and physiology, and all aspects must be considered when resolving reproductive problems. The differences in the reproductive system between the sexes and among species are extensive. Both sexes have primary sex organs and primary regulatory centers. Gonads and function-adapted, tubular genital organs constitute primary sex

organs in both sexes. The pituitary gland and the hypothalamus are the primary regulatory centers; thus, the regulatory function is, in part, neuroendocrine in nature. In pregnant females, the fetoplacental unit has a significant role in maintaining and terminating pregnancy.

For the temporal and physiologic features of the reproductive cycles of selected species, *see* TABLES 1–3.

THE GONADS AND TUBULAR GENITAL TRACT

Both sexes have a pair of gonads (ovaries or testes). However, in birds the right ovary does not develop; only the left ovary and oviduct are present in adult females. The main functions of the gonads are

gametogenesis and steroidogenesis. Both functions are regulated primarily by gonadotropins released by the anterior pituitary gland under the influence of the hypothalamus. Hypothalamic control of the pituitary is mediated by a peptide, gonadotropin-releasing hormone (GnRH); the secretion and release of GnRH are governed by CNS stimuli and, through a feedback mechanism, by hormones produced by other endocrine organs such as the gonads, pituitary, thyroid, and adrenal glands. (See also ENDOCRINE SYSTEM, p 538, et seq.)

The Ovaries: The size and location of the ovaries vary with the species. The ovaries can be directly examined by ultrasonography or by palpation per rectum only in larger animals (eg, cows, mares, and camelids). Once puberty is reached (see TABLE 3), the size and form of the ovaries are altered by cyclic functional structures, namely the corpus luteum (CL) and ovarian follicles. Follicle-stimulating hormone (FSH) is responsible for development of ovarian follicles and synthesis of estrogens. Once a certain estrogen level is attained, luteinizing hormone (LH) is released from the anterior pituitary gland in spontaneously ovulating species. This LH release triggers ovulation, which is followed by development of a new CL. The increase of luteal cells parallels an increase in progesterone output. In nonpregnant polyestrous and seasonally polyestrous females, the functional and morphologic life of the CL is terminated by endogenous prostaglandin (PG) $F_{2\alpha}$ from the uterus. As the CL regresses, a new ovulatory follicle(s) develops, which completes the estrous cycle. The hormonal changes during the estrous cycle can be monitored by laboratory assay of hormones in blood, milk, or feces. Estrual cycling is continuous after puberty unless interrupted by

pregnancy and, in some species, by season or lactation during the immediate postpartum period. Cycling may also be blocked by pathologic conditions of the ovaries (eg, nutritional atrophy or ovarian cysts) as well as by uterine disease (eg, pyometra), which may result in persistent luteal function. Estrogens and progesterone act locally, affecting target organs such as the tubular genital tract, and distally, regulating gonadotropin release by a feedback mechanism on both the hypothalamus and anterior pituitary. In addition, they play a prominent role in sexual behaviors, lactation, and the development of secondary sex characteristics.

The Testes: The testes function in both spermatogenesis and secretion of steroid hormones. Spermatogenesis is stimulated by FSH and augmented by androgens, primarily testosterone. Interstitial cells of the testes, under the influence of LH, produce testosterone. Testosterone and its metabolites are required for development and function of accessory glands, copulatory organs, male sex characteristics, and behavior. For optimal spermatogenesis, mammalian testes must descend into the scrotal cavity; however, steroidogenesis occurs in testes that remain within the abdomen, and the libido of cryptorchid males is usually not impaired. Photoperiod affects both sperm cell formation and steroidogenesis in males of species that have a seasonal reproductive pattern. Semen quality, libido, and mating ability are reduced during the seasonally anestrous period of females. Function of the testes can be assessed by evaluation of representative semen samples and hormone assays. Examination and measurement of the testes help predict potential sperm output and may reveal pathologic conditions.

TABLE 3 FEATURES OF THE REPRODUCTIVE CYCLE

Species	Age at Puberty	Cycle Type	Cycle Length	Duration of Estrus
Cattle	10–12 mo, usually first bred ~14–15 mo	Polyestrous all year	21 days (18–24)	18 hr (6–24)
Sheep	6–9 mo	Seasonally polyestrous, early fall to winter	17 days (14–20)	24–36 hr
Goat	5–7 mo	Seasonally polyestrous, early fall to late winter	21 days	24–48 hr
Pig	6–7 mo	Polyestrous all year	21 days (19–23)	40–60 hr
Horse	10–24 mo	Seasonally polyestrous, early spring through summer	~21 days (19–23)	5–7 days
Alpaca	12–18 mo	Polyestrous all year in North America	Not applicable	Up to 36 days
Dog	6–24 mo; earlier in smaller breeds, later in larger breeds	Monestrous all year	6–7 mo	9 days (3–21)
Cat	4–12 mo	Seasonally polyestrous, spring through early fall	14–21 days	6–7 days

The Female Tubular Genital Tract:

Except for the vestibule, which develops from the urogenital sinus, the female genital tract is derived from the embryonic paramesonephric ducts. Each of the segments is adapted to fulfill its function. The oviduct acquires the egg(s) and moves the resulting zygote(s) into the uterus, while its secretion provides a proper environment for survival of gametes, fertilization, and the first few critical days of embryonic life. Interference with motility or secretion leads to infertility. Species variation of the bicornual, Y-shaped uterus involves the size of the body and length of horns, which are adapted to accommodate species-specific number and form of fetuses and placentas. The cervix provides a protective barrier that is relatively effective against ascending infections. Morphologic and functional integrity of the uterus and cervix are required to establish and maintain pregnancy and for parturition. Infections contracted at mating or during parturition and the puerperium are common causes of

female infertility. Applicability of diagnostic methods for detection of uterine and cervical abnormalities depends on species, size of the animal, and anatomy of the cervix. Clinical diagnosis is by transrectal and abdominal palpation, vaginoscopy, hysteroscopy, radiography, and ultrasonography. In small animals, laparotomy or laparoscopy may be necessary to assist with diagnosis. Laboratory diagnostic aids include microbiologic and cytologic examination of exudate or secretion, histologic examination of biopsies, endometrial cytology, and hormone assays.

The posterior tract, consisting of the vagina, vestibule, and vulva, serves as the copulatory organ and as the last segment of the birth canal. It also provides a pathway for ascending infections, particularly when effectiveness of the vestibulovaginal sphincter or the vulvar labia is lost or reduced because of trauma, relaxation, or defective conformation of the perineal region. Puerperal infections commonly involve the entire tubular tract. In addition,

TABLE 3 FEATURES OF THE REPRODUCTIVE CYCLE (*continued*)

Best Time to Breed	First Estrus After Parturition	Comments
Insemination from midestrus until 6 hr after end of estrus	20–60 days	Ovulation 10–12 hr after end of estrus.
18–20 hr after onset of estrus	Next fall	Ovulation near end of estrus.
Daily during estrus	Next fall	Many intersexes born in hornless strains.
Daily during estrus	4–10 days after weaning	Ovulation usually ~40 hr after beginning of estrus.
Last few days of estrus, just before ovulation; should be bred at 2-day intervals	4–14 (9) days	Ovulation usually 1–2 days before end of estrus. Double ovulation occurs in ~20% of estrous periods, but twins rarely progress to term.
When a large, viable follicle is present	Fertile within 15–20 days	Alpacas are induced ovulators.
Second day after ovulation	4–5 mo	Proestrous bleeding 7–10 days. Ovulation usually 1–3 days after onset of estrus. Ova shed before first polar body has been extruded (primary oocyte).
Daily from day 2 of estrus	4–6 wk	Induced ovulation 24–48 hr after breeding. Pseudopregnancy lasts 40 days. Infertile matings delay onset of next cycle ~45 days.

vestibulovaginal infection perpetuated by urovagina and pneumovagina may sustain chronic infection of the uterus. However, the vestibule and vagina can be inflamed even when the uterus is normal or pregnant. Conversely, in closed-cervix pyometra in cows and bitches, the vagina and vestibule may essentially be normal.

The Male Tubular Genital Tract: In males, the tubular tract provides a pathway for sperm cells and seminal fluid. It begins in the testes as the rete testes and efferent ductules, which exit the testes and merge to become the head, body, and tail of the epididymis; it then continues as the ductus deferens. In mammals, the ductus deferens ascends into the abdominal cavity via the inguinal ring and passes over the dorsal aspect of the bladder to enter the pelvic urethra. The testes in birds are permanently retained in the abdominal cavity. The pelvic and penile urethras are shared as an outlet for semen and urine. Along this pathway, certain segments of the tract have evolved

morphologically and functionally to perform additional specific functions. The epididymides are involved in sperm cell maturation and storage and in selective absorption of abnormal spermatozoa. Ampullae and accessory sex glands (ie, seminal vesicles, prostate, bulbourethral glands) contribute to the formation of seminal plasma. The size, form, and function of the accessory sex glands vary among species. The seminal vesicles and the bulbourethral glands are absent in dogs. In bulls, the epididymides and seminal vesicles are common sites of infection. Epididymitis is also common in rams. Prostatic infections, hypertrophy, and malignancy are found primarily in dogs. Pathologic conditions of the epididymides can be diagnosed by scrotal palpation or ultrasonography in most animals. Other diseases or functional disturbances may require evaluation of one or several semen samples. Common semen collection techniques used in veterinary medicine include artificial vagina, electroejaculation, and post-mating recovery from an estrual

female. The preferred technique varies with the species and operator preference. The pelvic accessory sex organs can be assessed by transrectal palpation and ultrasonography in large animals and by digital palpation or transabdominal ultrasonography in small animals.

INFERTILITY

Interaction of the CNS, hypothalamus, pituitary gland, gonads, and their target organs results in finely coordinated sequences of physiologic events that lead to estrus and ovulation in females and to ejaculation of fertile semen by males. For optimal results, ovulation and deposition of semen into the female genital tract must be closely synchronized. Failure of any single functional event in either sex leads to infertility or sterility.

The ultimate manifestation of infertility is failure to produce offspring. In polytocous species, a subnormal number of offspring also constitutes infertility. In females, infertility may be due to failure to cycle, aberrations of the estrous cycle, failure to conceive, or prenatal and perinatal death of the conceptus. Major infertility problems in males are caused by disturbances of the production, transport, or storage of spermatozoa; aberration of libido; and partial or complete inability to mate.

Most (if not all) major infertility problems have a complex etiology, and several factors, singly or in combination, can cause reproductive failure. Pathogenesis may be equally complex.

Diagnostic Approach: Because the female bears the offspring, she reflects either success or failure of reproduction. However, the first diagnostic step (regardless of the complaint) is to establish the etiologic role of the female and the male. Additionally, each point of human involvement in the reproductive process, such as observation for estrus, preservation of semen, and insemination methodology, is a potential source of error. Such human errors can be detected or excluded by assessment of performance, with the main emphasis on techniques and procedures and their adequacy and quality.

Diagnostic methods have been developed to test the anatomic and functional soundness of both sexes. These include the signalment, a complete history, and clinical examination, supported by diagnostic aids such as endoscopy, ultrasonography, and laboratory tests (eg, hormone assays, microbiology, cytology, serology, cytogenetic

examination, genetic testing, and semen evaluation). The choice of diagnostic methods is determined by the species as well as by the size and temperament of the animal. Decisions with regard to type and extent of laboratory tests are based on history and information gained during the course of clinical examination. In each case of reproductive failure, the diagnostic plan should provide evidence to establish the role of the female, the male, and the breeding management program.

Reproductive problems are seldom accompanied by alarming signs of disease. Furthermore, there is a time interval between when a failure occurs and when it becomes apparent. Examples are intervals between unsuccessful service and return to estrus or failure to give birth. This lag period may allow recovery, yielding negative results on examination. Interpretation of results also must account for species differences and, in species with a seasonal reproductive pattern, the fact that infertility may be physiologic during certain parts of the year.

PRINCIPLES OF THERAPY

See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE REPRODUCTIVE SYSTEM, p 2606, and MANAGEMENT OF REPRODUCTION for the various species, p 2171, et seq.

The increasing demands for production efficiency, along with changes in management systems, have caused a shift in therapeutic strategies in several domestic species. Especially for food and fiber animals, the therapeutic approach of choice often is a combination of pharmacologic agents and correction of management problems targeting the entire herd, with a decreased emphasis on individual animals. This trend is also reflected in the prioritization of disease prevention and implementation of biosecurity programs. The increased use of hormonal pharmacologic agents for reproductive management on a whole-herd basis represents another aspect of this change. Other therapeutic trends in food animals are the result of consumer concerns regarding antimicrobial and hormone residues in tissues and milk, as well as the increasing interest in organic or natural foods.

In small animals, therapeutic strategy has undergone a different but equally dramatic transformation. The individual animal remains the focus of therapeutic efforts, but diagnostic techniques and treatments have become increasingly sophisticated, often reflecting or even presaging advances in human medicine.

More effective therapy for reproductive diseases comes with the risk of propagating a hereditary predisposition for lowered fertility. However, the heritability of most reproductive traits is rather low, so selection programs aimed at improving fertility require a longterm commitment to be successful.

Pharmacologic Control of Reproduction: Exogenous hormone therapy can be used to regulate or control reproduction. This control may take the form of suppression or induction and synchronization of reproductive activity. The same hormone may be used for both purposes. For example, progestogens are used to suppress estrus in the mare, bitch, and queen but are also used in the mare, cow, and sow to induce and synchronize estrus for managed mating programs. Steroid hormones with estrogenic, androgenic, and progestational effects are used in a wide variety of applications.

The gonadotropins and GnRH are used to alter gonadal function. Examples include superovulation of cattle with FSH, induction of ovulation in mares with human chorionic gonadotropin (hCG), and stimulation of testosterone production with GnRH for diagnosis of cryptorchidism in dogs and stallions.

PGF₂ α is used primarily to terminate luteal function. Clinical applications include induction or synchronization of estrus in polyestrous species; treatment of pyometra in dogs, cats, and cattle; and induction of abortion in luteal-dependent species such as goats, alpacas, dogs, and cats.

Depending on the species, glucocorticoids, prostaglandin, and oxytocin, alone or in combination, can be used to induce or manage labor. They should be used with caution at the appropriate time and dosage

and accompanied by careful observation for any problems that may develop with the dam or fetus.

Assisted Reproductive Technologies:

Many of the assisted reproductive technologies commonly used today had their origin in veterinary species as either research or commercial programs. Artificial insemination is commonly used to breed cattle, dogs, sheep, goats, pigs, and horses. Other technologies in use include embryo transfer (*see* p 2239) and in vitro fertilization in cattle and horses. Somatic cell nuclear transfer (cloning, *see* p 2075) is more rarely performed but has been reported for a variety of animal species.

Antimicrobial Treatment: Antimicrobial agents, most commonly antibiotics, are used for treatment of infections of the male and female reproductive tracts in all species (*see also* ANTIBACTERIAL AGENTS, p 2652, et seq). Drug selection should be based, whenever possible, on microbiologic culture and sensitivity tests. The dosage, route of administration, and interval between treatments vary among species. In food animals, proper withholding times must be observed for meat and milk after antibiotic use.

Surgical Treatment: Surgical repair is indicated for acquired conformational damage to the genital system of both sexes. Examples include epispioplasty, vestibulovaginal or cervical cerclage, and cesarean section in females and repair of preputial injuries in males. Surgical sterilization is also routinely done, either by gonadectomy in both sexes of most species or by ovariophterectomy in female cats and dogs.

CONGENITAL AND INHERITED ANOMALIES OF THE REPRODUCTIVE SYSTEM

INTERSEX CONDITIONS

Sex determination of the gonads is important for development of the sex phenotype (internal and external genitalia, secondary characteristics) and sexual behavior. A sex chromosome genotype of XY leads to the development of testes due to the sex-determining region of the Y chromosome (*SRY*) gene. The *SRY* gene

induces downstream factors such as *SRY*-box containing gene 9 (*SOX9*), anti-Müllerian hormone, and glial cell line-derived neurotrophic factor in Sertoli cells.

Intersex conditions have been described in several domestic animal species. True hermaphrodites are rare and have both ovarian and testicular tissue and exhibit anomalies of the external genitalia. The chromosomal makeup is variable and may

be a chimera, mosaic, or unknown.

Pseudohermaphroditism, often referred to as sex reversal syndrome, is more common. Animals have one or the other type of gonad and external genitalia of the opposite sex. Animals may be XY *SRY* negative or XX *SRY* negative. In horses, the most common type is 64XY *SRY* negative. Some cases of sex reversal are believed to be due to a recessive autosomal gene mutation.

The most common intersex condition, the male pseudohermaphrodite, has testicular tissue in the abdominal cavity or beneath the skin in the scrotal region, and external genital organs that resemble those of females. Miniature Schnauzers, Basset Hounds, and rarely, Persian cats may present with pseudohermaphroditism when affected by persistent paramesonephric (Müllerian) duct syndrome. Undescended testes are attached to the uterine horns, and the vasa deferentia are relocated in the wall of the uterus. There are bilateral oviducts, a complete uterus with a cervix, and a cranial portion of the vagina. Bilateral scrotal testes or unilateral or bilateral cryptorchidism may be present. Affected animals can present clinically with pyometra, urinary tract infection, prostate infection, or Sertoli cell tumor. The diagnosis is confirmed by presence of a 78, XY chromosome constitution, bilateral testes, and the presence of all paramesonephric (Müllerian) duct derivatives. Androgen-dependent masculinization is that of a normal male. Treatment is limited to castration and hysterectomy. The defect is inherited as an autosomal recessive trait in Miniature Schnauzers, and both females and males can be carriers. Homozygous affected dogs with a descended testis are generally fertile and capable of transmitting the trait to all offspring.

Polled intersex syndrome is well described in goats. Polled homozygotic males have decreased fertility due to segmental aplasia of the epididymides. They are often XX *SRY* negative.

Freemartinism: Freemartinism syndrome is well known in cattle but has also been described in sheep, goats, and camelids. It causes sterility in females born co-twin to males; ~92% of all heifers born co-twin to bull calves are sterile. Single-born freemartin females have been reported and are believed to result from the in utero death of a male co-twin. These animals exhibit varying degrees of female-to-male sex reversal of the internal and external genitalia. The tubular genital organs in affected animals range from cordlike bands to near-normal uterine horns. Freemartins

have a short vagina that ends blindly without communication with the uterus. The cervix is absent. The ovaries usually fail to develop and remain small. Vascular anastomosis of the chorionic placentas of the two fetuses results in transfer of anti-Müllerian hormone from the male to the female fetus, which inhibits development of the female tract.

Normal and freemartin cattle can be differentiated based on length of the vagina and on the presence or absence of a cervix. In calves 1–4 wk old, the normal vaginal length is 13–15 cm, whereas in a freemartin vaginal length is 5–6 cm. Vaginal length is easily measured by gently inserting a well-lubricated probe with a blunt end into the vagina. Cytogenetic examination can demonstrate XX and XY chromosome patterns in freemartins. The interchange of cells that occurs in the placental circulation between the fetuses can also be demonstrated by detecting two different blood types in a single animal.

Other Chromosomal Abnormalities:

Chromosomal abnormalities (XXY) have been described in males with azoospermia due to hypoplasia of the testes, epididymis, and vas deferens. Tortoise-shell or calico male cats possess two X chromosomes (XX/XXY, XY/XXY, or other chimeric or mosaic combination) and are sterile.

MALE GENITAL ABNORMALITIES

Abnormalities of the Testis and Epididymis:

Cryptorchidism: Cryptorchidism is a failure of one or both testicles to descend into the scrotum. It is seen in all domestic animals; it is common in stallions and boars and is the most common disorder of sexual development in dogs (13%). Cryptorchidism is caused by a combination of genetic, epigenetic, and environmental factors. Bilateral cryptorchidism results in sterility. Unilateral cryptorchidism is more common, and the male is usually fertile because of sperm production from the normally descended testicle. The undescended testicle may be located anywhere from just caudal of the kidney to within the inguinal canal and can be identified by transrectal or transabdominal ultrasonography. Abdominal testicles produce male hormones, and cryptorchid animals have normal secondary sex characteristics and mating behavior. Cryptorchidectomy is recommended for all companion animals because of the suspected inherited nature of the condition and predisposition to testicular neoplasia (seminomas, interstitial cell tumors).

Testicular hypoplasia has been described in several domestic species and is associated with chromosomal abnormalities in some cases. It is common in some family lines in camelids.

Anorchism is the complete absence of development of one or both testes. Unilateral anorchism has been described in horses and camelids. In camelids, the kidney ipsilateral to the missing testis is also missing.

Partial or complete segmental aplasia of the structures originating from the mesonephric duct (epididymis, ductus deferens, ampullae and seminal vesicles) has been described in bulls. Bilateral epididymal hypoplasia has been described in azoospermic stallions and camelids. In camelids, segmental aplasia of the epididymis is often associated with epididymal and rete testis cysts.

Abnormalities of the Penis and Prepuce:

Persistent penile frenulum is not uncommon. Affected bulls are unable to protrude the penis from the sheath and, in most cases, cannot achieve intromission. Attachment can be minimal (eg, 0.5 cm), or the preputial mucosa can be attached the full length of the ventral raphe of the free part of the penis. Genetic association is suspected in some breeds. Surgical correction should not be performed in bulls intended for seedstock breeding. Many male foals may appear to have a persistent frenulum at birth, but the condition resolves within a few days. If the condition persists, correction should not be attempted until the foal is at least 1 mo old.

Preputial prolapse occurs due to a lack of or a weak preputial retractor muscle in polled breeds. The condition is exacerbated when these breeds are crossed with Brahman cattle.
